Springer

---

**Springer Handbook  
of Computational Intelligence**

---

**Springer Handbooks** provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

## Preface

We are honored and happy to be able to make available this *Springer Handbook of Computational Intelligence*, a large and comprehensive account of both the state-of-the-art of the research discipline, complemented with some historical remarks, main challenges, and perspectives of the future. To follow a predominant tradition, we have divided this Springer Handbook into parts that correspond to main fields that are meant to constitute the area of computational intelligence, that is, fuzzy sets theory and fuzzy logic, rough sets, evolutionary computation, neural networks, hybrid approaches and systems, all of them complemented with a thorough coverage of some foundational issues, methodologies, tools, and techniques.

We hope that the handbook will serve as an indispensable and useful source of information for all readers interested in both the theory and various applications of computational intelligence. The formula of the Springer Handbook as a convenient single-volume publication project should help the potential readers find a proper tool or technique for solving their problems just by simply browsing through a clearly composed and well-indexed contents. The authors of the particular chapters, who are the best known specialists in their respective fields worldwide, are the best assurance for the handbook to serve as an excellent and timely reference.

On behalf of the entire computational intelligence community, we wish to express sincere thanks, first of all, to the Part Editors responsible for the scope, authors, and composition of the particular parts for their great job to arrange the most appropriate topics, their coverage, and identify expert authors. Second, we wish to thank all the authors for their great contributions in the sense of clarity, comprehensiveness, novelty, vision, and – above all – understanding of the real needs of readers of diverse interests.

All that efforts would not end up with the success without a total and multifaceted publisher's dedication and support. We wish to thank very much Dr. Werner Skolaut, Ms. Constanze Ober, and their collaborators from Springer, Heidelberg, and le-tex publishing GmbH, Leipzig, respectively, for their extremely effective and efficient handling of this huge and difficult project.

September 2014

## About the Editors

**Janusz Kacprzyk** graduated from the Department of Electronics, Warsaw University of Technology, Poland with an MSc in Automatic Control, a PhD in Systems Analysis and a DSc (*Habilitation*) in Computer Science from the Polish Academy of Sciences. He is Professor of Computer Science at the Systems Research Institute, Polish Academy of Sciences, Professor of Computerized Management Systems at WIT – Warsaw School of Information Technology, and Professor of Automatic Control at PIAP – Industrial Institute of Automation and Measurements, in Warsaw, Poland, and Department of Electrical and Computer Engineering, Cracow University of Technology, Poland. He is the author of 5 books, (co)editor of ca. 70 volumes, (co)author of ca. 500 papers. He is Editor-in-Chief of 6 book series and of 2 journals, and on the Editorial Boards of more than 40 journals.

**Witold Pedrycz** is a Professor and Canada Research Chair (CRC) in Computational Intelligence in the Department of Electrical and Computer Engineering, University of Alberta, Edmonton, Canada. He is also with the Systems Research Institute of the Polish Academy of Sciences, Warsaw. He also holds an appointment of special professorship in the School of Computer Science, University of Nottingham, UK. His main research directions involve computational intelligence, fuzzy modeling and granular computing, knowledge discovery and data mining, fuzzy control, pattern recognition, knowledge-based neural networks, relational computing, and software engineering. He has published numerous papers and is the author of 15 research monographs covering various aspects of computational intelligence, data mining, and software engineering. He currently serves as an Associate Editor of IEEE Transactions on Fuzzy Systems and is a member of a number of Editorial Boards of other international journals.

## About the Part Editors

**Cesare Alippi**

Politecnico di Milano  
Dip. Elettronica, Informazione e  
Ingegneria  
20133 Milano, Italy  
[alippi@elet.polimi.it](mailto:alippi@elet.polimi.it)

Part D

Cesare Alippi received his PhD in 1995 from Politecnico di Milano, Italy. Currently, he is Professor at the same institution. He has been a visiting researcher at UCL (UK), MIT (USA), ESPCI (F), CASIA (RC), USI (CH). Alippi is an IEEE Fellow, Vice-President Education of the IEEE Computational Intelligence Society, Associate Editor of the IEEE Computational Intelligence Magazine, Past Editor of the IEEE-TIM and IEEE-TNN(LS). In 2004 he received the IEEE Instrumentation and Measurement Society Young Engineer Award and in 2013 the IBM Faculty Award. His current research focuses on learning in non-stationary environments and intelligence for embedded systems. He holds 5 patents, has published 1 monograph book, 6 edited books and about 200 papers in international journals and conference proceedings.

**Thomas Bartz-Beielstein**

Cologne University of Applied Sciences  
Faculty of Computer Science and  
Engineering Science  
51643 Gummersbach, Germany  
[thomas.bartz-beielstein@fh-koeln.de](mailto:thomas.bartz-beielstein@fh-koeln.de)

Part E

Thomas Bartz-Beielstein is a Professor of Applied Mathematics at Cologne University of Applied Sciences (CUAS). His expertise lies in optimization, simulation, and statistical analysis of complex real-world problems. He has more than 100 publications on computational intelligence, optimization, simulation, and experimental research. He has been on the program committees of several international conferences and organizes the prestigious track *Evolutionary Computation in Practice* at GECCO. His books on experimental research are considered as milestones in this emerging field. He is speaker of the research center *Computational Intelligence plus* at CUAS and head of the SPOTSeven team.

**Christian Blum**

University of the Basque Country  
Dep. Computer Science and Artificial  
Intelligence  
20018 San Sebastian, Spain  
[christian.blum@ehu.es](mailto:christian.blum@ehu.es)

Part F

Christian Blum holds a Master's Degree in Mathematics (1998) from the University of Kaiserslautern, Germany, and a PhD degree in Applied Sciences (2004) from the Free University of Brussels, Belgium. He currently occupies a permanent post as Ikerbasque Research Professor at the University of the Basque Country, San Sebastian, Spain. His research interests include the development of swarm intelligence techniques and the combination of metaheuristics with exact approaches for solving difficult optimization problems. So far he has co-authored about 150 research papers.

**Oscar Castillo**

Tijuana Institute of Technology  
22379 Tijuana, Mexico  
[ocastillo@tectijuana.mx](mailto:ocastillo@tectijuana.mx)

Part G

Oscar Castillo holds the Doctor in Science degree in Computer Science from the Polish Academy of Sciences. He is a Professor of Computer Science in the Graduate Division, Tijuana Institute of Technology, Tijuana, Mexico. In addition, he serves as Research Director of Computer Science. Currently, he is Vice-President of HAFSA (Hispanic American Fuzzy Systems Association) and served as President of IFSA (International Fuzzy Systems Association). He belongs to the Mexican Research System with level II and is also a member of NAFIPS, IFSA, and IEEE. His research interests are in type-2 fuzzy logic, fuzzy control, and neuro-fuzzy and genetic-fuzzy hybrid approaches.

**Carlos A. Coello Coello**

CINVESTAV-IPN  
Dep. Computación  
D.F. 07300, México, Mexico  
[ccarlo@cs.cinvestav.mx](mailto:ccarlo@cs.cinvestav.mx)

**Part E**

Carlos A. Coello Coello received a PhD in Computer Science from Tulane University in 1996. He has made pioneering contributions to the research area currently known as evolutionary multi-objective optimization, mainly regarding the development of new algorithms. He is currently Professor at the Computer Science Department of CINVESTAV-IPN (Mexico City, México). He has co-authored more than 350 publications (his h-index is 62). He is Associate Editor of several journals, including *IEEE Transactions on Evolutionary Computation* and *Evolutionary Computation*. He has received Mexico's National Medal of Science in *Exact Sciences* and the IEEE Kiyo Tomiyasu Award. He is also an IEEE Fellow.

**Bernard De Baets**

Ghent University  
Dep. Mathematical Modelling, Statistics  
and Bioinformatics  
9000 Ghent, Belgium  
[bernard.debaets@ugent.be](mailto:bernard.debaets@ugent.be)

**Part A**

Bernard De Baets (1966) holds an MSc degree in Mathematics, a postgraduate degree in Knowledge Technology, and a PhD degree in Mathematics. He is a full professor at UGent (Belgium), where he leads KERMIT, an interdisciplinary team in mathematical modeling, having delivered 50 PhD graduates to date. His bibliography comprises nearly 400 journal papers, 60 book chapters, and 300 conference contributions. He acts as Co-Editor-in-Chief (2007) of *Fuzzy Sets and Systems*. He is a recipient of a Government of Canada Award, Honorary Professor of Budapest Tech (Hungary), Fellow of the International Fuzzy Systems Association, and has been nominated for the Ghent University Prometheus Award for Research.

**Roderich Groß**

University of Sheffield  
Dep. Automatic Control and Systems  
Engineering  
Sheffield, S1 3JD, UK  
[r.gross@sheffield.ac.uk](mailto:r.gross@sheffield.ac.uk)

**Part F**

Roderich Groß received a Diploma degree in Computer Science from TU Dortmund University in 2001 and a PhD degree in Engineering Sciences from the Université libre de Bruxelles in 2007. From 2005 to 2009 he was a fellow of the Japan Society for the Promotion of Science, a Research Associate at the University of Bristol, a Marie Curie Fellow at Unilever, and a Marie Curie Fellow at EPFL. Since 2010 he has been with the Department of Automatic Control and Systems Engineering at the University of Sheffield, where he is currently Senior Lecturer. His research interests include evolutionary and distributed robotics. He has authored over 60 publications on these topics. He is a Senior Member of the IEEE.

**Enrique Herrera Viedma**

University of Granada  
Dep. Computer Science and Artificial  
Intelligence  
18003 Granada, Spain  
[viedma@decsai.ugr.es](mailto:viedma@decsai.ugr.es)

**Part B**

Enrique Herrera-Viedma received his PhD degree in Computer Science from Granada University in 1996. He is Professor at Granada University in the Department of Computer Science and Artificial Intelligence and a member of the BoG in IEEE SMC. His interest topics are computing with words, fuzzy decision making, consensus, aggregation, social media, recommender systems, libraries, and bibliometrics. His h-index is 44 and presents over 7000 citations (WoS). In 2014 he was identified as Highly Cited Researcher by Thomson Reuters and Top Author in Computer Science according to Microsoft Academic Search.

**Luis Magdalena**

European Centre for Soft Computing  
33600 Mieres, Spain  
[luis.magdalena@softcomputing.es](mailto:luis.magdalena@softcomputing.es)

**Part B**

Luis Magdalena received the MS and PhD degrees in Telecommunication Engineering from the Technical University of Madrid, Spain, in 1988 and 1994. He has been Assistant (1990–1995) and Associate Professor (1995–2006) in Computer Science at the Technical University of Madrid. Since 2006 he has been Director General of the European Center for Soft Computing. His research interests include soft computing and its application. He has authored over 150 publications in the field. He has been President of the *European Society for Fuzzy Logic and Technologies* (2001–2005), Vice-President of the International Fuzzy Systems Association (2007–2011), and member of the IEEE Computational Intelligence Society AdCom (2011–2013).

**Jörn Mehnen**

Cranfield University  
Manufacturing Dep.  
Cranfield, MK43 0AL, UK  
[j.mehnen@cranfield.ac.uk](mailto:j.mehnen@cranfield.ac.uk)

**Part E**

Dr Jörn Mehnen is Reader in Computational Manufacturing at Cranfield University, UK and Privatdozent at TU Dortmund, Germany. He is also Deputy Director of the EPSRC Centre in Through-life Engineering Services at Cranfield University. His research activities are in real-world applications of computer sciences in mechanical engineering with special focus on evolutionary optimization, cloud manufacturing, and additive manufacturing.

**Patricia Melin**

Tijuana Institute of Technology  
Dep. Computer Science  
Chula Vista, CA 91909, USA  
[pmelin@ectijuana.mx](mailto:pmelin@ectijuana.mx)

**Part G**

Patricia Melin holds the Doctor in Science degree in Computer Science from the Polish Academy of Sciences. She has been a Professor of Computer Science in the Graduate Division, Tijuana Institute of Technology, Tijuana, Mexico since 1998. She serves as Director of Graduate Studies in Computer Science. Currently, she is Vice President of HAFSA (Hispanic American Fuzzy Systems Association). She is the founding Chair of the Mexican Chapter of the IEEE Computational Intelligence Society. She is member of NAFIPS, IFSA, and IEEE and belongs to the Mexican Research System with level III. Her research interests are in type-2 fuzzy logic, modular neural networks, pattern recognition, fuzzy control, and neuro-fuzzy and genetic-fuzzy hybrid approaches. She has published over 200 journal papers, 6 authored books, 20 edited books, and 200 papers in conference proceedings.

**Peter Merz**

University of Applied Sciences and Arts,  
Hannover  
Dep. Business Administration and  
Computer Science  
30459 Hannover, Germany  
[peter.merz@hs-hannover.de](mailto:peter.merz@hs-hannover.de)

**Part E**

Peter Merz received his PhD degree in Computer Science from the University of Siegen, Germany in 2000. Since 2009, he has been Professor at the University of Applied Sciences and Arts in Hannover. He is a well-known scientist in the field of evolutionary computation and meta-heuristics. His research interests center on fitness landscapes of combinatorial optimization problems and their analysis.

**Radko Mesiar**

STU in Bratislava  
Dep. Mathematics and Descriptive  
Geometry  
813 68 Bratislava, Slovakia  
[radko.mesiar@stuba.sk](mailto:radko.mesiar@stuba.sk)

**Part A**

Radko Mesiar received his PhD from Comenius University, Faculty of Mathematics and Physics, in 1979. He has been a member of the Department of Mathematics in the Faculty of Civil Engineering, STU Bratislava since 1978. He received his DSc in 1996 from the Czech Academy of Sciences. He has been a full professor since 1998. He is a fellow member of the Institute of Information and Automation at the Czech Academy of Sciences and of IRAFM, University of Ostrava (Czech Republic). He is co-author of two scientific monographs and five edited volumes. He is the author of more than 200 papers in WOS in leading journals. He is the co-founder of conferences AGOP, FSTA, ABLAT, and ISCAMI.

**Frank Neumann**

The University of Adelaide  
School of Computer Science  
Adelaide, SA 5005, Australia  
[frank.neumann@adelaide.edu.au](mailto:frank.neumann@adelaide.edu.au)

**Part E**

Frank Neumann received his diploma and PhD from the University of Kiel in 2002 and 2006, respectively. Currently, he is an Associate Professor and leader of the Optimisation and Logistics Group at the School of Computer Science, The University of Adelaide, Australia. He is the General Chair of ACM GECCO 2016. He is Vice-Chair of the IEEE Task Force on Theoretical Foundations of Bio-Inspired Computation, and Chair of the IEEE Task Force on Evolutionary Scheduling and Combinatorial Optimization. In his work, he considers algorithmic approaches and focuses on theoretical aspects of evolutionary computation as well as high impact applications in the areas of renewable energy, logistics, and sports.

**Marios Polycarpou**

University of Cyprus  
 Dep. Electrical and Computer  
 Engineering and KIOS Research Center  
 for Intelligent Systems and Networks  
 1678 Nicosia, Cyprus  
[mpolycar@ucy.ac.cy](mailto:mpolycar@ucy.ac.cy)

**Part D**

Marios Polycarpou is Professor of Electrical and Computer Engineering and the Director of the KIOS Research Center for Intelligent Systems and Networks at the University of Cyprus. His research expertise is in the areas of intelligent systems and control, computational intelligence, fault diagnosis, cooperative and adaptive control, and distributed agents. He is a Fellow of the IEEE. He has participated in more than 60 research projects/grants, funded by several agencies and industries in Europe and the United States. In 2011, he was awarded the prestigious European Research Council (ERC) Advanced Grant.

**Günther Raidl**

Vienna University of Technology  
 Inst. Computer Graphics and Algorithms  
 1040 Vienna, Austria  
[raidl@ads.tuwien.ac.at](mailto:raidl@ads.tuwien.ac.at)

**Part E**

Günther Raidl is Professor at the Vienna University of Technology, Austria, and heads the Algorithms and Data Structures Group. He received his PhD in 1994 and completed his Habilitation in Practical Computer Science in 2003. In 2005 he received a professorship position for combinatorial optimization. His research interests include algorithms and data structures in general and combinatorial optimization in particular, with a specific focus on metaheuristics, mathematical programming, and hybrid optimization approaches.

**Oliver Schütze**

CINVESTAV-IPN  
 Dep. Computación  
 D.F. 07300, México, Mexico  
[schuetze@cs.cinvestav.mx](mailto:schuetze@cs.cinvestav.mx)

**Part E**

Oliver Schütze received a PhD in Mathematics from the University of Paderborn, Germany in 2004. He is currently Professor at Cinvestav-IPN in Mexico City (Mexico). His research interests focus on numerical and evolutionary optimization where he addresses scalar and multi-objective optimization problems. He has co-edited 5 books and is co-author of more than 90 papers. He is a co-founder of SON (Set Oriented Numerics) and founder of the NEO (Numerical and Evolutionary Optimization) workshop series.

**Roman Słowiński**

Poznań University of Technology  
 Inst. Computing Science  
 60-965 Poznań, Poland  
[Roman.Slowinski@cs.put.poznan.pl](mailto:Roman.Slowinski@cs.put.poznan.pl)

**Part C**

Roman Słowiński is Professor and Founding Chair of the Laboratory of Intelligent Decision Support Systems at Poznań University of Technology. He is Academician and President of the Poznań Branch of the Polish Academy of Sciences and a member of Academia Europaea. In his research, he combines operations research and computational intelligence. He is renowned for his seminal research on using rough sets in decision analysis. He was laureate of the EURO Gold Medal (1991) and won the 2005 Prize of the Foundation for Polish Science. He is Doctor *Honoris Causa* of Polytech'Mons (2000), the University Paris Dauphine (2001), and the Technical University of Crete (2008).

**Carsten Witt**

Technical University of Denmark  
 DTU Compute, Algorithms, Logic and  
 Graphs  
 2800 Kgs., Lyngby, Denmark  
[cawi@imm.dtu.dk](mailto:cawi@imm.dtu.dk)

**Part E**

Carsten Witt is Associate Professor at the Technical University of Denmark. He received his PhD in Computer Science from the Technical University of Dortmund in 2004. His main research interests are the theoretical aspects of nature-inspired algorithms, in particular evolutionary algorithms, ant colony optimization and particle swarm optimization. He is a member of the Editorial Boards of Evolutionary Computation and Theoretical Computer Science and has co-authored a textbook.

**Yiyu Yao**

University of Regina  
Dep. Computer Science  
Regina, Saskatchewan, S4S 0A2, Canada  
[yyao@cs.uregina.ca](mailto:yyao@cs.uregina.ca)

**Part C**

Yiyu Yao is Professor of Computer Science in the Department of Computer Science, the University of Regina, Canada. His research interests include three-way decisions, rough sets, fuzzy sets, interval sets, granular computing, information retrieval, Web intelligence, and data mining. He is currently working on a triarchic theory of granular computing, a theory of three-way decisions and generalized rough sets.

## Contents

<b>List of Abbreviations .....</b>	<b>XLV</b>
<b>1 Introduction</b>	
<i>Janusz Kacprzyk, Witold Pedrycz .....</i>	1
1.1 Details of the Contents .....	2
1.2 Conclusions and Acknowledgments .....	4
<b>Part A Foundations</b>	
<b>2 Many-Valued and Fuzzy Logics</b>	
<i>Siegfried Gottwald .....</i>	7
2.1 Basic Many-Valued Logics .....	8
2.2 Fuzzy Sets .....	11
2.3 <i>t</i> -Norm-Based Logics .....	13
2.4 Particular Fuzzy Logics .....	16
2.5 Some Generalizations .....	21
2.6 Extensions with Graded Notions of Inference .....	23
2.7 Some Complexity Results .....	25
2.8 Concluding Remarks .....	27
<b>References .....</b>	<b>27</b>
<b>3 Possibility Theory and Its Applications: Where Do We Stand?</b>	
<i>Didier Dubois, Henry Prade .....</i>	31
3.1 Historical Background .....	32
3.2 Basic Notions of Possibility Theory .....	33
3.3 Qualitative Possibility Theory .....	38
3.4 Quantitative Possibility Theory .....	45
3.5 Some Applications .....	49
3.6 Some Current Research Lines .....	53
<b>References .....</b>	<b>54</b>
<b>4 Aggregation Functions on [0,1]</b>	
<i>Radko Mesiar, Anna Kolesárová, Magda Komorníková .....</i>	61
4.1 Historical and Introductory Remarks .....	61
4.2 Classification of Aggregation Functions .....	63
4.3 Properties and Construction Methods .....	66
4.4 Concluding Remarks .....	71
<b>References .....</b>	<b>72</b>
<b>5 Monotone Measures-Based Integrals</b>	
<i>Erich P. Klement, Radko Mesiar .....</i>	75
5.1 Preliminaries, Choquet, and Sugeno Integrals .....	76
5.2 Benvenuti Integral .....	80

5.3	Universal Integrals .....	82
5.4	General Integrals Which Are Not Universal .....	84
5.5	Concluding Remarks, Application Fields.....	86
	<b>References .....</b>	<b>87</b>

	<i>Humberto Bustince, Edurne Barrenechea, Javier Fernández, Miguel Pagola, Javier Montero .....</i>	89
6.1	Considerations Prior to the Concept of Extension of Fuzzy Sets .....	90
6.2	Origin of the Extensions .....	93
6.3	Type-2 Fuzzy Sets .....	94
6.4	Interval-Valued Fuzzy Sets .....	98
6.5	Atanasssov's Intuitionistic Fuzzy Sets or Bipolar Fuzzy Sets of Type 2 or IF Fuzzy Sets .....	103
6.6	Atanasssov's Interval-Valued Intuitionistic Fuzzy Sets .....	105
6.7	Links Between the Extensions of Fuzzy Sets .....	106
6.8	Other Types of Sets .....	106
6.9	Conclusions .....	108
	<b>References .....</b>	<b>108</b>
<b>7</b>	<b>F-Transform</b>	
	<i>Irina Perfilieva .....</i>	113
7.1	Fuzzy Modeling .....	113
7.2	Fuzzy Partitions.....	114
7.3	Fuzzy Transform .....	117
7.4	Discrete <i>F</i> -Transform .....	119
7.5	<i>F</i> -Transforms of Functions of Two Variables .....	120
7.6	$F^1$ -Transform .....	121
7.7	Applications.....	122
7.8	Conclusions .....	129
	<b>References .....</b>	<b>129</b>
<b>8</b>	<b>Fuzzy Linear Programming and Duality</b>	
	<i>Jaroslav Ramík, Milan Vlach.....</i>	131
8.1	Preliminaries .....	132
8.2	Fuzzy Linear Programming.....	135
8.3	Duality in Fuzzy Linear Programming.....	137
8.4	Conclusion .....	143
	<b>References .....</b>	<b>143</b>
<b>9</b>	<b>Basic Solutions of Fuzzy Coalitional Games</b>	
	<i>Tomáš Kroupa, Milan Vlach.....</i>	145
9.1	Coalitional Games with Transferable Utility .....	146
9.2	Coalitional Games with Fuzzy Coalitions .....	150
9.3	Final Remarks .....	155
	<b>References .....</b>	<b>156</b>

## Part B Fuzzy Logic

### 10 Basics of Fuzzy Sets

<i>János C. Fodor, Imre J. Rudas</i> .....	159
10.1 Classical Mathematics and Logic .....	160
10.2 Fuzzy Logic, Membership Functions, and Fuzzy Sets .....	160
10.3 Connectives in Fuzzy Logic .....	161
10.4 Concluding Remarks .....	168
<b>References</b> .....	168

### 11 Fuzzy Relations: Past, Present, and Future

<i>Susana Montes, Ignacio Montes, Tania Iglesias</i> .....	171
11.1 Fuzzy Relations .....	172
11.2 Cut Relations .....	174
11.3 Fuzzy Binary Relations .....	174
11.4 Particular Cases of Fuzzy Binary Relations .....	179
11.5 Present and Future of Fuzzy Relations .....	180
<b>References</b> .....	180

### 12 Fuzzy Implications: Past, Present, and Future

<i>Michał Baczyński, Balasubramaniam Jayaram, Sebastia Massanet, Joan Torrens</i> .....	183
12.1 Fuzzy Implications: Examples, Properties, and Classes .....	184
12.2 Current Research on Fuzzy Implications .....	187
12.3 Fuzzy Implications in Applications .....	193
12.4 Future of Fuzzy Implications .....	198
<b>References</b> .....	199

### 13 Fuzzy Rule-Based Systems

<i>Luis Magdalena</i> .....	203
13.1 Components of a Fuzzy Rule Based-System .....	204
13.2 Types of Fuzzy Rule-Based Systems .....	209
13.3 Hierarchical Fuzzy Rule-Based Systems .....	213
13.4 Fuzzy Rule-Based Systems Design .....	214
13.5 Conclusions .....	216
<b>References</b> .....	217

### 14 Interpretability of Fuzzy Systems: Current Research Trends and Prospects

<i>Jose M. Alonso, Ciro Castiello, Corrado Mencar</i> .....	219
14.1 The Quest for Interpretability .....	220
14.2 Interpretability Constraints and Criteria .....	224
14.3 Interpretability Assessment .....	227
14.4 Designing Interpretable Fuzzy Systems .....	229
14.5 Interpretable Fuzzy Systems in the Real World .....	233
14.6 Future Research Trends on Interpretable Fuzzy Systems .....	234
14.7 Conclusions .....	234
<b>References</b> .....	235

<b>15 Fuzzy Clustering – Basic Ideas and Overview</b>	
<i>Sadaaki Miyamoto</i> .....	239
15.1 Fuzzy Clustering .....	239
15.2 Fuzzy $c$ -Means .....	239
15.3 Hierarchical Fuzzy Clustering .....	245
15.4 Conclusion .....	246
References .....	247
<b>16 An Algebraic Model of Reasoning to Support Zadeh's CWW</b>	
<i>Enric Trillas</i> .....	249
16.1 A View on Reasoning .....	249
16.2 Models .....	250
16.3 Reasoning .....	251
16.4 Reasoning and Logic .....	254
16.5 A Possible Scheme for an Algebraic Model of Commonsense Reasoning .....	255
16.6 Weak and Strong Deduction: Refutations and Conjectures in a BFA (with a Few Restrictions) .....	260
16.7 Toward a Classification of Conjectures .....	262
16.8 Last Remarks .....	264
16.9 Conclusions .....	265
References .....	266
<b>17 Fuzzy Control</b>	
<i>Christian Moewes, Ralf Mikut, Rudolf Kruse</i> .....	269
17.1 Knowledge-Driven Control .....	269
17.2 Classical Control Engineering .....	270
17.3 Using Fuzzy Rules for Control .....	271
17.4 A Glance at Some Industrial Applications .....	276
17.5 Automatic Learning of Fuzzy Controllers .....	279
17.6 Conclusions .....	281
References .....	281
<b>18 Interval Type-2 Fuzzy PID Controllers</b>	
<i>Tufan Kumbasar, Hani Hagras</i> .....	285
18.1 Fuzzy Control Background .....	285
18.2 The General Fuzzy PID Controller Structure .....	286
18.3 Simulation Studies .....	291
18.4 Conclusion .....	292
References .....	293
<b>19 Soft Computing in Database and Information Management</b>	
<i>Guy De Tré, Sławomir Zadrożny</i> .....	295
19.1 Challenges for Modern Information Systems .....	295
19.2 Some Preliminaries .....	296
19.3 Soft Computing in Information Modeling .....	298
19.4 Soft Computing in Querying .....	302
19.5 Conclusions .....	309
References .....	309

---

<b>20 Application of Fuzzy Techniques to Autonomous Robots</b>	
<i>Ismael Rodríguez Fdez, Manuel Muñientes, Alberto Bugarín Díz</i>	313
20.1 Robotics and Fuzzy Logic .....	313
20.2 Wall-Following .....	314
20.3 Navigation .....	315
20.4 Trajectory Tracking .....	317
20.5 Moving Target Tracking .....	318
20.6 Perception .....	319
20.7 Planning .....	319
20.8 SLAM .....	320
20.9 Cooperation .....	320
20.10 Legged Robots .....	321
20.11 Exoskeletons and Rehabilitation Robots .....	322
20.12 Emotional Robots .....	323
20.13 Fuzzy Modeling .....	323
20.14 Comments and Conclusions .....	324
References .....	325

## Part C Rough Sets

<b>21 Foundations of Rough Sets</b>	
<i>Andrzej Skowron, Andrzej Jankowski, Roman W. Swiniarski</i>	331
21.1 Rough Sets: Comments on Development .....	331
21.2 Vague Concepts .....	332
21.3 Rough Set Philosophy .....	333
21.4 Indiscernibility and Approximation .....	333
21.5 Decision Systems and Decision Rules .....	336
21.6 Dependencies .....	337
21.7 Reduction of Attributes .....	337
21.8 Rough Membership .....	338
21.9 Discernibility and Boolean Reasoning .....	339
21.10 Rough Sets and Induction .....	340
21.11 Rough Set-Based Generalizations .....	340
21.12 Rough Sets and Logic .....	343
21.13 Conclusions .....	347
References .....	347

<b>22 Rough Set Methodology for Decision Aiding</b>	
<i>Roman Słowiński, Salvatore Greco, Benedetto Matarazzo</i>	349
22.1 Data Inconsistency as a Reason for Using Rough Sets .....	350
22.2 The Need for Replacing the Indiscernibility Relation by the Dominance Relation when Reasoning About Ordinal Data ..	351
22.3 The Dominance-based Rough Set Approach to Multi-Criteria Classification .....	353
22.4 The Dominance-based Rough Set Approach to Multi-Criteria Choice and Ranking .....	361
22.5 Important Extensions of DRSA .....	366

22.6	DRSA to Operational Research Problems .....	366
22.7	Concluding Remarks on DRSA Applied to Multi-Criteria Decision Problems.....	367
	References .....	367
<b>23</b>	<b>Rule Induction from Rough Approximations</b>	
	<i>Jerzy W. Grzymala-Busse .....</i>	371
23.1	Complete and Consistent Data .....	371
23.2	Inconsistent Data .....	375
23.3	Decision Table with Numerical Attributes .....	377
23.4	Incomplete Data .....	378
23.5	Conclusions .....	384
	References .....	384
<b>24</b>	<b>Probabilistic Rough Sets</b>	
	<i>Yiyu Yao, Salvatore Greco, Roman Słowiński .....</i>	387
24.1	Motivation for Studying Probabilistic Rough Sets.....	388
24.2	Pawlak Rough Sets .....	388
24.3	A Basic Model of Probabilistic Rough Sets .....	390
24.4	Variants of Probabilistic Rough Sets .....	391
24.5	Three Fundamental Issues of Probabilistic Rough Sets .....	394
24.6	Dominance-Based Rough Set Approaches .....	398
24.7	A Basic Model of Dominance-Based Probabilistic Rough Sets .....	399
24.8	Variants of Probabilistic Dominance-Based Rough Set Approach ...	400
24.9	Three Fundamental Issues of Probabilistic Dominance-Based Rough Sets .....	403
24.10	Conclusions .....	409
	References .....	409
<b>25</b>	<b>Generalized Rough Sets</b>	
	<i>JingTao Yao, Davide Ciucci, Yan Zhang .....</i>	413
25.1	Definition and Approximations of the Models.....	414
25.2	Theoretical Approaches .....	420
25.3	Conclusion .....	422
	References .....	423
<b>26</b>	<b>Fuzzy-Rough Hybridization</b>	
	<i>Masahiro Inuiguchi, Wei-Zhi Wu, Chris Cornelis, Nele Verbiest .....</i>	425
26.1	Introduction to Fuzzy-Rough Hybridization .....	425
26.2	Classification- Versus Approximation-Oriented Fuzzy Rough Set Models .....	427
26.3	Generalized Fuzzy Belief Structures with Application in Fuzzy Information Systems .....	437
26.4	Applications of Fuzzy Rough Sets .....	444
	References .....	447

## Part D Neural Networks

### 27 Artificial Neural Network Models

<i>Peter Tino, Lubica Benuskova, Alessandro Sperduti</i> .....	455
27.1 Biological Neurons .....	455
27.2 Perceptron .....	456
27.3 Multilayered Feed–Forward ANN Models .....	458
27.4 Recurrent ANN Models .....	460
27.5 Radial Basis Function ANN Models .....	464
27.6 Self–Organizing Maps .....	465
27.7 Recursive Neural Networks .....	467
27.8 Conclusion .....	469
<b>References</b> .....	470

### 28 Deep and Modular Neural Networks

<i>Ke Chen</i> .....	473
28.1 Overview .....	473
28.2 Deep Neural Networks .....	474
28.3 Modular Neural Networks .....	484
28.4 Concluding Remarks .....	492
<b>References</b> .....	492

### 29 Machine Learning

<i>James T. Kwok, Zhi-Hua Zhou, Lei Xu</i> .....	495
29.1 Overview .....	495
29.2 Supervised Learning .....	497
29.3 Unsupervised Learning .....	502
29.4 Reinforcement Learning .....	510
29.5 Semi-Supervised Learning .....	513
29.6 Ensemble Methods .....	514
29.7 Feature Selection and Extraction .....	518
<b>References</b> .....	519

### 30 Theoretical Methods in Machine Learning

<i>Badong Chen, Weifeng Liu, José C. Principe</i> .....	523
30.1 Background Overview .....	524
30.2 Reproducing Kernel Hilbert Spaces .....	525
30.3 Online Learning with Kernel Adaptive Filters .....	527
30.4 Illustration Examples .....	538
30.5 Conclusion .....	542
<b>References</b> .....	542

### 31 Probabilistic Modeling in Machine Learning

<i>Davide Bacciu, Paulo J.G. Lisboa, Alessandro Sperduti, Thomas Villmann</i> .....	545
31.1 Probabilistic and Information-Theoretic Methods .....	545
31.2 Graphical Models .....	552
31.3 Latent Variable Models .....	560
31.4 Markov Models .....	565
31.5 Conclusion and Further Reading .....	572
<b>References</b> .....	573

<b>32 Kernel Methods</b>	
<i>Marco Signoretto, Johan A. K. Suykens</i> .....	577
32.1 Background .....	578
32.2 Foundations of Statistical Learning .....	580
32.3 Primal–Dual Methods .....	586
32.4 Gaussian Processes .....	593
32.5 Model Selection .....	596
32.6 More on Kernels .....	597
32.7 Applications.....	600
<b>References</b> .....	601
<b>33 Neurodynamics</b>	
<i>Robert Kozma, Jun Wang, Zhigang Zeng</i> .....	607
33.1 Dynamics of Attractor and Analog Networks .....	607
33.2 Synchrony, Oscillations, and Chaos in Neural Networks.....	611
33.3 Memristive Neurodynamics.....	629
33.4 Neurodynamic Optimization.....	634
<b>References</b> .....	639
<b>34 Computational Neuroscience – Biophysical Modeling of Neural Systems</b>	
<i>Harrison Stratton, Jennie Si</i> .....	649
34.1 Anatomy and Physiology of the Nervous System .....	649
34.2 Cells and Signaling Among Cells.....	652
34.3 Modeling Biophysically Realistic Neurons .....	656
34.4 Reducing Computational Complexity for Large Network Simulations .....	660
34.5 Conclusions .....	662
<b>References</b> .....	662
<b>35 Computational Models of Cognitive and Motor Control</b>	
<i>Ali A. Minai</i> .....	665
35.1 Overview .....	665
35.2 Motor Control .....	667
35.3 Cognitive Control and Working Memory .....	670
35.4 Conclusion .....	674
<b>References</b> .....	674
<b>36 Cognitive Architectures and Agents</b>	
<i>Sebastien Hélie, Ron Sun</i> .....	683
36.1 Background .....	683
36.2 Adaptive Control of Thought–Rational (ACT–R) .....	685
36.3 Soar.....	688
36.4 CLARION.....	690
36.5 Cognitive Architectures as Models of Multi-Agent Interaction .....	693
36.6 General Discussion .....	694
<b>References</b> .....	695

---

<b>37 Embodied Intelligence</b>	
<i>Angelo Cangelosi, Josh Bongard, Martin H. Fischer, Stefano Nolfi</i>	697
37.1 Introduction to Embodied Intelligence	697
37.2 Morphological Computation for Body–Behavior Coadaptation	698
37.3 Sensory–Motor Coordination in Evolving Robots	701
37.4 Developmental Robotics for Higher Order Embodied Cognitive Capabilities	703
37.5 Conclusion	709

## List of Abbreviations

### Symbols

1-D	one-dimensional	ANOVA	analysis of variance
2-D	two-dimensional	ANYA	Angelov–Yager
3-CNF-SAT	three variables/clause-conjunctive normal form-satisfiability	AP	alternating-position crossover
3-D	three-dimensional	AP	automatic programming
		APA	affine projection algorithm
		API	application programming interface
		APS	aggregation pheromone system
		APSD	auto power spectral density
		AR	approximate reasoning
		AR	average ranking
		ARD	automatic relevance determination
		ARGOT	adaptive representation genetic optimization technique
		ARMOGA	adaptive range MOGA
		ASIC	application-specific integrated circuit
		ASP	answer-set programming
		ATP	adenosine triphosphate
		AUC	area under curve
		AUC	area under ROC curve
		AVITEWRITE	adaptive vector integration to endpoint handwriting
<b>A</b>			
A2A	all-to-all	BBB	blood brain barrier
AaaS	analytics-as-a-service	BCI	brain–computer interface
AANN	auto-associative neural network	BCO	bee colony optimization
ABC	artificial bee colony	BDAS	Berkeley data analytics stack
ACC	anterior cingulate cortex	BER	bit error rate
ACO	ant colony optimization	BeRoSH	behavior-based multiple robot system with host for object manipulation
ACP	active categorical perception	BFA	basic fuzzy algebra
ACS	action-centered subsystem	BG	basal ganglia
ACS	ant colony system	BIC	Bayesian information criterion
ACT-R	adaptive control of thought-rational	BINCSP	binary constraint satisfaction problem
AD	anomaly detection	BioHEL	bioinformatics-oriented hierarchical evolutionary learning
ADC	analog digital converter	BKS	Bandler–Kohout subproduct
ADF	additively decomposable function	BLB	bag of little bootstrap
ADF	automatically defined function	BMA	Bayes model averaging
ADGLIB	adaptive genetic algorithm optimization library	BMDA	bivariate marginal distribution algorithm
AER	address event representation	BMF	binary matrix factorization
AFPGA	adaptive full POD genetic algorithm	BMI	brain–machine interface
AFSA	artificial fish swarm algorithm	BnB	branch and bound
AI	anomaly identification	BOA	Bayesian optimization algorithm
AI	artificial intelligence	BP	bereitschafts potential
AIC	Akaike information criterion		
AICOMP	comparable based AI model		
AIGEN	generative AI model		
ALCS	anticipatory learning classifier system		
ALD	approximate linear dependency		
ALM	asset–liability management		
ALU	arithmetic logic unit		
ALU	arithmetic unit		
AM	amplitude modulation		
amBOA	adaptive variant of mBOA		
AMPGA	adaptive mixed-flow POD genetic algorithm		
AMS	anticipated mean shift		
AMT	active media technology		
ANN	artificial neural network		

BP	back-propagation	CNGM	computational neuro-genetic modeling
BPTT	back-propagation through time	CNN	cellular neural network
BSB	base system builder	CNS	central nervous system
BSD	bipolar satisfaction degree	COA	center of area
BSS	blind source separation	COG	center of gravity
BYY	Bayesian Yin-Yang	COGIN	coverage-based genetic induction
<b>C</b>			
c-granule	complex granule	COP	cluster of processors
CA	cellular automata	COP	constrained optimization problem
CA	classification accuracy	CORE	Computing Research and Education
CA	complete $F$ -transform-based fusion algorithm	cos	center of set
CAD	computer-aided design	COW	cluster of workstations
CAE	contrastive auto-encoder	CP	constraint programming
CAM	computer-assisted manufacturing	CP	contrapositive symmetry
CART	classification analysis and regression tree	CP net	conditional preference network
CBLS	constraint-based local search	CPF	centralized Pareto front
CBR	case-based reasoner	CPG	central pattern generator
CBR	case-based reasoning	CPSD	cross power spectral density
CC	coherence criterion	CPT	cummulative prospect theory
CCF	cross correlation function	CPU	central processing unit
CCG	controlling crossed genes	CR	commonsense reasoning
CD	contrastive divergence	CR	control register
CEA	cellular evolutionary algorithm	CRA	chemical reaction algorithm
CEBOT	cellular robot	CRI	compositional rule of inference
CF	collaborative filtering	CS	cell saving
CF	compact flash	CS1	cognitive system
cf	convergence factor	CSA	contractual service agreement
CFD	computational fluid dynamics	CSA	cumulative step-size adaptation
CFG	context-free grammar	CSM	covariate shift minimization
CFS	correlation feature selection	CSP	common spatial pattern
CG	center of gravity	CSP	constraint satisfaction problem
CG	Cohen–Grossberg	CST	class-shape transformation
cGA	compact genetic algorithm	CTMC	corticospinal tract
CGP	Cartesian GP	CUDA	continuous-time finite Markov chain
CI	computational intelligence	CW	compute unified device architecture
CIP	cross information potential	CW	computing with words
CIS	Computational Intelligence Society	CWW	control word
CLB	configurable logic block	CX	computing with words
clk	clock	<b>D</b>	
CLM	component level model	DA	dopamine
CMA	cingulate motor area	DACE	design and analysis of computer experiments
CMA	covariance matrix adaptation	DAE	denoising auto-encoder
CML	coupled map lattice	DAG	directed acyclic graph
cMOEA	cellular MOEA	DAL	logic for data analysis
CMOS	complementary metal-oxide-semiconductor	DB	database
CNF	conjunctive normal form	DBN	deep belief network
		dBOA	decision-graph BOA

---

DC	direct current	<b>E</b>	
DC/AD	change/activate-deactivate	EA	evolutionary algorithm
DCA	de-correlated component analysis	EAPR	early access partial reconfiguration
DE	differential evolution	EBNA	estimation of Bayesian network
dEA	distributed evolutionary algorithm		algorithm
DENFIS	dynamic neuro-fuzzy inference system	EC	embodied cognition
deSNN	dynamic eSNN	EC	evolutionary computation
DEUM	density estimation using Markov random fields algorithm	EC	evolutionary computing
DEUM	distribution estimation using Markov random fields	ECGA	extended compact genetic algorithm
DGA	direct genetic algorithm	ECGP	extended compact genetic programming
DIC	deviance information criterion	ECJ	Java evolutionary computation
DL	deep learning	ECoG	electrocorticography
DLPFC	dorsolateral prefrontal cortex	ECOS	evolving connectionist system
DLR	German Aerospace Center	EDA	estimation of distribution algorithm
DLS	dynamic local search	EDP	estimation of distribution programming
DM	displacement mutation operator	EEG	electroencephalogram
DM	decision maker	EFRBS	electroencephalography
DMA	direct memory access	EFuNN	evolutionary FRBS
dMOEA	distributed MOEA	EGA	evolving fuzzy neural network
DNA	deoxyribonucleic acid	EGNA	equilibrium genetic algorithm
DNF	disjunctive normal form	EGO	estimation of Gaussian networks
DNN	deep neural network	EHBSA	algorithm
DOE	design of experiment	EHM	efficient global optimization
DOF	degree of freedom	EI	edge histogram based sampling algorithm
DP	dynamic programming	EKM	edge histogram matrix
DPF	distributed Pareto front	EKMANI	expected improvement
DPLL	Davis–Putnam–Logemann–Loveland	ELSA	enhanced KM
DPR	dynamic partial reconfiguration	EM	enhanced Karnik–Mendel algorithm with
DRC	domain relational calculus	EM	new initialization
DREAM	distributed resource evolutionary	EMG	evolutionary local selection algorithm
	algorithm machine	EMNA	
DRRS	dynamically reconfigurable robotic	EMO	exchange mutation operator
	system	EMOA	expectation maximization
DRS	dominance resistant solution	EMSE	electromyography
DRSA	dominance-based rough set approach	EODS	estimation of multivariate normal
DSA	data space adaptation	EP	algorithm
DSMGA	dependency-structure matrix genetic	EP	evolutionary multiobjective optimization
	algorithm	EPTV	evolutionary multiobjective algorithm
DSP	digital signal processing	ER	excess mean square error
DSP	digital signal processor	ERA	enhanced opposite directions searching
DSS	decision support system	ERA	evolutionary programming
dtEDA	dependency-tree EDA	EP	exchange property
DTI	diffusion tensor imaging	EPTV	extended possibilistic truth value
DTLZ	Deb–Thiele–Laumanns–Zitzler	ER	edge recombination
DTRS	decision-theoretic rough set	ERA	epigenetic robotics architecture
DW	data word	ERA	Excellence in Research for Australia
		ERD	event-related desynchronization
		ERM	empirical risk minimization
		ERS	event-related synchronization
		ES	embedding system
		ES	evolution strategy

ESA	enhanced simple algorithm	FOU	footprint of uncertainty		
ESN	echo state network	FPGA	field programmable gate array		
eSNN	evolving spiking neural network	FPGA	full POD genetic algorithm		
ESOM	evolving self-organized map	FPID	fuzzy PID		
ETS	evolving Takagi–Sugeno system	FPM	fractal prediction machine		
EV	extreme value	FPSO	fuzzy particle swarm optimization		
EvoStar	Main European Events on Evolutionary Computation	FPU	floating point unit		
EvoWorkshops	European Workshops on Applications of Evolutionary Computation	FQL	fuzzy query language

		GPU	graphics processing unit		

GPX	greedy partition crossover	IEEE	Institute of Electrical and Electronics Engineers
GRASP	greedy randomized adaptive search procedure	IF	intuitionistic fuzzy
GRBM	Gaussian RBM	IFA	independent factor analysis
GRN	gene/protein regulatory network	IFVS	interval valued fuzzy set
GRN	gene regulatory network	IG	iterated greedy
GT2	generalized T2FS	IGR	interactive granular computing
GWAS	genome-wide association studies	IHA	iterative heuristic algorithm
GWT	global workspace theory	ILS	iterated local search
<b>H</b>			
H-PIPE	hierarchical probabilistic incremental program evolution	INCF	International Neuroinformatics Coordinating Facility
hBOA	hierarchical BOA	IO-HMM	input/output hidden Markov model
HCF	hyper-cube framework	IOB	input/output block
HCwL	hill climbing with learning	IoT	internet of things
HDL	hardware description language	IP	identity principle
HFB	higher frequency band	IP	inductive programming
HH	Hodgkin–Huxley	IPIF	intellectual property
HM	health management	IPL	intellectual property interface
HMM	hidden Markov model	IPOP	inferior parietal lobe
HPC	high-performance computing	IRGC	increasing population size
HS	Hilbert space	IRLS	interactive rough granular computing
HSS	heuristic space search	IRSA	iteratively re-weighted least squares
HT	Hough transform	ISE	indiscernibility-based rough set approach
HW	hardware	ISI	Integrated Synthesis Environment
HWICAP	hardware internal configuration access point	ISM	inter-spike interval
<b>I</b>			
i.i.d.	independent, identically distributed	IT2	insertion mutation operator
IASC	iterative algorithm with stop condition	IT2FC	interval type-2
IB	indicator based	IT2FS	interval T2FC
IBEA	indicator-based evolutionary algorithm	ITAE	interval T2FS
iBOA	incremental Bayesian optimization algorithm	ITL	information theoretic learning
IC	intelligent controller	IUMDA	incremental univariate marginal distribution algorithm
IC	interrupt controller	IVM	inversion mutation operator
ICA	independent component analysis	<b>J</b>	
ICAP	internal configuration access point	JDEAL	Java distributed evolutionary algorithms library
ICE	induced chromosome element exchanger	JEGA	John Eddy genetic algorithm
ICML	International Conference on Machine Learning	JMAF	java multi-criteria and multi-attribute analysis framework
IDA	intelligent distribution agent	<b>K</b>	
IDEA	iterated density estimation evolutionary algorithm	KAF	kernel adaptive filter
IE	inference engine	KAPA	kernel affine projection algorithm
		KB	knowledge base
		KDD	knowledge discovery and data mining

KGA	Kriging-driven genetic algorithm	LT	linguistic term
KKT	Karush–Kuhn–Tucker	LUT	look-up table
KL	Kullback–Leibler	LV	linguistic variable
KLMS	kernel least mean square	LVT	linguistic-variable-term
KM	Karnik–Mendel	LWPR	locally-weighted projection regression
KMC	kernel Maximum Correntropy		algorithm
KNN	$k$ nearest neighbor	LZ	leading zero
KPCA	kernel principal component analysis		
KRLS	kernel recursive least square		
KUR	Kurswae		

## L

---

LAN	local network
LASSO	least absolute shrinkage and selection operator
LB	logic block
LCS	learning classifier system
LDA	latent Dirichlet allocation
LDA	linear discriminant analysis
LDS	limited discrepancy search
LED	light emitting diode
LEM	learning from examples module
LERS	learning from examples using rough sets
LFA	local factor analysis
LFB	lower frequency band
LFDA	learning FDA
LFM	linguistic fuzzy modeling
LFP	local field potential
LGP	linear GP
LHS	latin hypercube sampling
LI	law of importation
LIFM	leaky integrate-and-fire
LLE	liquid–liquid equilibrium
LMI	linear matrix inequalities
LMS	least mean square
LNS	large neighborhood search
LO	leading one
LOCVAL	locational value
LOO	leave-one-out
LOOCV	leave-one-out cross-validation
LOTZ	leading ones trailing zeroes
LP	logic programming
LQR	linear-quadratic regulator
LR	logistic regression
LRP	lateralized readiness potential
LS	least square
LS	local search
LSM	liquid state machine
LSTM	long short term memory

## M

---

M1	motor cortex
M2M	machine-to-machine
MA	Markovian agent
MA	memetic algorithm
MAE	mean of the absolute error
MAFRA	Java mimetic algorithms framework
MAM	Markovian agent model
MAMP	multiple algorithms, multiple problems
MAMS	multiple algorithms and multiple problem instances
MAP	maximum a posteriori
MARS	multivariate adaptive regression splines
MASP	multiple algorithms and one single problem
mBOA	mixed Bayesian optimization algorithm
MCA	minor component analysis
MCDA	multi-criteria decision analysis
MCDA	multiple criteria decision aiding
MCDM	multiple criteria decision-making
MCS	maximum cardinality search
MCS	meta-cognitive subsystem
MDL	minimum description length
MDP	Markov decision process
MDS	multidimensional scaling
MEG	magnetoencephalogram
MEG	magnetoencephalography
MEL	minimal epistemic logic
MF	membership function
MG	Mackey–Glass
MG	morphological gradient
MH	metaheuristic
MIL	multi-instance learning
MIMIC	mutual information maximizing input clustering
MIML	multi-instance, multi-label learning
MISO	multiple inputs-single output
MKL	multiple kernel learning
ML	machine learning
ML	maximum likelihood
MLEM2	modified LEM2 algorithm

MLP	multilayer perceptron	MSE	mean square error
MLR	multiple linear regression	MSG	max-set of Gaussian landscape generator
MLR	multi-response linear regression	msMOEA	master-slave MOEA
MM	mathematical morphology	MT	medial temporal
MMA	multimemetic algorithm	MTFL	multi-task feature learning
MMAS	MAX-MIN ant system	MTL	multi-task learning
MMEA	model-based multiobjective evolutionary algorithm	MV	maximum value
MMLD	man-machine learning dilemma	MWRA	minimum-weight rooted arborescence
MN-EDA	Markov network EDA	<b>N</b>	
MNN	memristor-based neural network	NACS	non-action-centered subsystem
MNN	modular neural network	NASA	National Aeronautics and Space Administration
MOAMO	multiobjectivization-assisted multimodal optimization	NC	neural computation
MOE	multiobjective evolutionary	NC	novelty criterion
MoE	mixture of experts	NC	numerical control
MOEA	multiobjective evolutionary algorithm	NCL	negative correlation learning
MOEA/D	multiobjective evolutionary algorithm based on decomposition	NDS	nonlinear dynamical systems
MOGA	multiobjective genetic algorithm	NEAT	neuro-evolution of augmenting topologies
MoGFS	multiobjective genetic fuzzy system	NES	natural evolution strategy
MOM	mean of maxima	NeuN	neuronal nuclei antibody
MOMGA	multi-objective messy GA	NFA	non-Gaussian factor analysis
MOO	multi-objective optimization	NFI	neuro-fuzzy inference system
MOP	many-objective optimization problem	NFL	no free lunch
MOP	multiobjective problem	NHBSA	node histogram based sampling algorithm
MOP	multiobjective optimization problem	NIL	nondeterministic information logic
MOPSO	multiobjective particle swarm optimization	NIPS	neural information processing system
MOSAIC	modular selection and identification for control	NLMS	normalized LMS
MOSES	meta-optimizing semantic evolutionary search	NLPCA	nonlinear principal components
MOT	movement time	NMF	negative matrix and tensor factorization
MPE	mean percentage error	NMF	nonnegative matrix factorization
MPE	most probable explanation	NN	neural network
MPGA	mixed-flow POD genetic algorithm	NOW	networks of workstation
MPI	message passing interface	NP	neutrality principle
MPM	marginal product model	NP	nondeterministic polynomial-time
MPP	massively parallel machine	NPV	net present value
MPS	multiprocessor system	NR	noise reduction
MR	maximum ranking	NS	negative slope
MRCP	movement-related cortical potentials	NSGA	nondominated sorting genetic algorithm
MRI	magnetic resonance imaging	NSPSO	nondominated sorting particle swarm optimization
mRMR	minimal-redundancy-maximal-relevance	NURBS	nonuniform rational B-spline
mRNA	messenger RNA	<b>O</b>	
MRNN	memristor-based recurrent neural network	ODE	ordinary differential equation
MS	master/slave	OEM	original equipment manufacturer
MS	motivational subsystem		
MSA	minor subspace analysis		

OKL	online kernel learning	PLA	programmable logic array
OLAP	online analytical processing	PLB	processor local bus
OM	operational momentum	PLS	partial least square
OMA	ordered modular average	pLSA	probabilistic latent semantic analysis
OP	ordering property	PLV	phase lock value
OPB	on-chip peripheral bus	PM	parallel model
OPL	open programming language	PMBGA	probabilistic model-building genetic algorithm
OR	operations research	PMC	premotor cortex
OR	operational research	PMI	partial mutual information
OS	overshoot	PMX	partially-mapped crossover
OWA	ordered weighted average	PN	pyramidal neuron
OWMax	ordered weighted maximum	PNS	peripheral nervous system
OX1	order crossover	POD	proper orthogonal decomposition
OX2	order-based crossover	PoE	product of experts
<hr/>			
<b>P</b>			
PAC	probably approximately correct	POR	preference order relation
PAES	Pareto-archived evolution strategy	POS	position-based crossover
PAR	place and route	PP	parallel platform
PBC	perception-based computing	PPSN	parallel problem solving in nature
PBIL	population-based incremental learning	PR	partial reconfiguration
PbO	programming by optimization	PRAS	polynomial-time randomized approximation scheme
PC	probabilistic computing	PRM	partially reconfigurable module
PC-SAFT	perturbed chain statistical associating fluid theory	PRODIGY	program distribution estimation with grammar model
PCA	principal component analysis	PRR	partially reconfigurable region
PCVM	probabilistic classifier vector machine	PS	pattern search
PD	Parkinson disease	PSA	principal subspace analysis
PD	proportional-differential	PSCM	problem-space computational model
PDDL	planning domain definition language	PSD	power spectral density
PDE	partial differential equation	PSD	predictive sparse decomposition
pdf	probability density function	PSEA	Pareto sorting evolutionary algorithm
PDGP	parallel and distributed GP	PSNR	peak signal-to-noise ratio
PEEL	program evolution with explicit learning	PSO	particle swarm optimization
PERT	program evaluation and review technique	PSS	problem space search
PESA	Pareto-envelope based selection algorithm	PSTH	peri-stimulus-time histogram
PET	positron emission tomography	PTT	pursuit-tracking task
PFC	Pareto front computation	PV	principal value
PFC	prefrontal cortex	PVS	persistent vegetative state
PFM	precise fuzzy modeling	PWM	pulse width modulation
PHM	prognostics and health management	<hr/>	
PIC	peripheral interface controller	<b>Q</b>	
PID	proportional-integral-derivative	Q-Q	quantile–quantile
PII	probabilistic iterative improvement	QAP	quadratic assignment problem
PIPE	probabilistic incremental program evolution	QeSNN	quantum-inspired eSNN
		QIP	quadratic information potential
		QKLMs	quantized KLMS
		QP	quadratic programming

**R**

r.k.	reproducing kernel
RAF	representable aggregation function
RAM	random access memory
RANS	Reynolds-averaged Navier–Stokes
RB	rule base
RBF	radial basis function
RBM	Boltzmann machine
rBOA	real-coded BOA
RECCo	robust evolving cloud-based controller
RecNN	recursive neural network
REGAL	relational genetic algorithm learner
REML	restricted maximum likelihood estimator
RET	relevancy transformation
RFID	radio frequency identification
RFP	red fluorescent protein
RGB	red-green-blue
RGN	random generation number
RHT	randomized Hough transform
RII	randomized iterative improvement
RISC	reduced instruction set computer
RKHS	reproducing kernel Hilbert space
RL	reinforcement learning
RLP	randomized linear programming
RLS	randomized local search
RLS	recursive least square
RM-MEDA	regularity model based multiobjective EDA
RMI	remote method invocation
RMSE	root-mean-square error
RMSEP	root-mean-square error of prediction
RMTL	regularized multi-task learning
RN	regularization network
RNA	ribonucleic acid
RNN	recurrent neural network
ROC	receiver operating characteristic
ROI	region of interest
ROM	read only memory
ROM	reduced-order model
ROS	robot operating system
RP	readiness potential
RPC	remote procedure call
RPCL	rival penalized competitive learning
RS	rough set
rst	reset
RT	reaction time
RT	real-time
RTL	register transfer logic
RTRL	real-time recurrent learning

**RUL**  
**RWS**

remaining useful life  
roulette wheel selection

**S**

S-ACO	simple ant colony optimization
S-bit	section-bit
S3VM	semi-supervised support vector machine
SA	simple $F$ -transform-based fusion algorithm
SA	simulated annealing
SAE	sparse auto-encoder
SAMP	one single algorithm and multiple problems
SARSA	state-action-reward-state-action
SASP	one single algorithm and one single problem
SAT	satisfiability
SBF	subspace-based function
SBO	surrogate-based optimization
SBR	similarity based reasoning
SBS	sequential backward selection
SBSO	surrogate based shape optimization
SBX	simulated binary crossover
SC	soft computing
SC	surprise criterion
SCH	school
SCNG	sparse coding neural gas
SD	structured data
SDE	stochastic differential equation
SDPE	standard deviation percentage error
SEAL	simulated evolution and learning
SEMO	simple evolutionary multi-objective optimizer
SF	scaling factor
SFS	sequential forward selection
SG-GP	stochastic grammar-based genetic programming
SHCLVND	stochastic hill climbing with learning by vectors of normal distribution
SI	swarm intelligence
SIM	simple-inversion mutation operator
SISO	single input single output
SLAM	simultaneous localization and mapping
SLF	superior longitudinal fasciculus
SLS	stochastic local search
SM	scramble mutation operator
SM	surrogate model
SMA	supplementary motor area

---

SMO	sequential minimum optimization	T	
SMP	symmetric multiprocessor	T1	type-1
SMR	sensorimotor rhythm	T1FC	type-1 fuzzy controller
sMRI	structural magnetic resonance imaging	T1FS	type-1 fuzzy set
SMS-EMOA	S-metric selection evolutionary multiobjective algorithm	T2	type-2
SNARC	spatial-numerical association of response code	T2FC	type-2 fuzzy controller
SNE	stochastic neighborhood embedding	T2FS	type-2 fuzzy set
SNP	single nucleotide polymorphism	T2IC	type-2 intelligent controller
SNR	signal-noise-ratio	T2MF	type-2 membership function
SOC	self-organized criticality	TAG3P	tree adjoining grammar-guided genetic programming
SOFM	self-organized feature maps	TD	temporal difference
SOFNN	self-organizing fuzzy neural network	TDNN	time delay neural network
SOGA	single-objective genetic algorithm	TET	total experiment time
SOM	self-organizing map	TFA	temporal factor analysis
SPAM	set preference algorithm for multiobjective optimization	TGBF	truncated generalized Bell function
SPAN	spike pattern association neuron	TN	thalamus
SPD	strictly positive definite	TOGA	target objective genetic algorithm
SPEA	strength Pareto evolutionary algorithm	TR	type reducer
SPOT	sequential parameter optimization toolbox	TRC	tuple relational calculus
SPR	static partial reconfiguration	TS	tabu search
SQL	structured query language	TS	time saving
SR	stochastic resonance	TSK	Takagi–Sugeno–Kang
SR	symbolic regression	TSP	traveling salesman problem
SRD	standard reference dataset	TTGA	trainable threshold gate array
SRF	strength raw fitness	TWNFI	transductive weighted neuro-fuzzy inference system
SRM	spike response model	U	
SRM	structural risk minimization	UART	universal asynchronous receiver/transmitter
SRN	simple recurrent network	UAV	unmanned aerial vehicle
SRT	serial reaction time	UCF	user constraint file
SSM	state-space model	UCS	supervised classifier system
SSOCF	subset size-oriented common features	UCX	uniform cycle crossover
SSSP	single-source shortest path problem	UMDA	univariate marginal distribution algorithm
StdGP	standard GP	UML	universal modeling language
STDP	spike-timing dependent plasticity	UPMOPSO	user-preference multiobjective PSO
STDP	spike-timing dependent learning	US EPA	United States Environmental Protection Agency
STGP	strongly typed GP	UW	underwriter
SU	single unit	V	
SURE-REACH	sensorimotor, unsupervised, redundancy-resolving control architecture	VB	variational Bayes
SUS	stochastic universal sampling	VC	Vapnik–Chervonenkis
SVaR	simplified value at risk	VC	variable consistency

# Introduction

## 1. Introduction

**Janusz Kacprzyk, Witold Pedrycz**

This *Springer Handbook of Computational Intelligence* is a result of a broad project that has been launched by us to respond to an urgent need of a wide scientific and scholarly community for a comprehensive reference source on Computational Intelligence, a field of science that has for some decades enjoyed a growing popularity both in terms of the theory and methodology as well as numerous applications. As it is always the case in such situations, after some time once an area has reached maturity, and there is to some extent a consent in the community as to which paradigms, and tools and techniques may be useful and promising, the time will come when some

state of the art exposition, exemplified by this Springer Handbook, would be welcome. We think that *this* is the right moment.

The first and most important question that can be posed by many people, notably those who work in more traditional and relatively well-defined fields of science, is what *Computational Intelligence* is. There are many definitions that try to capture the very essence of that field, emphasize different aspects, and – by necessity – somehow reflect the individual research interests, preferences, prospective application areas, etc.

However, it seems that in recent years there has been a wider and wider consent as to what basically Computational Intelligence is. Let us start with a citation coming from the Constitution of the IEEE (Institute of Electrical and Electronics Engineers) CIS (Computational Intelligence Society) – Article I, Section 5:

*The Field of Interest of the Society is the theory, design, application, and development of biologically and linguistically motivated computational paradigms emphasizing neural networks, connectionist systems, genetic algorithms, evolutionary programming, fuzzy systems, and hybrid intelligent systems in which these paradigms are contained.*

It seems that this is extremely up to the point, and we have basically followed this general philosophy in the composition of the Springer Handbook.

Let us first extend a little bit the above essential and comprehensive description of what computational intelligence is interested in, what deals with, which tools and techniques it uses, etc. Computational Intelligence is a broad and diverse collection of nature inspired computational methodologies and approaches, and tools and techniques that are meant to be used to model and solve complex real-world problems in various areas of science and technology in which the traditional approaches based on strict and well-defined tools and techniques, exemplified by *hard* mathematical modeling, optimization, control theory, stochastic analyses, etc., are either not feasible or not efficient. Of course, the term *nature inspired* should be meant in a broader sense of being *biologically inspired, socially inspired*, etc.

Those complex problems that are of interest of computational intelligence are often what may be called ill-posed which may make their exact solution, using the traditional hard tools and techniques, impossible.

However, we all know that such problems are quite effectively and efficiently solved in real life by human being, or – more generally – by living species. One can easily come to a conclusion that one should develop new tools, maybe less *precise* and not so well mathematically founded, that would provide a solution, maybe not optimal but good enough. This is exactly what Computational Intelligence is meant to provide.

Briefly speaking, it is most often considered that computational intelligence includes as its main components fuzzy logic, (artificial) neural networks, and

evolutionary computation. Of course, these main elements should be properly meant. For instance, one should understand that fuzzy logic is to be complemented by rough set theory or multivalued logic, neural networks should be more generally meant as including all kinds of connectionist systems and also learning systems, and evolutionary computation should be viewed as the area including swarm intelligence, artificial immune systems, bacterial algorithms, etc. One can also add in this context many other approaches like the Dempster–Shafer theory, chaos theory, etc.

## 1.1 Details of the Contents

The afore-mentioned view of the very essence of computational intelligence has been followed by us when dividing the handbook into parts, which correspond to the particular fields that constitute the area of Computational Intelligence, and also in the selection of field editors, and then their selection of proper authors. We have been very fortunate to be able to attract as the field editors and authors of chapters the best people in the respective fields.

### 1.1.1 Part A Foundations

For obvious reasons, we start the *Springer Handbook of Computational Intelligence* with *Part A, Foundations*, which deliver a constructive survey of some carefully chosen topics that are of importance for virtually all ensuing parts of the handbook. This part, edited by Professors Radko Mesiar and Bernard De Baets, involved foundational works on multivalued logics, possibility theory, aggregation functions, measure-based integrals, the essence of extensions of fuzzy sets, *F*-transforms, mathematical programming, and games under imprecision and fuzziness. It is easy to see that the contributions cover topics that are of profound relevance.

### 1.1.2 Part B Fuzzy Logic

*Part B, Fuzzy Logic*, edited by Professors Luis Magdalena and Enrique Herrera-Viedma, attempts to present the most relevant elements and issues related to a vast area of fuzzy logic. First of all, a comprehensive account of foundations of fuzzy sets theory has been provided, emphasizing both theoretical and application oriented aspects. This has been followed by

a state-of-the-art presentation of the concept, properties, and applications of fuzzy relations, including a brief historical perspective and future challenges. A similar account of the past, present, and future of an extremely important concept of fuzzy implications has then been authoritatively covered.

Then, various issues related to fuzzy systems modeling have been presented; notably the concept and properties of fuzzy-rule-based systems which are the core of fuzzy modeling, and the problem of interpretability of fuzzy systems. Fuzzy clustering, which is one of the most widely used tools and techniques, encountered in virtually all problems related to data analysis, modeling, control, etc., is then exposed, with focus on the past, present, and future challenges. Then, issues related to Zadeh's seminal idea of computing with words have been thoroughly studied from many perspectives, in particular a logical and algebraic one.

Since fuzzy (logic) control is undoubtedly the most vigorously reported industrial application of fuzzy logic, this subject has been presented in detail, both for the *conventional* fuzzy sets and their extensions, especially type 2 and interval type-2 fuzzy sets. Applications of fuzzy logic in autonomous robotics have been presented.

An account of fundamental issues and solutions related to the use of fuzzy logic in database and information management has then been given.

### 1.1.3 Part C Rough Sets

*Part C, Rough Sets*, edited by Professors Roman Słowiński and Yiyu Yao, starts with a comprehensive, rigorous, yet readable presentation of foundations of

rough sets, followed by a similar exposition focused on the use of rough sets to decision making, aiding, and support. Then, rule induction is considered as a tool for modeling, decision making, and data analysis.

A number of important extensions of the basic concept of a rough set have then been presented, including the concept of a probabilistic rough set and a generalized rough set, along with a lucid exposition of their properties and possible applications.

A crucial problem of a fuzzy-rough hybridization is then discussed, followed by a more general exposition of rough systems.

### 1.1.4 Part D Neural Networks

*Part D, Neural Networks*, edited by Professors Cesare Alippi and Marios Polycarpou, starts with a general presentation of artificial neural network models, followed by presentations of some mode specific types exemplified by deep and modular neural networks.

Much attention in this part is devoted to machine learning, starting from a very general overview of the area and main tools and techniques employed, theoretical methods in machine learning, probabilistic modeling in machine learning, kernel methods in machine learning, etc.

An important problem area called neurodynamics is the subject of a next state-of-the-art survey, followed by a review of basic aspects, models, and challenges of computational neuroscience considered basically from the point of view of biophysical modeling of neural systems. Cognitive architectures, notably for agent-based systems, and a related problem of computational models of cognitive and motor control have then been presented in much detail.

Advanced issues involved in the so-called embodied intelligence, and neuroengineering, and neuromorphic engineering, emerging as promising paradigms for modeling and problem solving, have then been dealt with.

Evolving connectionist systems, which constitute a novel, very promising architectures for the modeling of various processes and systems have been surveyed. An important part is on real-world applications of machine learning completes this important part.

### 1.1.5 Part E Evolutionary Computation

*Part E, Evolutionary Computation*, edited by Professors Frank Neumann, Carsten Witt, Peter Merz, Car-

los A. Coello Coello, Oliver Schütze, Thomas Bartz-Beielstein, Jörn Mehnen, and Günther Raidl, concerns the third fundamental element of what is traditionally being considered to be the core of Computational Intelligence.

First, comprehensive surveys of genetic algorithms, genetic programming, evolution strategies, parallel evolutionary algorithms are presented, which are readable and constructive so that a large audience might find them useful and – to some extent – ready to use. Some more general topics like the estimation of distribution algorithms, indicator-based selection, etc., are also discussed.

An important problem, from a theoretical and practical point of view, of learning classifier systems is presented in depth.

Multiobjective evolutionary algorithms, which constitute one of the most important group, both from the theoretical and applied points of view, are discussed in detail, followed by an account of parallel multiobjective evolutionary algorithms, and then a more general analysis of many multiobjective problems.

Considerable attention has also been paid to a presentation of hybrid evolutionary algorithms, such as memetic algorithms, which have emerged as a very promising tool for solving many real-world problems in a multitude of areas of science and technology. Moreover, parallel evolutionary combinatorial optimization has been presented.

Search operators, which are crucial in all kinds of evolutionary algorithms, have been prudently analyzed. This analysis was followed by a thorough analysis of various issues involved in stochastic local search algorithms.

An interesting survey of various technological and industrial applications in mechanical engineering and design has been provided. Then, an account of the use of evolutionary combinatorial optimization in bioinformatics is given.

An analysis of a synergistic integration of metaheuristics, notably evolutionary computation, and constraint satisfaction, constraint programming, graph coloring, tree decomposition, and similar relevant problems completes the part.

### 1.1.6 Part F Swarm Intelligence

*Part F, Swarm Intelligence*, edited by Professors Christian Blum and Roderich Gross, starts with a concise yet comprehensive introduction to swarm intelligence in optimization and robotics, two fields of

science in which this type of metaheuristics has been considered, and demonstrated to be powerful and useful.

Then, a preference-based multiobjective particle swarm optimization model is covered as a good tool for airfoil design. An ant colony optimization model for the minimum-weight rooted arborescence problem, which may be a good model for many diverse problem in computer science, decision analysis, data analysis, etc. is discussed.

An intelligent swarm of Markovian agents is the topic of a thorough analysis, which highlights the power and universality of this model. Moreover, a probabilistic modeling of swarm systems is surveyed.

Then some explicitly nature inspired algorithms based on how some species behave are presented, notably, a honey bee social foraging algorithm for resource allocation. Collective behavior modes and reconfigurability are discussed in swarm robotics, complemented by an exposition of problems and solutions related to the collective manipulation and construction.

### 1.1.7 Part G Hybrid Systems

*Part G, Hybrid Systems*, edited by Professors Oscar Castillo and Patricia Melin, starts with papers on various types of controllers developed with the aid of computational intelligence tools and techniques that are employed in a highly synergistic way.

First, an interesting and visionary study of robust evolving cloud-based controller which combines new conceptual ideas with novel computing architecture is provided. Then evolving embedded fuzzy controllers as well as the bio-inspired optimization of type-2 fuzzy controllers are surveyed. New hybrid modeling and solution tools are then presented; notably multiobjective genetic fuzzy systems. The use of modular neural networks and type-2 fuzzy logic is shown to be effective and efficient in various pattern recognition problems.

A novel idea of using chemical algorithms for the optimization of interval type-2 and type-1 fuzzy controllers for autonomous mobile robots is shown.

Finally, the implementation of bio-inspired optimization methods on graphic processing units is presented and its efficiency is emphasized.

## 1.2 Conclusions and Acknowledgments

To summarize, the coverage of topics in the particular parts has certainly provided a comprehensive, rigorous yet readable state-of-the-art survey of main research directions, developments and challenges in Computational Intelligence.

Both more advanced readers, who may look for details, and novice readers, who may look for some more general and readable introduction that could be employed in their later works, would certainly find this handbook useful.

# Many-Value

## 2. Many-Valued and Fuzzy Logics

Siegfried Gottwald

In this chapter, we consider particular classes of infinite-valued propositional logics which are strongly related to  $t$ -norms as conjunction connectives and to the real unit interval as a set of their truth degrees, and which have their implication connectives determined via an adjointness condition.

Such systems have in the last 10 years been of considerable interest, and the topic of important results. They generalize well-known systems of infinite-valued logic, and form a link to as different areas as, e.g., linear logic and fuzzy set theory.

We survey the most important ones of these systems, always explaining suitable algebraic semantics and adequate formal calculi, but also mentioning complexity issues.

Finally, we mention a type of extension which allows for graded notions of provability and entailment.

Classical *two-valued* logic is characterized by two basic principles. The *principle of extensionality* states that the truth value of any compound sentence depends only on the truth values of the components. The *Principle of bivalence*, also known as *tertium non datur*, states that any sentence is either true or false, nothing else is possible. Intuitively, a sentence is understood here as a formulation which has a truth value, i.e., which

is true or false. In everyday language this excludes formulations like questions, requests, and commands. Nevertheless, this explanation sounds like a kind of circular formulation. So formally one first fixes a certain formalized language, and then lays down formal criteria of what should count as a well-formed formula of this language, and particularly what should count as a sentence.

The principle of bivalence excludes hence *self-contradictory* formulations which are true as well as false, and it also excludes so-called truth value gaps, i. e., formulations which are neither true nor false.

Based on the understanding that a sentence is a formulation which has a truth value, many-valued logic generalizes the understanding of what a truth value is and hence allows for *more* values as only the two classical values *true* and *false*. To indicate this generalization, we speak here of *truth degrees* in the case of many-valued logics. And this allows the additional convention to have the name truth value reserved for the values *true* and *false* in their standard understanding in the sense of classical logic.

There are many possibilities to choose particular sets of truth degrees. Thus there are quite different systems of many-valued logic. However, each partic-

ular one of these systems  $\mathbb{L}$  has a fixed set of truth degrees  $\mathcal{W}_{\mathbb{L}}$ . Furthermore, each such system has its set  $\mathcal{D}_{\mathbb{L}} \subset \mathcal{W}_{\mathbb{L}}$  of designated truth degrees: formulas of the corresponding formalized language are *logically valid* iff they always have a designated truth degree.

Instead of the principle of bivalence each system  $\mathbb{L}$  of many-valued logic satisfy a *principle of multivalence* in the sense that any sentence has to have exactly one truth degree out of  $\mathcal{W}_{\mathbb{L}}$ . And the *principle of extensionality* now states that the truth degree of any compound sentence depends only on the truth degrees of the components.

Fuzzy logics are particular infinite-valued logics which have, at least in their most simple forms, the real unit interval  $[0, 1]$  as their truth degree sets, and which have the degree 1 as their only designated truth degree.

## 2.1 Basic Many-Valued Logics

If one looks systematically for many-valued logics which have been designed for quite different applications, one finds four main types of systems:

- The Łukasiewicz logics  $\mathbb{L}_\kappa$  as explained in [2.1];
- The Gödel logics  $\mathbb{G}_\kappa$  from [2.2];
- The product logic  $\Pi$  studied in [2.3];
- The Post logics  $\mathbb{P}_m$  for  $2 \leq m \in \mathbb{N}$  from [2.4].

The first two types of many-valued logics each offer a uniformly defined family of systems which differ in their sets of truth degrees and comprise finitely valued logics for each one of the truth degree sets  $\mathcal{W}_n = \{0, \frac{1}{n-1}, \frac{2}{n-1}, \dots, 1\}$ ,  $n \geq 2$ , together with an infinite-valued system with truth degree set  $\mathcal{W}_\infty = [0, 1]$ . Common reference to the finite-valued and the infinite-valued cases is formally indicated by choosing  $\kappa \in \{n \in \mathbb{N} \mid n \geq 2\} \cup \{\infty\}$  as an index.

For the fourth type an infinite-valued version is lacking.

In their original presentations, these logics look rather different, regarding their propositional parts. For the first-order extensions, however, there is a unique strategy: one adds a universal and an existential quantifier such that quantified formulas get, respectively, as their truth degrees the infimum and the supremum of all the particular cases in the range of the quantifiers.

As a reference for these and also other many-valued logics in general, the reader may consult [2.5].

Our primary interest here is in the infinite-valued versions of these logics. These ones have the closest connections to the fuzzy logics discussed later on. Therefore, we further on write simply  $\mathbb{L}$  instead of  $\mathbb{L}_\infty$ , and  $\mathbb{G}$  instead of  $\mathbb{G}_\infty$ .

For simplicity of notation, later on we often will use the same symbol for a connective and its truth degree function. It shall always become clear from the context what actually is meant.

### 2.1.1 The Gödel Logics

The simplest ones of these logics are the *Gödel logics*  $\mathbb{G}_\kappa$  which have a conjunction  $\wedge$  and a disjunction  $\vee$  defined by the minimum and the maximum, respectively, of the truth degrees of the constituents

$$u \wedge v = \min\{u, v\}, \quad u \vee v = \max\{u, v\}. \quad (2.1)$$

These Gödel logics have also a negation  $\approx$  and an implication  $\rightarrow_{\mathbb{G}}$  defined by the truth degree functions

$$\approx u = \begin{cases} 1, & \text{if } u = 0; \\ 0, & \text{if } u > 0. \end{cases} \quad u \rightarrow_{\mathbb{G}} v = \begin{cases} 1, & \text{if } u \leq v; \\ v, & \text{if } u > v. \end{cases} \quad (2.2)$$

The systems differ in their truth degree sets: for each  $2 \leq \kappa \leq \infty$  the truth degree set of  $\mathbb{G}_\kappa$  is  $\mathcal{W}_\kappa$ .

As shown by Dummett [2.6], the infinite-valued propositional Gödel logic  $\mathsf{G}$  has an *adequate axiomatization* which is provided by an adequate axiomatization of the intuitionistic propositional logic enriched with the additional axiom schema

$$(\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi). \quad (2.3)$$

Later on, in Sect. 2.5, we will recognize another axiomatization because  $\mathsf{G}$  is a particular  $t$ -norm-based logic.

### 2.1.2 The Łukasiewicz Logics

The Łukasiewicz logics  $\mathsf{L}_\kappa$ , again with  $2 \leq \kappa \leq \infty$ , have originally been designed in [2.1] with only two primitive connectives, an implication  $\rightarrow_L$  and a negation  $\neg$  characterized by the truth degree functions

$$\neg u = 1 - u, \quad u \rightarrow_L v = \min\{1, 1 - u + v\}. \quad (2.4)$$

The systems differ in their truth degree sets: for each  $2 \leq \kappa \leq \infty$  the truth degree set of  $\mathsf{L}_\kappa$  is  $\mathcal{W}_\kappa$ .

However, it is possible to define further connectives from these primitive ones. With

$$\begin{aligned} \varphi \& \psi &=_{\text{df}} \neg(\varphi \rightarrow_L \neg\psi), \\ \varphi \vee \psi &=_{\text{df}} \neg\varphi \rightarrow_L \psi \end{aligned} \quad (2.5)$$

one gets a (strong) conjunction and a (strong) disjunction with truth degree functions

$$\begin{aligned} u \& v &= \max\{u + v - 1, 0\}, \\ u \vee v &= \min\{u + v, 1\}, \end{aligned} \quad (2.6)$$

usually called the Łukasiewicz (arithmetical) *conjunction* and the Łukasiewicz (arithmetical) *disjunction*. It should be mentioned that these connectives are linked together via a De Morgan's law using the standard negation of this system

$$\neg(u \& v) = \neg u \vee \neg v. \quad (2.7)$$

With the additional definitions

$$\begin{aligned} \varphi \wedge \psi &=_{\text{df}} \varphi \& (\varphi \rightarrow_L \psi) \\ \varphi \vee \psi &=_{\text{df}} (\varphi \rightarrow_L \psi) \rightarrow_L \psi \end{aligned} \quad (2.8)$$

one gets another (weak) conjunction  $\wedge$  with truth degree function min, and a further (weak) disjunction  $\vee$

with max as truth degree function, i. e., one has the conjunction and the disjunction of the Gödel logics also available.

The infinite-valued propositional Łukasiewicz logic  $\mathsf{L}$ , with implication and negation as primitive connectives, has an adequate axiomatization consisting of the axiom schemata:

$$\begin{aligned} (\mathsf{L}_\infty 1) \quad & \varphi \rightarrow_L (\psi \rightarrow_L \varphi), \\ (\mathsf{L}_\infty 2) \quad & (\varphi \rightarrow_L \psi) \rightarrow_L ((\psi \rightarrow_L \chi) \rightarrow_L (\varphi \rightarrow_L \chi)), \\ (\mathsf{L}_\infty 3) \quad & (\neg\psi \rightarrow_L \neg\varphi) \rightarrow_L (\varphi \rightarrow_L \psi), \\ (\mathsf{L}_\infty 4) \quad & ((\varphi \rightarrow_L \psi) \rightarrow_L \psi) \rightarrow_L ((\psi \rightarrow_L \varphi) \rightarrow_L \varphi) \end{aligned}$$

together with the rule of detachment as the only inference rule.

Later on, in Sect. 2.5, we will recognize another axiomatization because  $\mathsf{L}$  is a particular  $t$ -norm-based logic.

### 2.1.3 The Product Logic

The *product logic*  $\Pi$ , in detail explained in [2.3], has the real unit interval as truth degree set, has a fundamental conjunction  $\odot$  with the ordinary product of reals as its truth degree function, and has an implication  $\rightarrow_\Pi$  with the truth degree function

$$u \rightarrow_\Pi v = \begin{cases} 1, & \text{if } u \leq v; \\ \frac{u}{v}, & \text{if } u < v. \end{cases} \quad (2.9)$$

Additionally, it has a truth degree constant  $\bar{0}$  to denote the truth degree zero.

In this context, a negation and a further conjunction are defined as

$$\begin{aligned} \approx \varphi &=_{\text{df}} \varphi \rightarrow_\Pi \bar{0}, \\ \varphi \wedge \psi &=_{\text{df}} \varphi \odot (\varphi \rightarrow_\Pi \psi). \end{aligned} \quad (2.10)$$

Routine calculations show that both connectives coincide with the corresponding ones of the infinite-valued Gödel logic  $\mathsf{G}$ . And also the disjunction  $\vee$  of this Gödel logic becomes available, now via the definition

$$\begin{aligned} \varphi \vee \psi &=_{\text{df}} ((\varphi \rightarrow_\Pi \psi) \rightarrow_\Pi \psi) \\ &\quad \wedge ((\psi \rightarrow_\Pi \varphi) \rightarrow_\Pi \varphi). \end{aligned} \quad (2.11)$$

There is, however, no natural way to combine with this (infinite valued) product logic a whole family of finite-valued systems by simply restricting the set of truth degrees to some  $\mathcal{W}_m$  as in the previous two cases:

besides  $\mathcal{W}_2$  no such set is closed under the ordinary product, and for  $\mathcal{W}_2$  the product coincides, e.g., with the minimum operation.

Later on, in Sect. 2.4, we will recognize an adequate axiomatization because also the product logic  $\Pi$  is a particular  $t$ -norm-based logic. Contrary to the previous cases of  $\mathbb{G}$  and  $\mathbb{L}$ , however, there is no essentially different axiomatization known as this later one.

### 2.1.4 The Post Logics

The Post system  $P_m$  for  $m \geq 2$  has truth degree set  $\mathcal{W}_m$ . These propositional systems have been originally formulated uniformly in negation and disjunction as basic connectives with the following truth degree functions

$$\approx u = \begin{cases} 1, & \text{for } u = 0, \\ u - \frac{1}{m-1}, & \text{for } u \neq 0, \end{cases}$$

$$u \vee v = \max\{u, v\}.$$

Contrary to the previous systems, the definition of negation here does not seem to be given in a uniform way independent of the number of truth degrees. However, it is always just a cyclic permutation of all the truth degrees (in their natural order).

For the sets of designated truth degrees, a canonical choice does not exist; already Post [2.4] has discussed the possibility that there may be chosen truth degrees different from 1 as designated ones. Nevertheless,  $\mathcal{D}^P = \{1\}$  is a kind of standard choice.

The set of basic connectives of each one of the Post systems  $P_m$  is functionally complete, i. e., allows to represent every possible truth degree function (over  $\mathcal{W}_m$ ). Therefore, each one of the Post systems  $P_m$ , with  $\mathcal{D}_P = \{1\}$  as the set of designated truth degrees, covers its corresponding Łukasiewicz system with the same set of truth degrees – in the sense that the set of  $L_m$ -tautologies is a subset of the set of  $P_m$ -tautologies, and that this set of  $P_m$ -tautologies does not contain any formula  $\varphi$  whose Łukasiewicz negation  $\neg\varphi$  is  $L_m$ -satisfiable. And the same holds true for the corresponding  $m$ -valued Gödel system  $\mathbb{G}_m$ .

If one enriches all the finitely many-valued (propositional) Łukasiewicz systems  $L_m$  with truth degree constants for all their truth degrees, then these enriched systems  $L_m^*$  become functionally complete. And this means that the extended  $m$ -valued Łukasiewicz systems  $L_m^*$  and the  $m$ -valued Post logics become interdefinable (for each fixed number  $m$  of truth degrees). Hence there is in principle no essential difference between both

types of (finitely valued) systems: all what can be expressed in the *Post world* can also be expressed in the (extended) *Łukasiewicz world*, and vice versa.

We omit to discuss adequate axiomatizations because these Post logics will not be of particular interest later on in this chapter. The interested reader might consult [2.5].

### 2.1.5 Algebraic Semantics

All these previously discussed many-valued logics have been introduced by their standard semantics.

Besides these standard semantics, all these many-valued logics have also *algebraic semantics* determined by suitable classes  $\mathcal{K}$  of truth degree structures. The situation is similar here to the case of classical logic: the logically valid formulas in classical logic are also just all those formulas which are valid in all Boolean algebras.

Of course, these structures have the same signature as the language  $\mathcal{L}$  of the corresponding logic, and they have to have – in the case that one discusses the corresponding first order logics – suprema and infima for all those subsets which may appear as value sets of formulas. Particularly, hence, they have to be (partially) ordered, or at least preordered.

For each formula  $\varphi$  of the language  $\mathcal{L}$  of the corresponding logic, for each such (generalized truth degree) structure  $\mathbf{A}$ , and for each evaluation  $e$  which maps the set of atomic formulas of  $\mathcal{L}$  into the carrier of  $\mathbf{A}$ , one has to define a value  $\text{Val}(\varphi, e)$ , and finally one has to define what it means that such a formula  $\varphi$  is *valid* in  $\mathbf{A}$ . Then a formula  $\varphi$  is *logically valid* w.r.t. this class  $\mathcal{K}$  iff  $\varphi$  is valid in all structures from  $\mathcal{K}$ .

#### Gödel and Łukasiewicz Logics

It is remarkable that for both these types of many-valued logics corresponding algebraic semantics have mainly been developed for the infinite-valued systems, and have been considered in the context of completeness proofs.

For the infinite-valued Gödel logic  $\mathbb{G}$  such a class of structures is, according to the completeness proof given by Dummett [2.6], the class of all *Heyting algebras*, i. e., of all relatively pseudo-complemented lattices, which satisfy the prelinearity condition

$$(u \rightarrow v) \cup (v \rightarrow u) = 1. \quad (2.12)$$

Here  $\cup$  is the lattice join and  $\rightarrow$  the relative pseudo-complement.

For the infinite-valued Łukasiewicz logic  $\mathbf{L}$  the corresponding class of structures is the class of all *MV-algebras*, first introduced again within a completeness proof by Chang [2.7], and more recently extensively studied in [2.8].

It is interesting to recognize that all these structures – prelinear Heyting algebras, MV-algebras, and product algebras – are Abelian lattice-ordered semi-groups with an additional *residuation* operation.

For the finite-valued logics from both families, separately developed algebraic semantics did not yet find considerable interest.

### Product Logic

The product logic, as introduced in [2.3], was from the very beginning designed as a logic which had, in parallel, a standard semantics – provided by the real unit interval and by a product-based conjunction as a fundamental connective – as well as an algebraic semantics, formed by the class of all product algebras – introduced in [2.3] again within a completeness proof.

We shall not explain more details here because this whole approach proved to become paradigmatic for the development of *t-norm-based infinite-valued logics*, a topic which shall be discussed later on, starting with Sect. 2.3.

### Post Logics

Contrary to the situation for the Łukasiewicz and the Gödel systems, for the Post systems in their original form there exist only very few syntactically oriented studies toward constituting or investigating logical calculi for these systems. Instead, for the Post systems one mainly was interested in the corresponding algebraic structures, which were suitable to form an algebraic semantics, and investigated such structures earlier, and in more detail, as similar structures for the Łukasiewicz and the Gödel systems. Rosenbloom in a paper [2.9] of 1942 was the first one to do this. His algebraic struc-

tures shall here be called P-algebras for short – but not be considered in detail: the interested reader might, e.g., consult [2.5].

One of the main reasons for the difficulty and complexity of the defining conditions of P-algebras is the fact that the Post systems as well as the P-algebras have only two primitive notions, their connectives resp. their basic operations, but have maximal expressive power in the sense of being functionally complete. That this choice of the primitive notions really is the main obstacle toward a simplification became clear as Epstein [2.10] in 1960 changed these basic operations and found a much simpler class of definitionally equivalent algebras, now called Post algebras.

What are not covered by these basic considerations are possible infinite-valued generalizations of these logical calculi, or of these Post algebras. Approaches toward this problem started, e.g., with papers on generalizations of the notion of Post algebras like [2.11–13]. The most influential paper, however, which also discussed the corresponding logical systems was the paper [2.14] of Rasiowa in which Post algebras of the order  $\omega + 1$  and the corresponding systems of infinitely many-valued (first-order) logic have been introduced. The algebraic theory of these Post algebras of the order  $\omega + 1$  is partly given in [2.14].

Another such infinitely many-valued generalization of the standard Post systems is discussed, e.g., in [2.15, 16], Post algebras of the order  $\omega + \omega^*$ .

The Post algebras of finite or infinite order and the systems of many-valued logic related with them seem to be of particular importance for investigations in computer science, which rely on many-valued logic as a toolbox, because these Post systems are functionally complete and well suited to study the representability of truth degree functions on the basis of some predetermined set of basic truth degree functions, as determined, e.g., by available electronic components, cf. [2.17] for a still good introduction.

## 2.2 Fuzzy Sets

A fuzzy set  $A$  is usually a fuzzy subset of a given set  $\mathbb{X}$  and characterized by its membership function  $\mu_A : \mathbb{X} \mapsto [0, 1]$ . The set  $\mathbb{X}$  is often called the *universe of discourse*. This notation derives from [2.18]. So these fuzzy sets are (possibly) first-level objects of a cumulative hierarchy, with the elements of  $\mathbb{X}$  as urelements. But the usual applications do not need higher level

fuzzy sets. And also for our discussion of the background logic such higher level fuzzy sets do not matter.

### 2.2.1 Set Algebra for Fuzzy Sets

Mathematically, it is customary to identify such a fuzzy subset of  $\mathbb{X}$  with its membership function. Accordingly,

$\mu_A(a)$  and  $A(a)$  both are used to denote the membership degree of the object  $a \in \mathbb{X}$  w.r.t. the fuzzy set  $A$ . For any binary operation  $*$  between membership degrees the pointwise approach means to define from it a binary operation  $\circledast$  for fuzzy sets such that the fuzzy set  $A \circledast B$  is characterized by

$$A \circledast B(x) = A(x) * B(x) \quad \text{for all } x \in \mathbb{X}. \quad (2.13)$$

Hence, Zadeh's *standard intersection*  $A \cap B$  and *union*  $A \cup B$  are characterized by

$$\begin{aligned} A \cap B(x) &= \min\{A(x), B(x)\}, \\ A \cup B(x) &= \max\{A(x), B(x)\}. \end{aligned} \quad (2.14)$$

Additionally, again following the first proposal from [2.18], one usually also defines the *complement*  $C_{\mathbb{X}}A$  of a fuzzy set  $A$  by the condition

$$C_{\mathbb{X}}A(x) = 1 - A(x) \quad \text{for all } x \in \mathbb{X}. \quad (2.15)$$

However, in [2.18] also other versions of such binary operations had been mentioned: an algebraic product  $AB$  and an algebraic sum  $A + B$  defined through

$$\begin{aligned} AB(x) &= \min\{A(x) \cdot B(x)\}, \\ A + B(x) &= \min\{A(x) + B(x), 1\} \end{aligned} \quad (2.16)$$

as well as an absolute difference  $|A - B|$  defined by

$$|A - B|(x) = |A(x) - B(x)|. \quad (2.17)$$

It is interesting to notice, and shall be explained in more detail in Sect. 2.2.2, that the operations (2.16) can be seen as generalized kinds of intersection and union operations, respectively. However, these operations are *not idempotent*: one has in general  $AA \neq A$  as well as  $A + A \neq A$ .

## 2.2.2 Fuzzy Sets and Many-Valued Logic

It is well known that there is a strong parallelism between the standard set algebraic operations of intersection, union, and complementation, and classical logic, namely, the operations of conjunction, disjunction, and negation, determined by their truth value functions *et*, *vel*, *non*, respectively. So one usually defines, e.g., the intersection  $M \cap N$  of sets  $M, N$  by the condition

$$x \in M \cap N \iff x \in M \wedge x \in N, \quad (2.18)$$

with  $\wedge$  for the conjunction operation of classical logic here.

In more abstract terms, the idea here is that these operations are defined in such a way that the power set algebra  $\mathcal{P}(M)$  of any set  $M$  is (isomorphic to) the direct product  $W^M = \prod_{a \in M} W$  of the Boolean algebra  $W = \{1, 0\}$ , *et*, *vel*, *non* of truth values of classical logic.

A similar relationship can be recognized between the set algebra of fuzzy sets and suitable many-valued logics. It is simply necessary to consider the set of membership degrees for the fuzzy sets as set of truth degrees for a corresponding many-valued logic. So one can consider the operations (2.14) as intersection and union related to the Gödel logic  $G$ , or also related to the Łukasiewicz logic  $L$ . Similarly, the complementation (2.15) is related to the negation operation of the Łukasiewicz logics, and the *algebraic* operations in (2.16) are an intersection operation with respect to product logic, and a union operations with respect to (the strong disjunction of) Łukasiewicz logic. Even the operation (2.17) can be defined via Łukasiewicz logic: one gets immediately via the corresponding truth degree functions

$$|u - v| = \neg((u \rightarrow_L v) \wedge (v \rightarrow_L u)). \quad (2.19)$$

In more abstract terms, again, the set algebraic operations with respect to a particular  $[0, 1]$ -valued logic  $\mathbb{L}$  should be defined in such a way that the class  $\mathcal{F}(\mathbb{X}) = [0, 1]^{\mathbb{X}}$  of fuzzy subsets of a universe of discourse  $\mathbb{X}$  is (isomorphic to) the direct product  $W^{\mathbb{X}} = \prod_{a \in \mathbb{X}} W$  of the truth degree algebra  $W = ([0, 1], \dots)$  of this particular  $[0, 1]$ -valued logic.

## 2.2.3 *t*-Norms and *t*-Conorms

For the previously mentioned nonidempotent intersection operation, i.e., the algebraic product from (2.16), and for further similar possibilities the mathematically oriented part of the fuzzy community reached, mainly in the first half of the 1980s, a consensus that such generalized intersection operations should be defined via (2.13) from a triangular norm  $*$ . Such *triangular norms – t-norms* for short – had first been considered in the context of probabilistic metric spaces to get a suitable version of a triangle inequality, cf. e.g. [2.19], and found since independent interest in different contexts, cf. [2.20, 21]. They are *isotonic*, *associative*, and *commutative* binary operations in the unit interval which have 1 as their *neutral element*. This means that they make the unit interval an *ordered monoid*.

The class of all *t*-norms is, however, very large and not yet really well understood. So the question

appears to restrict to suitable subclasses, e.g., to the continuous *t*-norms or to the left-continuous ones. (For a *t*-norm  $T$  left-continuity means that all the unary functions  $T_a$  with  $T_a(x) = T(a, x)$  for each  $a \in [0, 1]$  are left-continuous. For continuity the conditions (i) that  $T$  is continuous as a binary function and (ii) that all the  $T_a$  are continuous coincide [2.5, 20].) Standard examples for continuous *t*-norms are the min-operation in  $[0, 1]$ , also called *Gödel t-norm*  $T_G$ , the arithmetic product in  $[0, 1]$ , also called *product t-norm*  $T_P$ , and the *Łukasiewicz t-norm*  $T_L : (u, v) \mapsto \max\{u + v - 1, 0\}$  which is the truth degree function of the strong conjunction in the Łukasiewicz many-valued systems. And a standard example for a left-continuous *t*-norm which is not continuous is the *nilpotent minimum*  $T_{NM}$  defined as

$$T_{NM}(u, v) = \begin{cases} \min\{u, v\}, & \text{if } u + v > 1 \\ 0 & \text{otherwise.} \end{cases} \quad (2.20)$$

These examples for continuous *t*-norms are even characteristic in the sense that each continuous *t*-norm is an ordinal sum of isomorphic versions of  $T_L$ ,  $T_P$ ,  $T_G$ , cf. [2.20] and also [2.5].

To explain what is meant by an isomorphic version of some *t*-norm, one has to start from an *order automorphism*  $f$  of the unit interval, i.e., from a continuous 1–1 onto map  $f : [0, 1] \rightarrow [0, 1]$  with  $f(0) = 0$  and  $f(1) = 1$ . Is now  $T$  a *t*-norm and  $T^* : [0, 1]^2 \rightarrow [0, 1]$  defined by

$$T^*(x, y) = f^{-1}(T(f(x), f(y))), \quad (2.21)$$

which equivalently means

$$f(T^*(x, y)) = T(f(x), f(y)), \quad (2.22)$$

then  $T^*$  is again a *t*-norm and called an *isomorphic version* of  $T$ , and  $T$ ,  $T^*$  are *isomorphic t-norms*.

Parallel with *t*-norms one often also considers *t-conorms*: these are isotonic, associative, and commutative binary operations in the unit interval which have 0 as their neutral element. For the set algebra of fuzzy sets they define (possibly) nonidempotent unions, and for the background logics they constitute (possibly) nonidempotent disjunctions.

There is a natural 1–1 duality between *t*-norms and *t*-conorms. By

$$1 - S(u, v) = T(1 - u, 1 - v) \quad (2.23)$$

one determines a *t*-conorm  $S$  for any *t*-norm  $T$ , and conversely determines a *t*-norm  $T$  for any *t*-conorm  $S$ . This relationship connects, e.g. the truth degree function  $(u, v) \mapsto \max\{u + v - 1, 0\}$  of the Łukasiewicz strong conjunction with that one of the corresponding strong disjunction  $(u, v) \mapsto \min\{u + v, 1\}$ .

Obviously (2.23) constitutes, for the background logic, a de Morgan connection between suitably chosen conjunctions and disjunctions – as long as the function  $u \mapsto 1 - u$  acts as the truth degree function of a negation. And indeed this is the truth degree function of the negation of the Łukasiewicz systems, which was already used in the definition (2.15) of the complement of a fuzzy set.

Summing up, one has for the background logic idempotent *weak* connectives for conjunction and disjunction, determined by the minimum and the maximum operation in  $[0, 1]$ . Furthermore, one is interested to have (possibly) nonidempotent *strong* connectives for conjunction and disjunction, determined by a *t*-norm and a *t*-conorm, usually one the dual of the other according to (2.23).

## 2.3 *t*-Norm-Based Logics

From the point of view of many-valued logic, a *t*-norm is a suitable candidate for a truth degree function of some generalized conjunction connective. Accepting this, one is essentially concerned with systems of many-valued logic with infinite truth degree set  $[0, 1]$ . And additionally one prefers to consider such systems which have the truth degree 1 as the only designated truth degree. (This means, e.g., that a formula of the language of such a system counts as logically valid just in case it always assumes this designated truth degree 1. This

notion, as well as the other notions from many-valued logic are explained in detail, e.g., in [2.5].)

### 2.3.1 Basic Ideas

Such a system of many-valued logic is called *t-norm based* (on some particular *t*-norm  $T$ ) iff all the other connectives of it have associated truth degree functions which are defined from this *t*-norm  $T$ , using possibly some truth degree constants. Usually one considers to-

gether with the conjunction connective  $\&$  with the truth degree function  $T$  an implication connective  $\rightarrow$  with the truth degree function  $I_T$  characterized by

$$I_T(u, v) =_{\text{df}} \sup\{z \mid T(u, z) \leq v\}, \quad (2.24)$$

the so-called *R-implication* connected with  $T$ , and a *standard negation connective*  $\neg$  with truth degree function  $\mathbf{n}_T$ , given as

$$\mathbf{n}_T(u) =_{\text{df}} I_T(u, 0). \quad (2.25)$$

As shall be explained in the Sect. 2.3.2, the definition (2.24) determines a reasonable implication function just in the case that the *t-norm*  $T$  is left continuous. Here *reasonable* essentially means that  $\rightarrow_T$  satisfies a suitable version of the rule of detachment.

In more technical terms it means that for left continuous *t-norms*  $T$  condition (2.24) defines a *residuation operator*  $I_T$ , previously sometimes also called  $\varphi$ -operator, cf. [2.22]. And it means also, under this assumption of left continuity of  $T$ , that condition (2.24) is equivalent to the *adjointness condition*

$$T(u, w) \leq v \iff w \leq I_T(u, v), \quad (2.26)$$

i.e., that the operations  $T$  and  $I_T$  form an *adjoint pair*.

Forced by these results one usually restricts, in this logical context, the considerations to left continuous – or even to continuous – *t-norms*.

But together with this restriction of the *t-norms*, a generalization of the possible truth degree sets sometimes is useful: one may accept each subset of the unit interval  $[0, 1]$  as a truth degree set which is closed under the particular *t-norm*  $T$  and its residuum.

The restriction to *continuous t-norms* enables even the definition of the operations *max* and *min*, which make  $[0, 1]$  into an (linearly) ordered lattice. On the one hand, one has from straightforward calculations that always

$$\min\{u, v\} = T(u, I_T(u, v)), \quad (2.27)$$

and on the other hand one gets always [2.23, 24]

$$\max\{u, v\} = \min\{I_T(I_T(u, v), v), I_T(I_T(v, u), u)\}. \quad (2.28)$$

It is a routine matter to check that the infinite-valued Gödel logic  $\mathbb{G}$ , the infinite-valued Łukasiewicz logic  $\mathbb{L}$ ,

and also the product logic  $\Pi$  all are *t-norm-based logics* in the present sense.

The systems of fuzzy logic we discuss here are also sometimes called *R-fuzzy logics*, stressing the fact that our implication connectives  $\rightarrow$  have as truth degree functions  $I_T$  the residuation operations, characterized by (2.24) or (2.26). Besides these R-fuzzy logics one occasionally, e.g., in [2.25, 26], discusses so-called *S-fuzzy logics* which are also based on some *t-norm*, but additionally take the Łukasiewicz negation  $\mathbf{n}_L(u) = 1 - u$  or also some other negation function, sometimes together with a further *t-conorm*, as a basic connective.

These S-fuzzy logics define their implication connective like material implication might be defined in classical logic. However, these logics lose, in general, the rule of detachment as a sound rule of inference if they have the degree 1 as the only designated truth degree – or they allow all positive reals from  $(0, 1]$  as designated truth degrees.

For a complete development of such *t-norm-based logics* one needs adequate axiomatizations. This seems to be, however, a difficult goal – essentially because of its dependency from the particular choice of the *t-norms* which determine these logics. Therefore, the first successful approaches intended to axiomatize common parts of a whole class of such logics. This will be discuss later in Sect. 2.4.

### 2.3.2 Left and Full Continuity of *t-Norms*

As had been mentioned in the previous section, the adjointness condition is an algebraic equivalent of the analytical notion of left continuity. This will be proved here.

#### Definition 2.1

A *t-norm*  $T$  is left continuous (continuous) iff all the unary functions  $T_a : x \mapsto T(x, a)$  for  $a \in [0, 1]$  are left continuous (continuous).

This definition of continuity for *t-norms* via their unary parametrizations coincides with the usual definition of continuity for a binary function, cf. [2.20].

#### Proposition 2.1

A *t-norm*  $T$  is left continuous iff  $T$  and its *R-implication*  $I_T$  form an adjoint pair.

Proofs are given, e.g., in [2.5, 20, 22].

It is interesting, and important later on, to also notice that the continuity of a *t*-norm has an algebraic equivalent.

### **Proposition 2.2**

A *t*-norm  $T$  is continuous iff  $T$  and  $I_T$  satisfy the equation

$$T(a, I_T(a, b)) = \min\{a, b\}. \quad (2.29)$$

*Proof:* Assume first that  $T$  is continuous. Then one has for  $a \leq b \in [0, 1]$  immediately  $T(a, I_T(a, b)) = T(a, 1) = a = \min\{a, b\}$ . And one has for  $b < a$

$$\begin{aligned} T(a, I_T(a, b)) &= T(a, \max\{z \mid T(a, z) \leq b\}) \\ &= \max\{T(a, z) \mid T(a, z) \leq b\} \leq b \end{aligned} \quad (2.30)$$

already by the left continuity of  $T$ . Continuity of  $T$  furthermore gives from  $0 = T(a, 0) \leq b < a = T(a, 1)$  the existence of some  $c \in [0, 1]$  with  $b = T(a, c)$ , and thus  $T(a, I_T(a, b)) = b = \min\{a, b\}$  by (2.30).

Assume conversely (2.29). Then the adjointness condition forces  $T$  to be left continuous. Hence for the continuity of  $T$  one has to show that  $T$  is also right continuous.

Suppose that this is not the case. Then there exist  $a, b \in [0, 1]$ , and also a decreasing sequence  $(x_i)_{i \geq 0}$  with  $\lim_{i \rightarrow \infty} x_i = b$  such that  $T(a, b) \neq \inf_i T(a, x_i)$ , i. e., such that  $T(a, b) < \inf_i T(a, x_i)$ . Consider now some  $d$  with  $T(a, b) < d < \inf_i T(a, x_i) \leq a$ . Then there does not exist some  $c \in [0, 1]$  with  $d = T(a, c)$ , because otherwise one would have  $d = T(a, c) > T(a, b)$ , hence  $c > b$  and thus  $\inf_i T(a, x_i) \leq T(a, c) = d$  from the fact that  $b = \lim_{i \rightarrow \infty} x_i$  and there thus exists some integer  $k$  with  $x_k \leq c$ . This means that the lack of right continuity for  $T$  contradicts condition (2.29). ■

### **2.3.3 Extracting an Algebraic Framework**

For the problem of adequate axiomatization of (classes of) *t*-norm-based systems of many-valued logic there is an important difference to the standard approach toward semantically based systems of many-valued logic: here there is no single, *standard* semantical matrix for the general approach.

The most appropriate way out of this situation seems to be: to find some suitable class(es) of algebraic structures which can be used to characterize these logical systems, and which preferably should be algebraic varieties, i. e., equationally definable.

From an algebraic point of view, the following conditions seem to be structurally important for *t*-norms:

- $\langle [0, 1], T, 1 \rangle$  is a commutative semigroup with a neutral element, i. e., a commutative monoid,
- $\leq$  is a (lattice) ordering in  $[0, 1]$  which has 0 as universal lower bound and 1 as universal upper bound,
- Both structures *fit together*:  $T$  is nondecreasing w.r.t. this lattice ordering.

Thus it seems reasonable to consider commutative lattice-ordered monoids as the truth degree structures for the *t*-norm-based systems.

In general, however, commutative lattice-ordered monoids may have different elements as the universal upper bound of the lattice and as the neutral element of the monoid. This is not the case for the *t*-norm-based systems, they make  $[0, 1]$  into an *integral* commutative lattice-ordered monoid as truth degree structure, namely, one in which the universal upper bound of the lattice ordering and the neutral element of the monoidal structure coincide.

Furthermore, one also likes to have the *t*-norm  $T$  combined with another operation, its *R*-implication operator, which forms together with  $T$  an adjoint pair: i. e., the commutative lattice-ordered monoid formed by the truth degree structure has also to be a *residuated* one.

Summing up, hence, we are going to consider *residuated lattices*, i. e., algebraic structures  $\langle L, \cap, \cup, *, \rightarrow, 0, 1 \rangle$  such that  $L$  is a lattice under  $\cap, \cup$  with the universal lower bound 0 and the universal upper bound 1, and a commutative lattice-ordered monoid under  $*$  with neutral element 1, and such that the operations  $*$  and  $\rightarrow$  form an adjoint pair, i. e., satisfy

$$x * z \leq y \iff z \leq (x \rightarrow y). \quad (2.31)$$

In this framework one additionally introduces, following the understanding of the negation connective given in (2.25), a further operation — by

$$\neg x =_{\text{df}} x \rightarrow 0. \quad (2.32)$$

### **Definition 2.2**

A lattice-ordered monoid  $\langle L, *, 1, \leq \rangle$  is *divisible* iff for all  $a, b \in L$  with  $a \leq b$  there exists some  $c \in L$  with  $a = b * c$ .

For linearly ordered residuated lattices, one has another nice and useful characterization of divisibility.

**Proposition 2.3**

A linearly ordered residuated lattice  $\langle L, \cap, \cup, *, \rightarrow, 0, 1 \rangle$  is divisible, i. e., corresponds to a divisible lattice-ordered monoid  $\langle L, *, 1, \leq \rangle$ , iff one has  $a \cap b = a * (a \rightarrow b)$  for all  $a, b \in L$ . (Of course,  $\leq$  here is the lattice ordering of the lattice  $\langle L, \cap, \cup \rangle$ .)

*Proof:* We first show that one has in each residuated lattice

$$a * (a \rightarrow b) = b \Leftrightarrow \exists x (a * x = b) \quad (2.33)$$

for all  $a, b \in L$ . Of course, in the case  $a * (a \rightarrow b) = b$  there exists an  $x$  such that  $a * x = b$ . So suppose  $a * c = b$  for some  $c \in L$ . If one then would have  $a * (a \rightarrow b) \neq b$ , this would mean  $a * (a \rightarrow b) < b = a * c$  because one always has  $a * (a \rightarrow b) \leq b$  by the adjointness condition, and this hence would mean  $c \not\leq a \rightarrow b$  (because otherwise  $c \leq a \rightarrow b$  and hence  $b = a * c \leq a * (a \rightarrow b)$  would be the case) and therefore also  $a * c = c * a \not\leq b$  by the adjointness condition, a contradiction. Thus (2.33) is established.

Supposing now the divisibility of  $\langle L, \cap, \cup, *, \rightarrow, 0, 1 \rangle$ , then one has for all  $b \leq a \in L$  from the existence of an  $x$  such that  $(b = a * x)$  immediately  $a * (a \rightarrow b) = b = a \cap b$ . Otherwise one has  $a \leq b$  by the linearity of the ordering and hence  $a \rightarrow b = 1$  from the adjointness property, thus  $a * (a \rightarrow b) = a * 1 = a = a \cap b$ .

Assuming on the other hand that one always has  $a \cap b = a * (a \rightarrow b)$ ; furthermore, for all  $a \leq b \in L$  from  $a = a \cap b = b \cap a$  one gets the equation  $a = b * (b \rightarrow a)$ , and hence there is an  $x$  such that  $a = b * x$ . ■

Using this result, we can restate Proposition 2.2 in the following way.

**Corollary 2.1**

A  $t$ -algebra  $[0, 1]_T = \langle [0, 1], \min, \max, T, I_T, 0, 1 \rangle$  is divisible iff the  $t$ -norm  $T$  is continuous.

## 2.4 Particular Fuzzy Logics

Now we shall discuss the core systems of  $t$ -norm-based logics. Of course, it would be preferable to be able to axiomatize each single  $t$ -norm-based logic directly. However, actually there is no way to do so. Hence other approaches have been developed. The core idea is first to develop systems which cover large parts which are common to all those  $t$ -norm-based logics.

A further restriction is suitable w.r.t. the class of residuated lattices because each  $t$ -algebra  $[0, 1]_T$  is linearly ordered, and thus makes particularly the wff  $(\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$  valid. Following H  ejek [2.23, 24], one calls *BL-algebras* those divisible residuated lattices which also satisfy the *prelinearity* condition (2.12).

**Definition 2.3**

A structure  $\mathbf{L} = \langle L, \vee, \wedge, *, \rightarrow, \mathbf{0}, \mathbf{1} \rangle$  is a *BL-algebra* iff:

- i)  $\langle L, \vee, \wedge, \mathbf{0}, \mathbf{1} \rangle$  is a bounded lattice with lattice ordering  $\leq$ ,
- ii)  $\langle L, *, \mathbf{1}, \leq \rangle$  is a lattice-ordered Abelian monoid,
- iii) The operations  $*$  and  $\rightarrow$  satisfy the *adjointness* condition

$$x * y \leq z \iff x \leq y \rightarrow z, \quad (2.34)$$

- iv) the *prelinearity* condition (2.12) is satisfied,
- v) the *divisibility* condition is satisfied, i. e., one has always

$$x * (x \rightarrow y) = x \wedge y. \quad (2.35)$$

It is interesting to notice that the prelinearity condition (2.12) can equivalently be characterized in another form, which will become important later on.

**Proposition 2.4**

In residuated lattices there are equivalent

- (i)  $(x \rightarrow y) \cup (y \rightarrow x) = 1$ ,
- (ii)  $((x \rightarrow y) \rightarrow z) * ((y \rightarrow x) \rightarrow z) \leq z$ .

The proof is by routine calculations, cf., e.g., [2.5, 23].

The first successful approach came from H  ejek who presented 1998 in the seminal monograph [2.23] the logic BL of all continuous  $t$ -norms, i. e., the common part of all the  $t$ -norm-based logics which are determined by a continuous  $t$ -norm. Inspired by this work a short time later Esteva and Godo [2.27] introduced 2001 the logic MTL of all left-continuous  $t$ -norms.

These logics are characterized by algebraic semantics: BL by the class of all  $t$ -algebras with a continuous  $t$ -norm, and MTL by the class of all  $t$ -algebras with a left-continuous  $t$ -norm. All those  $t$ -algebras are particular cases of residuated lattices.

It should be noticed, however, that already in 1996 Höhle [2.28] introduced the monoidal logic ML characterized by the class of all residuated lattices as their algebraic semantics.

And it should also be mentioned that, in the case of logics which are determined by an algebraic semantics, the problem of their adequate axiomatization becomes particularly well manageable, if the algebraic semantics is given as a variety of algebraic structures, i.e., as an equationally definable class of algebraic structures.

### 2.4.1 The Logic BL of All Continuous $t$ -Norms

The class of  $t$ -algebras (with a continuous  $t$ -norm or not) is not a variety: it is not closed under direct products because each  $t$ -algebra is linearly ordered. Hence one may expect that it would be helpful for the development of a logic of continuous  $t$ -norms to extend the class of all divisible  $t$ -norm algebras in a moderate way to get a variety.

And indeed this idea works: it was developed by Hájek and in detail explained in [2.23].

The core point is that one considers instead of the divisible  $t$ -algebras  $[0, 1]_T$ , which are linearly ordered integral monoids, lattice-ordered integral monoids which satisfy the condition (2.35), which have an additional residuation operation connected with the semi-group operation via an adjointness condition (2.26), and which also satisfy the *prelinearity condition*

$$(x \rightarrow y) \vee (y \rightarrow x) = 1, \quad (2.36)$$

or equivalently

$$(x \rightarrow y) \rightarrow z \rightarrow (((y \rightarrow x) \rightarrow z) \rightarrow z) = 1. \quad (2.37)$$

The axiomatization of Hájek [2.23] for the *basic  $t$ -norm logic BL* (in [2.5] denoted BTL), i.e., for the class of all well-formed formulas which are valid in all BL-algebras, is given in a language  $\mathcal{L}_T$  which has as basic vocabulary the connectives  $\rightarrow, \&$  and the truth degree constant  $\bar{0}$ , taken in each BL-algebra  $\langle L, \cap, \cup, *, \rightarrow, \mathbf{0}, \mathbf{1} \rangle$  as the operations  $\rightarrow, *$  and the element  $\mathbf{0}$ .

This  $t$ -norm-based logic BL has the following axiom schemata:

- (Ax<sub>BL</sub>1)  $(\varphi \rightarrow \psi) \rightarrow ((\psi \rightarrow \chi) \rightarrow (\varphi \rightarrow \chi)),$
- (Ax<sub>BL</sub>2)  $\varphi \& \psi \rightarrow \varphi,$
- (Ax<sub>BL</sub>3)  $\varphi \& \psi \rightarrow \psi \& \varphi,$
- (Ax<sub>BL</sub>4)  $(\varphi \rightarrow (\psi \rightarrow \chi)) \rightarrow (\varphi \& \psi \rightarrow \chi),$
- (Ax<sub>BL</sub>5)  $(\varphi \& \psi \rightarrow \chi) \rightarrow (\varphi \rightarrow (\psi \rightarrow \chi)),$
- (Ax<sub>BL</sub>6)  $\varphi \& (\varphi \rightarrow \psi) \rightarrow \psi \& (\psi \rightarrow \varphi),$
- (Ax<sub>BL</sub>7)  $((\varphi \rightarrow \psi) \rightarrow \chi) \rightarrow (((\psi \rightarrow \varphi) \rightarrow \chi) \rightarrow \chi),$
- (Ax<sub>BL</sub>8)  $\bar{0} \rightarrow \varphi,$

and has as its (only) inference rule the rule of detachment.

Starting from the primitive connectives  $\rightarrow, \&$ , and the truth degree constant  $\bar{0}$ , the language  $\mathcal{L}_T$  of BL is extended by definitions of further connectives

$$\varphi \wedge \psi =_{\text{df}} \varphi \& (\varphi \rightarrow \psi), \quad (2.38)$$

$$\varphi \vee \psi =_{\text{df}} ((\varphi \rightarrow \psi) \rightarrow \psi) \wedge ((\psi \rightarrow \varphi) \rightarrow \varphi), \quad (2.39)$$

$$\neg \varphi =_{\text{df}} \varphi \rightarrow \bar{0}, \quad (2.40)$$

where  $\varphi, \psi$  are formulas of the language of that system.

Calculations (in BL-algebras) show that the additional connectives  $\wedge, \vee$  just have the lattice operations  $\cap, \cup$  as their truth degree functions.

The system BL is an implicative logic in the sense of Rasiowa [2.29]. So one gets a general soundness and completeness result.

#### Theorem 2.1 General Completeness

A formula  $\varphi$  of the language  $\mathcal{L}_T$  is derivable within the axiomatic system BL iff  $\varphi$  is valid in all BL-algebras.

However, it is shown in [2.23] that already the class of all BL-chains, i.e., of all linearly ordered BL-algebras, provides an adequate algebraic semantics.

#### Theorem 2.2 General Chain Completeness

A formula  $\varphi$  of  $\mathcal{L}_T$  is derivable within the axiomatic system BL iff  $\varphi$  is valid in all BL-chains.

But even more is provable and leads back to the starting point of the whole approach: the theorems of BL are just those formulas which hold true w.r.t. all divisible  $t$ -algebras. This was, extending preliminary results from [2.24], finally proved in [2.30].

#### Theorem 2.3 Standard Completeness

The class of all formulas which are provable in the sys-

tem BL coincides with the class of all formulas which are logically valid in all  $t$ -algebras with a continuous  $t$ -norm.

The main steps in the proof are to show (i) that each BL-algebra is a subdirect product of subdirectly irreducible BL-chains, i. e., of linearly ordered BL-algebras which are not subdirect products of other BL-chains, and (ii) that each subdirectly irreducible BL-chain can be embedded into the ordinal sum of some BL-chains which are either trivial one-element BL-chains, or linearly ordered MV-algebras, or linearly ordered product algebras, such that (iii) each such ordinal summand is locally embedable into a  $t$ -norm-based residuated lattice with a continuous  $t$ -norm, cf. [2.24, 30] and again [2.5].

This is a lot more of algebraic machinery as necessary for the proof of the General Completeness Theorem 2.1 and thus offers a further indication that the extension of the class of divisible  $t$ -algebras to the class of BL-algebras made the development of the intended logical system easier. But even more can be seen from this proof: *the class of BL-algebras is the smallest variety which contains all the divisible  $t$ -algebras*, i. e., all the  $t$ -algebras determined by a continuous  $t$ -norm. And the algebraic reason for this is that each variety may be generated from its subdirectly irreducible elements, cf. again [2.31, 32].

Yet another generalization of Theorem 2.1 deserves to be mentioned. To state it, let us call *schematic extension* of BL every extension which consists in an addition of axiom schemata to the axiom schemata of BL. And let us denote such an extension by  $\text{BL} + C$ . And call  $\text{BL}(C)$ -algebra each BL-algebra  $\mathbf{A}$  which makes  $\mathbf{A}$ -valid all formulas of  $C$ , i. e., which is a model of  $C$ .

Then one can prove, as done in [2.23], an even more general completeness result.

#### **Theorem 2.4 Strong General Completeness**

For each set  $C$  of axiom schemata and any formula  $\varphi$  of  $\mathcal{L}_T$  there are equivalent:

- i)  $\varphi$  is derivable within  $\text{BL} + C$ ;
- ii)  $\varphi$  is valid in all  $\text{BL}(C)$ -algebras;
- iii)  $\varphi$  is valid in all  $\text{BL}(C)$ -chains.

For the standard semantics this result holds true only in a restricted form: one has to restrict the consideration to *finite* sets  $C$  of axiom schemata, i. e., to finite theories. For the Łukasiewicz logic  $L$ , which is

the extension of BL by the schema  $\neg\neg\varphi \rightarrow \varphi$  of double negation, this has already been shown in [2.23]. And for arbitrary continuous  $t$ -norms this follows from results of Haniková [2.33, 34].

#### **Theorem 2.5 Strong Standard Completeness**

For each finite set  $C$  of axiom schemata and any formula  $\varphi$  of  $\mathcal{L}_T$  there are equivalent:

- i)  $\varphi$  is derivable within  $\text{BL} + C$ ;
- ii)  $\varphi$  is valid in all  $t$ -algebras which are models of  $C$ .

### **2.4.2 The Logic MTL of All Left Continuous $t$ -Norms**

The guess of Esteva and Godo [2.27] has been that one should arrive at the logic of left continuous  $t$ -norms if one starts from the logic of continuous  $t$ -norms and deletes the continuity condition, i. e., the divisibility condition (2.35).

The algebraic approach needs only a small modification: in the definition of the BL-algebras one has simply to delete the divisibility condition. The resulting algebraic structures have been called *MTL-algebras*. They again form a variety.

Following this idea, one has to modify the previous axiom system in a suitable way. And one has to delete the definition (2.38) of the connective  $\wedge$ , because this definition (together with suitable axioms) essentially codes the divisibility condition. The definition (2.39) of the connective  $\vee$  remains unchanged.

As a result one now considers a new system MTL of mathematical fuzzy logic, characterized semantically by the class of all MTL-algebras. It is connected with the axiom system:

- (Ax<sub>MTL</sub>1)  $(\varphi \rightarrow \psi) \rightarrow ((\psi \rightarrow \chi) \rightarrow (\varphi \rightarrow \chi))$ ,
- (Ax<sub>MTL</sub>2)  $\varphi \& \psi \rightarrow \varphi$ ,
- (Ax<sub>MTL</sub>3)  $\varphi \& \psi \rightarrow \psi \& \varphi$ ,
- (Ax<sub>MTL</sub>4)  $(\varphi \rightarrow (\psi \rightarrow \chi)) \rightarrow (\varphi \& \psi \rightarrow \chi)$ ,
- (Ax<sub>MTL</sub>5)  $(\varphi \& \psi \rightarrow \chi) \rightarrow (\varphi \rightarrow (\psi \rightarrow \chi))$ ,
- (Ax<sub>MTL</sub>6)  $\varphi \wedge \psi \rightarrow \varphi$ ,
- (Ax<sub>MTL</sub>7)  $\varphi \wedge \psi \rightarrow \psi \wedge \varphi$ ,
- (Ax<sub>MTL</sub>8)  $\varphi \& (\varphi \rightarrow \psi) \rightarrow \varphi \wedge \psi$ ,
- (Ax<sub>MTL</sub>9)  $0 \rightarrow \varphi$ ,
- (Ax<sub>MTL</sub>10)  $((\varphi \rightarrow \psi) \rightarrow \chi) \rightarrow (((\psi \rightarrow \varphi) \rightarrow \chi) \rightarrow \chi)$ ,

together with the rule of detachment (w.r.t. the implication connective  $\rightarrow$ ) as (the only) inference rule.

Again, the system MTL is an implicative logic in the sense of Rasiowa [2.29], giving a general soundness and completeness result as for the previous system BL. Proofs of these results were given in [2.27].

### Theorem 2.6 General Completeness

A formula  $\varphi$  of the language  $\mathcal{L}_T$  is derivable within the system MTL iff  $\varphi$  is valid in all MTL-algebras.

Furthermore it is shown, in [2.27], that again already the class of all MTL-chains provides an adequate algebraic semantics.

### Theorem 2.7 General Chain Completeness

A formula  $\varphi$  of  $\mathcal{L}_T$  is derivable within the axiomatic system MTL iff  $\varphi$  is valid in all MTL-chains.

And again, similar as for the BL-case, even more is provable: the system MTL characterizes just these formulas which hold true w.r.t. all those  $t$ -norm-based logics which are determined by a left continuous  $t$ -norm, cf. [2.35].

### Theorem 2.8 Standard Completeness

The class of formulas which are provable in the system MTL coincides with the class of formulas which are logically valid in all  $t$ -algebras with a left continuous  $t$ -norm.

This result again means, as the similar one for the logic of continuous  $t$ -norms, that the variety of all MTL-algebras is the smallest variety which contains all  $t$ -algebras with a left continuous  $t$ -norm.

Also for MTL an extended completeness theorem similar to Theorem 2.4 holds true. (The notions MTL +  $C$  and MTL( $C$ )-algebra are used similar to the BL case.)

### Theorem 2.9 Strong General Completeness

For each set  $C$  of axiom schemata and any formula  $\varphi$  of  $\mathcal{L}_T$  the following are equivalent:

- i)  $\varphi$  is derivable within the system MTL +  $C$ ;
- ii)  $\varphi$  is valid in all MTL( $C$ )-algebras;
- iii)  $\varphi$  is valid in all MTL( $C$ )-chains.

For much more information on completeness matters for different systems of fuzzy logic the reader may consult [2.36].

## 2.4.3 Extensions of MTL

Because of the fact that the BL-algebras are the divisible MTL-algebras, one gets another adequate axiomatization of the basic  $t$ -norm logic BL.

### Proposition 2.5

$$\text{BL} = \text{MTL} + \{\varphi \wedge \psi \rightarrow \varphi \& (\varphi \rightarrow \psi)\}.$$

*Proof:* Routine calculations in MTL-algebras give  $x * (x \rightarrow y) \leq x$  and  $x * (x \rightarrow y) \leq y$ , and hence the inequality  $x * (x \rightarrow y) \leq x \cap y$ . In those MTL-algebras which are models of

$$\varphi \wedge \psi \rightarrow \varphi \& (\varphi \rightarrow \psi). \quad (2.41)$$

also the converse inequality holds true, hence even  $x * (x \rightarrow y) = x \cap y$ . Thus the class of models of (2.41) is the class of all BL-algebras. So the result follows from the Completeness Theorem 2.1. ■

### Proposition 2.6

$$\text{L} = \text{BL} + \{\neg\neg\varphi \rightarrow \varphi\}$$

*Proof:* BL-algebras which also satisfy the equation  $(x \rightarrow 0) \rightarrow 0 = x$  can be shown to be MV-algebras, cf. [2.5, 37]. And each MV-algebra is also a BL-algebra. Hence  $\text{BL} + \{\neg\neg\varphi \rightarrow \varphi\}$  is characterized by the class of all MV-algebras, so it is L according to Sect. 2.4.1. (There is also a syntactic proof available given in [2.23].) ■

### Proposition 2.7

$$\begin{aligned} \Pi = \text{BL} + & \{\varphi \wedge \neg\varphi \rightarrow 0, \\ & \neg\neg\chi \rightarrow ((\varphi \& \chi \rightarrow \psi \& \chi) \rightarrow (\varphi \rightarrow \psi))\}. \end{aligned}$$

*Proof:* This is essentially the original characterization of the product logic  $\Pi$  as given in [2.3]. ■

### Proposition 2.8

$$\text{G} = \text{BL} + \{\varphi \rightarrow \varphi \& \varphi\}.$$

*Proof:* The prelinear Heyting algebras are just those BL-algebras for which the semigroup operation  $*$  coincides with the lattice meet:  $* = \wedge$ , cf. [2.5, 38], and each Heyting algebra is also a BL-algebra. So the result follows again via Sect. 2.4.1. ■

Similar remarks apply to further extensions of MTL.

#### 2.4.4 Logics of Particular $t$ -Norms

It is easy to recognize that two isomorphic (left continuous)  $t$ -norms  $T_1, T_2$  determine the same  $t$ -norm-based logic: any order automorphism of  $[0, 1]$  which transforms  $T_1$  into  $T_2$  according to (2.21) is an isomorphism between the  $t$ -algebras  $[0, 1]_{T_1}$  and  $[0, 1]_{T_2}$ .

A continuous  $t$ -norm  $T$  is called *archimedean* iff  $T(x, x) < x$  holds true for all  $0 < x < 1$ . And a  $t$ -norm  $T$  has *zero divisors* iff there exist  $0 < a, b$  such that  $T(a, b) = 0$ .

It is well known that each continuous archimedean  $t$ -norm with zero divisors is isomorphic to the Łukasiewicz  $t$ -norm  $T_L$ , cf. [2.5, 20].

##### Proposition 2.9

Each  $t$ -norm-based logic, which is determined by a continuous archimedean  $t$ -norm with zero divisors, has the same axiomatizations as the infinite-valued Łukasiewicz logic  $L$ .

Furthermore, a continuous  $t$ -norm  $T$  is called *strict* iff it is strictly monotonous, i. e., satisfies for all  $z \neq 0$

$$x < y \iff T(x, z) < T(y, z).$$

Again it is well known that each strict continuous  $t$ -norm is isomorphic to the product  $t$ -norm  $T_P$ , cf. [2.5, 20].

##### Proposition 2.10

Each  $t$ -norm-based logic which is determined by a strict continuous  $t$ -norm has the same axiomatizations as the infinite-valued product logic  $\Pi$ .

But there is a general solution of the axiomatization problem of those  $t$ -norm-based logics which are determined by a continuous  $t$ -norm.

In [2.39], Esteva et al. study the variety  $\mathbb{BL}$  of all BL-algebras. They prove that each of its subvarieties which is generated by a single  $T$ -algebra over  $[0, 1]$ ,  $T$  a continuous  $t$ -norm, is finitely axiomatizable. Additionally, they provide an algorithm to determine these finitely many axioms.

So the following main result is reached:

##### Theorem 2.10

Each  $t$ -norm-based fuzzy logic  $\mathcal{L}_T$  determined by a continuous  $t$ -norm  $T$  is a finite axiomatic extension of the basic fuzzy logic BL.

For left continuous  $t$ -norms a similar result is lacking.

#### 2.4.5 Extensions to First-Order Logics

The extensions of these propositional logics to first-order ones follows the standard lines of approach: one has to start from a first-order language ( $\mathcal{L}$  with the two standard quantifiers  $\forall, \exists$ ) and a suitable residuated lattice  $\mathbf{A}$ , and has to define  $\mathbf{A}$ -interpretations  $\mathbf{M}$  by fixing a nonempty domain  $M = |\mathbf{M}|$  and by assigning to each predicate symbol of  $\mathcal{L}$  an  $\mathbf{A}$ -valued relation in  $M$  (of suitable arity) and to each constant an element from (the support of)  $\mathbf{A}$ .

Usually one supposes that the first-order language  $\mathcal{L}$  has only predicate symbols and no function symbols. The insertion of function symbols proves to be a delicate matter, essentially because it is not completely clear what the basic properties of the identity predicate should be. The core problem is whether such an identity relation should be a crisp one or should be really graded. The paper [2.40] also surveys these problems of the identity relation.

The satisfaction relation is defined in the standard way. The quantifiers  $\forall$  and  $\exists$  are interpreted as taking the infimum or supremum, respectively, of all the values of the relevant instances.

To be sure that this approach works well one has either to suppose that the underlying lattices of the interpretations are complete lattices, or at least that all the necessary infima and suprema do exist in these lattices. Interpretations over lattices which satisfy this last mentioned condition are called *safe* by Hájek [2.23].

For the logic  $\mathbf{BL}$  of continuous  $t$ -norms, Hájek [2.23] added the axioms:

- ( $\forall 1$ )  $(\forall x)\varphi(x) \rightarrow \varphi(t)$ , where  $t$  is substitutable for  $x$  in  $\varphi$ ,
- ( $\exists 1$ )  $\varphi(t) \rightarrow (\exists x)\varphi(x)$ , where  $t$  is substitutable for  $x$  in  $\varphi$ ,
- ( $\forall 2$ )  $(\forall x)(\chi \rightarrow \varphi) \rightarrow (\chi \rightarrow (\forall x)\varphi)$ , where  $x$  is not free in  $\chi$ ,

- ( $\exists 2$ )  $(\forall x)(\varphi \rightarrow \chi) \rightarrow ((\exists x)\varphi \rightarrow \chi)$ , where  $x$  is not free in  $\chi$ ,  
 ( $\forall 3$ )  $(\forall x)(\chi \vee \varphi) \rightarrow \chi \vee (\forall x)\varphi$ , where  $x$  is not free in  $\chi$

and the rule of generalization to the propositional calculus yielding the system BL $\forall$ .

Then he was able to prove the following completeness theorem.

### Theorem 2.11 General Chain Completeness

A first-order formula  $\varphi$  is BL $\forall$ -provable iff it is valid in all safe interpretations over BL-chains.

This result can be extended to a lot of other first-order fuzzy logics, e.g., to MTL $\forall$ .

We will not discuss further completeness results here but refer to the extended survey [2.40]. But it should be mentioned that, as suprema are not always maxima and infima not always minima, the truth degree of an existentially/universally quantified formula may not be the maximum/minimum of the truth degrees of the instances. It is, however, interesting to have conditions which characterize models in which the truth degrees of each existentially/universally quantified formula is witnessed as the truth degree of an instance. Cintula and Hájek [2.41] study this problem.

The topic of first-order fuzzy logics with identity deserves some attention. The core problem is, as in any many-valued logic, whether the identity symbol should be interpreted by the standard, i.e., *two-valued* identity relation, or whether one should allow for graded identity relations inside the interpretations.

Direct translations of the identity axioms of classical first-order logic into, e.g., the language of the Łukasiewicz systems force that the interpretation of the identity symbol has to be the standard identity relation,

cf. [2.42]. Similarly, for a wide class of first-order fuzzy logics the addition of the axioms:

$$\text{Id1 } x \approx y \vee \neg x \approx y$$

$$\text{Id2 } x \approx x$$

$$\text{Id3 } x \approx y \rightarrow (\varphi(x, \vec{z}) \rightarrow \varphi(y, \vec{z})), \text{ for } y \text{ substitutable for } x \text{ in } \varphi$$

forces that the identity symbol  $\approx$  can only be understood as meaning standard identity. A general completeness theorem like Theorem 2.11 remains valid in this case too, cf. [2.40].

For the case of the Łukasiewicz logics, however, a slight modification of the standard identity axioms – particularly of the Leibniz schema, as given in [2.43], allows for graded identity relations, cf. also [2.5]. For fuzzy logics, in general similarity relations, i.e., graded equivalence relations offer such an approach [2.23, 44]. For the restricted case of Horn formulas an approach is offered by Bělohlávek and Vychodil [2.45, 46]. They consider a first-order language with function symbols and the identity symbol  $\approx$  as the only predicate symbol. Their models for sets of Horn formulas therefore have to be algebraic structures with graded identity relations. However, the aim of these authors is not to develop an identity logic, they mainly are interested to use the approach to characterize classes of algebraic structures with graded identity relations and to find *fuzzified* versions of results from universal algebra.

These authors even consider fuzzy sets of Horn formulas, i.e., they work in a Pavelka-style fuzzy logic as explained later in Sect. 2.6.1. But because this type of approach can be mirrored in standard fuzzy logics with sufficiently many truth degree constants, (Sect. 2.6.1) this approach is already discussed here.

## 2.5 Some Generalizations

The standard approach toward  $t$ -norm-based logics, as explained in Sects. 2.4.1 and 2.4.2, has been modified in various ways. The main background ideas are the extension or the modification of the expressive power of these logical systems.

### 2.5.1 Adding a Projection Operator

A first, quite fundamental addition to the standard vocabulary of the languages of  $t$ -norm-based systems was proposed in [2.47]: a unary propositional operator  $\Delta$ ,

also known as *Baaz' Delta*, which has for  $t$ -algebras the semantics

$$\begin{aligned} \Delta(x) &= 1 && \text{for } x = 1, \\ \Delta(x) &= 0 && \text{for } x \neq 1. \end{aligned} \tag{2.42}$$

This unary connective can be added to the systems BL and MTL via the additional axioms

$$(\Delta 1) \quad \Delta\varphi \vee \neg\Delta\varphi,$$

$$(\Delta 2) \quad \Delta(\varphi \vee \psi) \rightarrow (\Delta\varphi \vee \Delta\psi),$$

- (Δ3)  $\Delta\varphi \rightarrow \varphi ,$
- (Δ4)  $\Delta\varphi \rightarrow \Delta\Delta\varphi ,$
- (Δ5)  $\Delta(\varphi \rightarrow \psi) \rightarrow (\Delta\varphi \rightarrow \Delta\psi) .$

This addition leaves all the essential theoretical results, like correctness and completeness theorems, valid: of course w.r.t. suitably expanded algebraic structures.

### 2.5.2 Adding an Idempotent Negation

A second stream of papers discusses the addition of an idempotent negation, i.e., a negation which satisfies the double negation law, for those cases where the standard negation of the  $t$ -norm-based system is not idempotent. This is, e.g., the case for the product logic which, as explained at the end of Sect. 2.1.3, has the Gödel negation (2.2) as its standard negation. By the way, it should be noticed that (routine calculations show that) this nonidempotent Gödel negation is the standard negation of all those  $t$ -norm algebras with a  $t$ -norm  $\otimes$  which does not have zero-divisors. A very general approach is given in [2.48], and a more particular axiomatization problem discussed in [2.49].

### 2.5.3 Logics with Additional Strong Conjunctions

A third stream of papers, partly related to the previously mentioned one, is devoted to the problem of a unified treatment of different, usually two,  $t$ -norms and their related connectives within one logical system. Here the focus is on the join of the systems based on the Łukasiewicz  $t$ -norm and on the product  $t$ -norm. The great advantage of this unification is that the Łukasiewicz  $t$ -norm essentially allows to treat the addition, as may be seen from the truth degree function (2.6) of the Łukasiewicz (arithmetical) disjunction, and that the product  $t$ -norm adds the treatment of the usual product: and this means that the elementary arithmetic (in the unit interval) can be discussed in this combined system. This combined system has been considered in two strongly related forms, denoted by  $\text{ŁΠ}$  and  $\text{ŁΠ}_{\frac{1}{2}}$ . The distinction between both systems is that  $\text{ŁΠ}$  has both  $t$ -norms  $\&$  and  $\odot$  and their related (residual) implications and negations among their basic connectives, and that  $\text{ŁΠ}_{\frac{1}{2}}$  adds a truth degree constant for the truth degree  $\frac{1}{2}$ . These two systems are discussed in detail in [2.50–54].

### 2.5.4 Logics Without a Truth Degree Constant

A fourth stream of papers intends to weaken the systems BL and MTL in such a way that one deletes the explicit reference to the truth degree constant  $\overline{0}$  and considers the *falsity free* fragments of the previous systems. From the algebraic point of view their characteristic structures become the *hoops* which in general are defined as algebraic structures  $H = \langle H, *, \Rightarrow, \mathbf{1} \rangle$  such that  $\langle H, *, \mathbf{1} \rangle$  is a commutative monoid and that the further binary operation  $\Rightarrow$  satisfies the equations

$$\begin{aligned} x \Rightarrow x &= \mathbf{1}, \\ x * (x \Rightarrow y) &= y * (y \Rightarrow x), \\ (x * y) \Rightarrow z &= x \Rightarrow (y \Rightarrow z). \end{aligned}$$

The definition

$$x \sqsubseteq y =_{\text{df}} x \Rightarrow y = \mathbf{1}$$

provides an ordering  $\sqsubseteq$  with the universal upper bound  $\mathbf{1}$  which makes  $\langle H, *, \mathbf{1} \rangle$  an ordered monoid, and which has the additional property that the operations  $*$ ,  $\Rightarrow$  become an adjoint pair w.r.t. this ordering.

In particular, hoops with the additional property

$$x \Rightarrow (y \Rightarrow z) \sqsubseteq (y \Rightarrow (x \Rightarrow z)) \Rightarrow z$$

can in a natural way be generated from  $t$ -algebras with continuous  $t$ -norms, as has been shown in [2.55]. So one has a kind of competing generalization of  $t$ -algebras. And for this kind of algebraic semantics, one can find adequate axiomatizations for the corresponding hoop logics quite similar to the approaches of Sects. 2.4.1 and 2.4.2. The details have been developed in [2.56].

### 2.5.5 Logics with a Noncommutative Strong Conjunction

And a fifth stream discusses the generalization of the algebraic semantics from the case of commutative lattice-ordered monoids with residuation to the case of non-commutative lattice-ordered semigroups. In this context, one tries to define noncommutative BL-algebras or noncommutative MTL-algebras, and similarly defines noncommutative  $t$ -norms, also called pseudo- $t$ -norms. And these considerations become combined with the design of an adequate axiomatization, with similar results as in Sects. 2.4.1 and 2.4.2. Important papers on this topic are [2.57–63].

And finally it should be mentioned that Hájek [2.64] even gives a common generalization of all of these generalized fuzzy logics, thus giving up divisibility, the falsity constant, and commutativity. The corresponding

algebras are called *fleas* (or *flea algebras*), and the logic is the *flea logic*  $\text{FIL}$ . There are examples of fleas on  $(0, 1]$  not satisfying divisibility, nor commutativity, and having no least element.

## 2.6 Extensions with Graded Notions of Inference

The systems of  $t$ -norm-based logics discussed up to now have been designed to formalize the logical background for fuzzy sets, and they have degrees of truth for their formulas. But they all have crisp notions of consequence, i. e., of entailment and of provability.

Having in mind that fuzzy logics, also in their form as formalized logical systems, should be a (mathematical) tool for approximate reasoning makes it desirable that they should be able to deal with graded inferences too. This means inferences which start from *fuzzy sets of formulas*, and offer consequence hulls which again are fuzzy sets of formulas.

### 2.6.1 Pavelka-Style Approaches

This problem was first treated by Pavelka [2.65–67]. The basic monograph elaborating this approach is [2.44]. Accordingly, such approaches are sometimes called *Pavelka-style*, but they have – with emphasis on the syntactic side of the matter – also been coined approaches with *evaluated syntax*. Here we will call them *GI-approaches*.

Such an approach with graded inferences has to deal with fuzzy sets  $\Sigma^{\approx}$  of formulas, i. e., besides formulas  $\varphi$  also their membership degrees  $\Sigma^{\approx}(\varphi)$  in  $\Sigma^{\approx}$ . And these membership degrees are just the truth degrees. We may assume that these degrees again form a residuated lattice  $\mathbf{L} = \langle L, \cap, \cup, *, \rightarrow\!, 0, 1 \rangle$ . Thus we (slightly) generalize the standard notion of fuzzy set (with membership degrees from the real unit interval). Therefore, the appropriate language has the same logical connectives as in the previous considerations.

A GI-approach is an easy matter as long as the entailment relationship is considered. An evaluation  $e$  is a *model* of a fuzzy set  $\Sigma^{\approx}$  of formulas iff

$$\Sigma^{\approx}(\varphi) \leq e(\varphi) \quad (2.43)$$

holds for each formula  $\varphi$ . This immediately yields that the semantic consequence hull of  $\Sigma^{\approx}$  should be char-

acterized by the membership degrees

$$C^{\text{sem}}(\Sigma^{\approx})(\psi) = \bigwedge \{e(\psi) \mid e \text{ model of } \Sigma^{\approx}\} \quad (2.44)$$

for each formula  $\psi$ .

For a syntactic characterization of this entailment relation, it is necessary to have some calculus  $\mathbb{K}$  which treats formulas of the language together with truth degrees. So the language of this calculus has to extend the language of the basic logical system by having also symbols for the truth degrees. We indicate these symbols by overlined letters like  $\bar{a}, \bar{c}$ , and realize the common treatment of formulas and truth degrees by considering *evaluated formulas*, i. e., ordered pairs  $(\bar{a}, \varphi)$  consisting of a truth degree symbol and a formula. This transforms each fuzzy set  $\Sigma^{\approx}$  of formulas into a (usual) set of evaluated formulas, again denoted by  $\Sigma^{\approx}$ .

So  $\mathbb{K}$  has to allow to derive evaluated formulas from sets of evaluated formulas, using suitable axioms and rules of inference. These axioms are usually only formulas  $\varphi$  which, however, are used in the derivations as the corresponding evaluated formulas  $(\bar{1}, \varphi)$ . The rules of inference have to deal with evaluated formulas.

Each  $\mathbb{K}$ -derivation of an evaluated formula  $(\bar{a}, \varphi)$  counts as a derivation of  $\varphi$  to the degree  $a \in L$ . The *provability degree* of  $\varphi$  from  $\Sigma^{\approx}$  in  $\mathbb{K}$  is the supremum over all these degrees. The syntactic consequence hull of  $\Sigma^{\approx}$  is the fuzzy set  $C_{\mathbb{K}}^{\text{syn}}$  of formulas characterized by the membership function

$$C_{\mathbb{K}}^{\text{syn}}(\Sigma^{\approx})(\psi) = \bigvee \{a \in L \mid \mathbb{K} \text{ derives } (\bar{a}, \psi) \text{ out of } \Sigma^{\approx}\} \quad (2.45)$$

for each formula  $\psi$ .

Despite the fact that  $\mathbb{K}$  is a standard calculus for evaluated formulas, this is – for infinite truth degree structures – an *infinitary* notion of provability for usual formulas.

For the infinite-valued Łukasiewicz logic  $L$ , this machinery works particularly well because it needs in an essential way the continuity of the residuation operation. The corresponding calculus  $\mathbb{K}_L$  has as axioms any axiom system of the infinite-valued Łukasiewicz logic  $L$  which provides together with the rule of detachment an adequate axiomatization of  $L$ , but  $\mathbb{K}_L$  replaces this standard rule of detachment by the generalized form

$$\frac{(\bar{a}, \varphi) \quad (\bar{c}, \varphi \rightarrow \psi)}{(\bar{a} * \bar{c}, \psi)} \quad (2.46)$$

for evaluated formulas.

The soundness result then says that the  $\mathbb{K}_L$ -provability of an evaluated formula  $(\bar{a}, \varphi)$  means that  $a \leq e(\varphi)$  holds for every valuation  $e$ . And this just means that the formula  $\bar{a} \rightarrow \varphi$  is valid; however, as a formula of an *extended* propositional language which has all the truth degree constants among its vocabulary. Of course, for this extended language the evaluations  $e$  have to satisfy  $e(\bar{a}) = a$  for each  $a \in [0, 1]$ .

The soundness and completeness results for  $\mathbb{K}_L$  say that a *strong completeness theorem* holds true giving

$$C^{\text{sem}}(\Sigma^{\approx})(\psi) = C^{\text{syn}}_{\mathbb{K}_L}(\Sigma^{\approx})(\psi) \quad (2.47)$$

for each formula  $\psi$  and each fuzzy set  $\Sigma^{\approx}$  of formulas.

If one takes the previously mentioned turn and extends the standard language of propositional  $L$  by truth degree constants for all degrees  $a \in [0, 1]$ , and if one reads each evaluated formula  $(\bar{a}, \varphi)$  as the formula  $\bar{a} \rightarrow \varphi$ , then a slight modification  $\mathbb{K}_L^+$  of the former calculus  $\mathbb{K}_L$  again provides an adequate axiomatization: one has to add the *bookkeeping axioms*

$$\begin{aligned} (\bar{a} \& \bar{c}) &\equiv \overline{a * c}, \\ (\bar{a} \rightarrow \bar{c}) &\equiv \overline{a \succ_{\mathbb{L}} c}, \end{aligned}$$

as explained, e.g., in [2.44]. And if one is interested to have evaluated formulas together with the extension of the language by truth degree constants, one has also to add the *logical constant introduction rule*

$$\frac{(\bar{a}, \varphi)}{\bar{a} \rightarrow \varphi}.$$

However, even a stronger result is available which refers only to a notion of derivability over a countable language. The completeness result (2.47), for  $\mathbb{K}_L^+$  instead of  $\mathbb{K}_L$ , becomes already provable if one adds truth degree constants only for all the *rationals* in  $[0, 1]$ , as

was shown in [2.23]. And this extension of  $L$ , known as Rational Pavelka Logic, is even a conservative one, cf. [2.68], i.e.,  $\mathbb{K}_L^+$  proves only such *constant-free* formulas of the language with rational constants which are already provable in the standard infinite-valued Łukasiewicz logic  $L$ .

So the GI-approach with graded notion of provability and entailment can suitably be mirrored inside standard fuzzy logics with sufficiently many truth degree constants.

For more details the reader may also consult, e.g., [2.23, 44, 69].

## 2.6.2 A Lattice Theoretic Approach

For completeness, we also mention a much more abstract approach toward fuzzy logics with graded notions of entailment as the previously explained one for the  $t$ -norm-based fuzzy logics is.

The background for this generalization by *Gerla*, in detail explained in [2.70], is that (already) in systems of classical logic the syntactic as well as the semantic consequence relations, i. e., the provability as well as the entailment relations, are closure operators within the set of formulas. This is a fundamental observation made by *Tarski* [2.71] already in 1930. And the same holds true for the Pavelka style extensions of Sect. 2.6.1 and the operators  $C^{\text{sem}}$  and  $C^{\text{syn}}$  introduced in (2.44) and (2.45), respectively: they are generalized closure operators.

The context, chosen in [2.70], is that of  $L$ -fuzzy sets, with  $\mathbf{L} = \langle L, \leq \rangle$  an arbitrary complete lattice. A *closure operator* in  $\mathbf{L}$  is a mapping  $J : L \rightarrow L$  satisfying for arbitrary  $x, y \in L$  the well-known conditions

$$\begin{aligned} x \leq J(x) && \text{(increasingness),} \\ x \leq y \Rightarrow J(x) &\leq J(y) && \text{(isotonicity),} \\ J(J(x)) &= J(x) && \text{(idempotency).} \end{aligned}$$

And a *closure system* in  $\mathbf{L}$  is a subclass  $C \subseteq L$  which is closed under arbitrary lattice meets.

For fuzzy logic such closure operators and closure systems are considered in the lattice  $\mathcal{F}_L(\mathbb{F})$  of all fuzzy subsets of the set  $\mathbb{F}$  of formulas of some suitable formalized language.

An *abstract fuzzy deduction system* now is an ordered pair  $\mathcal{D} = (\mathcal{F}_L(\mathbb{F}), D)$  determined by a closure operator  $D$  in the lattice  $\mathcal{F}_L(\mathbb{F})$ . And the *fuzzy theories*  $T$  of such an abstract fuzzy deduction system, also called  $\mathcal{D}$ -theories, are the fixed points of  $D$ :  $T = D(T)$ , i. e., the deductively closed fuzzy sets of formulas.

A rather abstract setting is also chosen for the semantics of such an abstract fuzzy deduction system: an *abstract fuzzy semantics*  $\mathcal{M}$  is nothing but a class of elements of the lattice  $\mathcal{F}_L(\mathbb{F})$ , i.e., a class of fuzzy sets of formulas. These fuzzy sets of formulas are called *models*. The only restriction is that the universal set over  $\mathbb{F}$ , i.e., the fuzzy subset of  $\mathbb{F}$  which has always membership degree one, is not allowed as a model. The background idea here is that, for each standard interpretation  $\mathfrak{A}$  (in the sense of many-valued logic – including an evaluation of the individual variables) for the formulas of  $\mathbb{F}$ , a model  $M$  is determined as the fuzzy set which has for each formula  $\varphi \in \mathbb{F}$  the truth degree of  $\varphi$  in  $A$  as membership degree. Accordingly, the satisfaction relation  $\models_{\mathcal{M}}$  coincides with inclusion: for models  $M \in \mathcal{M}$  and fuzzy sets  $\Sigma$  of formulas one has

$$M \models_{\mathcal{M}} \Sigma \leftrightarrow \Sigma \subseteq M. \quad (2.48)$$

## 2.7 Some Complexity Results

Each (left-continuous)  $t$ -norm  $T$  determines four important sets of formulas:

- $1TAUT(T)$ : The set of all 1-tautologies.
- $posTAUT(T)$ : The set of all positive tautologies.
- $1SAT(T)$ : The set of 1-satisfiable formulas.
- $posSAT(T)$ : The set of all positively satisfiable formulas.

Here a 1-tautology is a formula valid in  $[0, 1]_T$ , i.e., having for each evaluation of propositional variables by elements of  $[0, 1]$  the value 1 in  $[0, 1]_T$ . And a positive tautology is a formula which has for each evaluation a positive value in  $[0, 1]_T$ . Similarly 1-satisfiability means to have the  $[0, 1]_T$  value 1 for some evaluation, and positive satisfiability means to have for some evaluation a positive  $[0, 1]_T$ -value.

In the same way, one defines analogous sets corresponding to sets of  $t$ -norms; in particular, with  $BL$  referring to the set of all continuous  $t$ -norms, one defines

$$\begin{aligned} 1TAUT(BL) &= \bigcap \{1TAUT(T) \mid T \text{ a continuous } t\text{-norm}\}, \\ posTAUT(BL) &= \bigcap \{posTAUT(T) \mid T \text{ a continuous } t\text{-norm}\}, \end{aligned}$$

and similarly for the satisfiability cases.

In this setting, one has a semantic and a syntactic consequence operator, both being closure operators, i.e., one has for each fuzzy set  $\Sigma$  of formulas from  $\mathbb{F}$  a semantic as well as a syntactic consequence hull, given by

$$\begin{aligned} C^{\text{sem}}(\Sigma) &= \bigcap \{M \in \mathcal{M} \mid M \models_{\mathcal{M}} \Sigma\}, \\ C^{\text{syn}}(\Sigma) &= D(\Sigma). \end{aligned} \quad (2.49)$$

Similar to the classical case one has  $C^{\text{sem}}(M) = M$  for each model  $M \in \mathcal{M}$ , i.e., each such model provides a  $C^{\text{sem}}$ -theory.

However, a general completeness theorem is not available. What one needs instead, in search for a completeness result, that are specifications which restrict the full generality of this approach, and lead mainly back to situations which have been discussed in the previous sections.

There are interesting results on the computational complexity of these sets. So it was, already in [2.23], shown that if the  $t$ -norm  $T$  is  $T_L$ , or  $T_G$ , or  $T_P$ , then  $1TAUT(T)$  and  $posTAUT(T)$  are co-NP-complete, and  $1SAT(T)$  and  $posSAT(T)$  are NP-complete. This result was partly strengthened in [2.34] yielding that  $1TAUT(T)$  is co-NP-complete for each continuous  $t$ -norm  $T$ .

The corresponding results have been proved in [2.72, 73] for the logic  $BL$  of continuous  $t$ -norms.

### Theorem 2.12

$1TAUT(BL)$  and  $posTAUT(BL)$  are co-NP-complete, and  $1SAT(BL)$  as well as  $posSAT(BL)$  are NP-complete.

Furthermore, there are several results on equality or inequality among the sets involved [2.23, 73]. So one has, e.g.,

$$1SAT(G) = posSAT(G) = 1SAT(P) = posSAT(P),$$

but also

$$1SAT(L) \neq posSAT(L)$$

and

$$posSAT(BL) = posSAT(L).$$

For the 1-tautologicity the papers [2.74–76] contain interesting results relating the property of a formula

being a 1-tautology of one of the logics  $L, G, \Pi$  to the property of being a 1-tautology of finitely many finite-valued logics of estimated complexity, and similar results for  $\text{ITAUT(BL)}$ . For example,  $\varphi$  is in  $\text{ITAUT}(L)$  if and only if it is a 1-tautology of the finitely valued Łukasiewicz logic  $L_m$  for  $m$  being  $2^{\#(\varphi)}$  where  $\#(\varphi)$  is the number of occurrences of variables in  $\varphi$ .

Remind that for predicate logics  $\mathbb{L}_{\mathcal{K}}\forall$ , the general models are safe interpretations over any *linearly ordered*  $\mathbb{L}_{\mathcal{K}}$ -algebra, and the standard models – for  $t$ -norm-based logics – are interpretations over any  $t$ -algebra which is also an  $\mathbb{L}_{\mathcal{K}}$ -algebra.

### Definition 2.4

Let  $\varphi$  be a closed formula of the language of  $\mathbb{L}_{\mathcal{K}}\forall$ :

1.  $\varphi$  is a *general*  $\mathbb{L}_{\mathcal{K}}\forall$ -tautology if  $\varphi$  is valid in each safe interpretation over any *linearly ordered*  $\mathbb{L}_{\mathcal{K}}$ -algebra;  $\text{genTAUT}(\mathbb{L}_{\mathcal{K}}\forall)$  is the set of all general  $\mathbb{L}_{\mathcal{K}}\forall$ -tautologies.
2.  $\varphi$  is a *standard*  $\mathbb{L}_{\mathcal{K}}\forall$ -tautology if  $\varphi$  is valid in each safe interpretation over any *standard*  $\mathbb{L}_{\mathcal{K}}$ -algebra;  $\text{stTAUT}(\mathbb{L}_{\mathcal{K}}\forall)$  is the set of all standard  $\mathbb{L}_{\mathcal{K}}\forall$ -tautologies.
3.  $\varphi$  is  $\mathbb{L}_{\mathcal{K}}\forall$ -satisfiable if  $\varphi$  is valid in some safe interpretation over some *linearly ordered*  $\mathbb{L}_{\mathcal{K}}$ -algebra;  $\text{genSAT}(\mathbb{L}_{\mathcal{K}}\forall)$  is the set of all  $\mathbb{L}_{\mathcal{K}}\forall$ -satisfiable sentences.
4.  $\varphi$  is *standardly*  $\mathbb{L}_{\mathcal{K}}\forall$ -satisfiable if  $\varphi$  is valid in some interpretation over some *standard*  $\mathbb{L}_{\mathcal{K}}$ -algebra;  $\text{stSAT}(\mathbb{L}_{\mathcal{K}}\forall)$  is the set of all standardly  $\mathbb{L}_{\mathcal{K}}\forall$ -satisfiable formulas.

It was already shown in [2.23] that if  $\mathbb{L}$  is the logic BL or one of its specifications  $L, G, \Pi$ , then  $\text{genTAUT}(\mathbb{L}\forall)$  is  $\Sigma_1$ -complete and  $\text{genSAT}(\mathbb{L}\forall)$  is  $\Pi_1$ -complete. And this result has been extended in [2.77] to any  $t$ -norm-based logic  $\mathbb{L}_T\forall$  for a continuous  $t$ -norm  $T$ .

For standard semantics the situation is different. Already *Ragaz* [2.78, 79] proved that the set  $\text{stTAUT}(L\forall)$  of standard tautologies of the infinite-valued Łukasiewicz logic is  $\Pi_2$ -complete. Generalizing this, *Hájek* [2.23] also showed that  $\text{stTAUT}(G\forall) = \text{genTAUT}(G\forall)$  and that therefore the set  $\text{stTAUT}(G\forall)$  of standard tautologies of the infinite-valued Gödel logic is  $\Sigma_1$ -complete.

These results have been considerably extended by *Montagna* [2.80] yielding the following facts.

### Theorem 2.13

1. For each set  $\mathcal{K}$  of continuous  $t$ -norms containing a  $t$ -norm different from  $T_G$ , the set  $\text{stTAUT}(\mathbb{L}_{\mathcal{K}}\forall)$  is  $\Pi_2$ -hard.
2. If  $\mathcal{K}$  is a nonempty set of continuous  $t$ -norms containing a  $t$ -norm which has, in its ordinal sum representation, a product component or a nonextremal (this means being neither first nor last summand) Łukasiewicz component then  $\text{stTAUT}(\mathbb{L}_{\mathcal{K}}\forall)$  is not arithmetical.

The arithmetical complexity of the set  $\text{stTAUT}(\mathbb{L}_T\forall)$  remains undetermined if  $T$  is, e.g., one of the  $t$ -norms  $L \oplus L$ ,  $G \oplus L$ ,  $L \oplus G$ , or  $L \oplus G \oplus L$ , with  $\oplus$  denoting the ordinal sum operation.

For standard satisfiability *Hájek* [2.23] proved that the sets  $\text{stSAT}(G\forall)$  and  $\text{stSAT}(L\forall)$  are  $\Pi_1$ -complete. He also proved, in [2.81], that the set  $\text{stSAT}(\Pi\forall)$  is not arithmetical, and gave in [2.82] also the following result.

### Theorem 2.14

If  $\otimes$  is a continuous  $t$ -norm whose first ordinal sum component is  $G$ , or  $L$ , then  $\text{stSAT}(\mathbb{L}_{\otimes}\forall)$  is  $\Pi_1$ -complete.

The reason is that one has, under these assumptions,

$$\text{stSAT}(\mathbb{L}_{\otimes}\forall) = \text{stSAT}(G\forall),$$

as well as

$$\text{stSAT}(\mathbb{L}_{\otimes}\forall) = \text{stSAT}(L\forall).$$

*Montagna* [2.83] added for the product logic  $\Pi$  the more general.

### Theorem 2.15

If  $\mathcal{K}$  is a nonempty set of continuous  $t$ -norms containing  $T_P$ , or a  $t$ -norm whose first ordinal summand is  $T_P$ , then  $\text{stSAT}(\mathbb{L}_{\mathcal{K}}\forall)$  is not arithmetical.

The complexity of  $\text{stSAT}(\mathbb{L}_T\forall)$  for continuous  $t$ -norms  $T$  which do not have a first component in their ordinal sum representation is an open problem.

More complexity results are surveyed in [2.77] and more recently in [2.84, 85].

## 2.8 Concluding Remarks

The reader who is interested in further results, or in more details, might consult the recent *Handbook of Mathematical Fuzzy Logic* [2.86]. This Handbook surveys the whole field of mathematical fuzzy logics and offers the most actual state of the art in this field. For the wider topic of many-valued logics, [2.5] is still the best reference.

There is one approach, however, which is not discussed here and only shortly mentioned in [2.86]: a version of Church-style type theory based on suitable mathematical fuzzy logics, called *fuzzy type theory*, and

developed by Novák [2.87]. This fuzzy-type theory is particularly used for linguistic modeling. A good survey is [2.88].

There are further topics also often treated under the heading *fuzzy logic* which have been omitted in this survey. Here the focus was on what is called mathematical fuzzy logic or also *fuzzy logic in narrow sense*. Those other topics mainly are classified as *fuzzy logic in wider sense*. They include topics like fuzzy implications, approximate, and commonsense reasoning – and some of them are discussed elsewhere in this Handbook.

# 3. Possibility Theory and Its Applications: Where Do We Stand?

Didier Dubois, Henry Prade

Part A | 3

This chapter provides an overview of possibility theory, emphasizing its historical roots and its recent developments. Possibility theory lies at the crossroads between fuzzy sets, probability, and nonmonotonic reasoning. Possibility theory can be cast either in an ordinal or in a numerical setting. Qualitative possibility theory is closely related to belief revision theory, and commonsense reasoning with exception-tainted knowledge in artificial intelligence. Possibilistic logic provides a rich representation setting, which enables the handling of lower bounds of possibility theory measures, while remaining close to classical logic. Qualitative possibility theory has been axiomatically justified in a decision-theoretic framework in the style of Savage, thus providing a foundation for qualitative decision theory. Quantitative possibility theory is the simplest framework for statistical reasoning with imprecise probabilities. As such, it has close connections with random set theory and confidence intervals, and can provide a tool for uncertainty propagation with limited statistical or subjective information.

Possibility theory is an uncertainty theory devoted to the handling of incomplete information. To a large extent, it is comparable to probability theory because

it is based on set functions. It differs from the latter by the use of a pair of dual set functions (possibility and necessity measures) instead of only one. Besides,

it is not additive and makes sense on ordinal structures. The name *Theory of Possibility* was coined by Zadeh [3.1], who was inspired by a paper by Gaines and Kohout [3.2]. In Zadeh's view, possibility distributions were meant to provide a graded semantics to natural language statements; on this basis, possibility degrees can be attached to other statements, as well as dual necessity degrees expressing graded certainty. However, possibility and necessity measures can also be the basis of a full-fledged representation of partial belief that parallels probability, without compulsory reference to linguistic information [3.3, 4]. It can be seen either as a coarse, nonnumerical version of probability theory, or a framework for reasoning with extreme probabilities, or yet a simple approach to reasoning with imprecise probabilities [3.5].

Besides, possibility distributions can also be interpreted as representations of preference, thus standing for a counterpart to a utility function. In this case, possibility degrees estimate degrees of feasibility of alternative choices, while necessity measures can represent priorities [3.6]. The possibility theory framework is also bipolar [3.7] because distributions may either restrict the possible states of the world (negative information pointing out the impossible), or model sets of actually observed possibilities (positive information pointing out the possible). Negative information refers to pieces of knowledge that are supposedly correct and act as constraints. Possibility and necessity measures rely on negative information.

Positive information refers to reports of actually observed states, or to sets of preferred choices. They induce two other set functions: guaranteed possibility measures and its dual, that are decreasing w.r.t. set inclusion [3.8].

After reviewing pioneering contributions to possibility theory, we recall its basic concepts namely the four set functions at work in possibility theory. Then we present the two main directions along which possibility theory has developed: the qualitative and quantitative settings. Both approaches share the same basic *maxitivity* axiom. They differ when it comes to conditioning, and to independence notions. We point out the connections with a coarse numerical integer-valued approach to belief representation, proposed by Spohn [3.9], now known as ranking theory [3.10].

In each setting, we discuss current and prospective lines of research. In the qualitative approach, we review the connections between possibility theory and modal logic, probabilistic logic and its applications to non-monotonic reasoning, logic programming and the like, probabilistic counterparts of Bayesian belief networks, the framework of soft constraints and the possibilistic approach to qualitative decision theory, and more recent investigations in formal concept analysis and learning. On the quantitative side, we review quantitative possibilistic networks, the connections between possibility theory, belief functions and imprecise probabilities, the connections with non-Bayesian statistics, and the application of quantitative possibility to risk analysis.

## 3.1 Historical Background

Zadeh was not the first scientist to speak about formalising notions of possibility. The modalities *possible* and *necessary* have been used in philosophy at least since the Middle Ages in Europe, based on Aristotle's and Theophrastus' works [3.11]. More recently these notions became the building blocks of modal logics that emerged at the beginning of the 20th century from the works of C.I. Lewis (see Cresswell [3.12]). In this approach, possibility and necessity are all-or-nothing notions, and handled at the syntactic level. More recently, and independently from Zadeh's view, the notion of possibility, as opposed to probability, was central in the works of one economist, and in those of two philosophers.

### 3.1.1 G.L.S. Shackle

A graded notion of possibility was introduced as a full-fledged approach to uncertainty and decision in 1940–1970 by the English economist Shackle [3.13], who called *degree of potential surprise* of an event its degree of impossibility, that is, retrospectively, the degree of necessity of the opposite event. Shackle's notion of possibility is basically epistemic, it is a *character of the chooser's particular state of knowledge in his present*. Impossibility is understood as disbelief. Potential surprise is valued on a disbelief scale, namely a positive interval of the form  $[0, y^*]$ , where  $y^*$  denotes the absolute rejection of the event to which it is assigned. In case everything is possible, all mutually exclusive

hypotheses have zero surprise. At least one elementary hypothesis must carry zero potential surprise. The degree of surprise of an event, a set of elementary hypotheses, is the degree of surprise of its least surprising realization. Shackle also introduces a notion of conditional possibility, whereby the degree of surprise of a conjunction of two events  $A$  and  $B$  is equal to the maximum of the degree of surprise of  $A$ , and of the degree of surprise of  $B$ , should  $A$  prove true. The disbelief notion introduced later by Spohn [3.9, 10] employs the same type of convention as potential surprise, but uses the set of natural integers as a disbelief scale; his conditioning rule uses the subtraction of natural integers.

### 3.1.2 D. Lewis

In his 1973 book [3.14], the philosopher *David Lewis* considers a graded notion of possibility in the form of a relation between possible worlds he calls *comparative possibility*. He connects this concept of possibility to a notion of similarity between possible worlds. This asymmetric notion of similarity is also comparative, and is meant to express statements of the form: *a world  $j$  is at least as similar to world  $i$  as world  $k$  is*. Comparative similarity of  $j$  and  $k$  with respect to  $i$  is interpreted as the comparative possibility of  $j$  with respect to  $k$  viewed from world  $i$ . Such relations are assumed to be complete pre-orderings and are instrumental in defining the truth conditions of counterfactual statements (of the form *If I were rich, I would buy a big boat*). Comparative possibility relations  $\geq_{\Pi}$  obey the key axiom: for all events  $A, B, C$

$$A \geq_{\Pi} B \text{ implies } C \cup A \geq_{\Pi} C \cup B.$$

This axiom was later independently proposed by the first author [3.15] in an attempt to derive a possibilistic counterpart to comparative probabilities. Inde-

pendently, the connection between numerical possibility degrees and similarity was investigated by *Sudkamp* [3.16].

### 3.1.3 L.J. Cohen

A framework very similar to the one of Shackle was proposed by the philosopher *Cohen* [3.17] who considered the problem of legal reasoning. He introduced so-called *Baconian probabilities* understood as degrees of provability. The idea is that it is hard to prove someone guilty at the court of law by means of pure statistical arguments. The basic feature of degrees of provability is that a hypothesis and its negation cannot both be provable together to any extent (the contrary being a case for inconsistency). Such degrees of provability coincide with what is known as necessity measures.

### 3.1.4 L.A. Zadeh

In his seminal paper [3.1], *Zadeh* proposed an interpretation of membership functions of fuzzy sets as possibility distributions encoding flexible constraints induced by natural language statements. *Zadeh* tentatively articulated the relationship between possibility and probability, noticing that what is probable must preliminarily be possible. However, the view of possibility degrees developed in his paper refers to the idea of graded feasibility (degrees of ease, as in the example of *how many eggs can Hans eat for his breakfast*) rather than to the epistemic notion of plausibility laid bare by Shackle. Nevertheless, the key axiom of *maxitivity* for possibility measures is highlighted. In the two subsequent articles [3.18, 19], *Zadeh* acknowledged the connection between possibility theory, belief functions and upper/lower probabilities, and proposed their extensions to fuzzy events and fuzzy information granules.

## 3.2 Basic Notions of Possibility Theory

The basic building blocks of possibility theory originate in *Zadeh's* paper [3.1] and were first extensively described in the authors' book [3.20], then further on in [3.3, 21]. More recent accounts are in [3.4, 5]. In this section, possibility theory is envisaged as a stand-alone theory of uncertainty.

### 3.2.1 Possibility Distributions

Let  $S$  be a set of states of affairs (or descriptions thereof), or states for short. This set can be the domain of an attribute (numerical or categorical), the Cartesian product of attribute domains, the set of interpretations of a propositional language etc.. A possibility distribu-

tion is a mapping  $\pi$  from  $S$  to a totally ordered scale  $L$ , with top denoted by 1 and bottom by 0. In the finite case  $L = \{1 = \lambda_1 > \dots > \lambda_n > \lambda_{n+1} = 0\}$ . The possibility scale can be the unit interval as suggested by Zadeh, or generally any finite chain, or even the set of nonnegative integers. It is often assumed that  $L$  is equipped with an order-reversing map denoted by  $\lambda \in L \mapsto 1 - \lambda$ .

The function  $\pi$  represents the state of knowledge of an agent (about the actual state of affairs), also called an *epistemic state* distinguishing what is plausible from what is less plausible, what is the normal course of things from what is not, what is surprising from what is expected. It represents a flexible restriction on what is the actual state with the following conventions (similar to probability, but opposite to Shackle's potential surprise scale (If  $L = \mathbb{N}$ , the conventions are opposite: 0 means possible and  $\infty$  means impossible.)):

- $\pi(s) = 0$  means that state  $s$  is rejected as impossible;
- $\pi(s) = 1$  means that state  $s$  is totally possible (= plausible).

The larger  $\pi(s)$ , the more possible, i.e., plausible the state  $s$  is. Formally, the mapping  $\pi$  is the membership function of a fuzzy set [3.1], where membership grades are interpreted in terms of plausibility. If the universe  $S$  is exhaustive, at least one of the elements of  $S$  should be the actual world, so that  $\exists s, \pi(s) = 1$  (normalization). This condition expresses the consistency of the epistemic state described by  $\pi$ .

Distinct values may simultaneously have a degree of possibility equal to 1. In the Boolean case,  $\pi$  is just the characteristic function of a subset  $E \subseteq S$  of mutually exclusive states (a disjunctive set [3.22]), ruling out all those states considered as impossible. Possibility theory is thus a (fuzzy) set-based representation of incomplete information.

### 3.2.2 Specificity

A possibility distribution  $\pi$  is said to be at least as specific as another  $\pi'$  if and only if for each state of affairs  $s$ :  $\pi(s) \leq \pi'(s)$  [3.23]. Then,  $\pi$  is at least as restrictive and informative as  $\pi'$ , since it rules out at least as many states with at least as much strength. In the possibilistic framework, extreme forms of partial knowledge can be captured, namely:

- *Complete knowledge*: for some  $s_0, \pi(s_0) = 1$  and  $\pi(s) = 0, \forall s \neq s_0$  (only  $s_0$  is possible)

- *Complete ignorance*:  $\pi(s) = 1, \forall s \in S$  (all states are possible).

Possibility theory is driven by the *principle of minimal specificity*. It states that *any hypothesis not known to be impossible cannot be ruled out*. It is a minimal commitment, cautious information principle. Basically, we must always try to maximize possibility degrees, taking constraints into account.

Given a piece of information in the form  $x$  is  $F$ , where  $F$  is a fuzzy set restricting the values of the ill-known quantity  $x$ , it leads to represent the knowledge by the inequality  $\pi \leq \mu_F$ , the membership function of  $F$ . The minimal specificity principle enforces the possibility distribution  $\pi = \mu_F$ , if no other piece of knowledge is available. Generally there may be impossible values of  $x$  due to other piece(s) of information. Thus, given several pieces of knowledge of the form  $x$  is  $F_i$ , for  $i = 1, \dots, n$ , each of them translates into the constraint  $\pi \leq \mu_{F_i}$ ; hence, several constraints lead to the inequality  $\pi \leq \min_{i=1}^n \mu_{F_i}$  and on behalf of the minimal specificity principle, to the possibility distribution

$$\pi = \min_{i=1}^n \pi_i,$$

where  $\pi_i$  is induced by the information item  $x$  is  $F_i$ . It justifies the use of the minimum operation for combining information items. It is noticeable that this way of combining pieces of information fully agrees with classical logic, since a classical logic base is equivalent to the logical conjunction of the logical formulas that belong to the base, and its models is obtained by intersecting the sets of models of its formulas. Indeed, in propositional logic, asserting a proposition  $\phi$  amounts to declaring that any interpretation (state) that makes  $\phi$  false is impossible, as being incompatible with the state of knowledge.

### 3.2.3 Possibility and Necessity Functions

Given a simple query of the form *does event A occur?* (is the corresponding proposition  $\phi$  true?) where  $A$  is a subset of states, the response to the query can be obtained by computing degrees of possibility and necessity, respectively (if the possibility scale  $L = [0, 1]$ )

$$P(A) = \sup_{s \in A} \pi(s); \quad N(A) = \inf_{s \notin A} 1 - \pi(s).$$

$P(A)$  evaluates to what extent  $A$  is consistent with  $\pi$ , while  $N(A)$  evaluates to what extent  $A$  is certainly

implied by  $\pi$ . The possibility–necessity duality is expressed by  $N(A) = 1 - \Pi(A^c)$ , where  $A^c$  is the complement of  $A$ . Generally,  $\Pi(S) = N(S) = 1$  and  $\Pi(\emptyset) = N(\emptyset) = 0$  (since  $\pi$  is normalized to 1). In the Boolean case, the possibility distribution comes down to the disjunctive (epistemic) set  $E \subseteq S$  [3.3, 24]:

- $\Pi(A) = 1$  if  $A \cap E \neq \emptyset$ , and 0 otherwise: function  $\Pi$  checks whether proposition  $A$  is logically consistent with the available information or not.
- $N(A) = 1$  if  $E \subseteq A$ , and 0 otherwise: function  $N$  checks whether proposition  $A$  is logically entailed by the available information or not.

More generally, possibility and necessity measures represent degrees of plausibility and belief, respectively, in agreement with other uncertainty theories (see Sect. 3.4). Possibility measures satisfy the basic *maxitivity* property  $\Pi(A \cup B) = \max(\Pi(A), \Pi(B))$ . Necessity measures satisfy an axiom dual to that of possibility measures, namely  $N(A \cap B) = \min(N(A), N(B))$ . On infinite spaces, these axioms must hold for infinite families of sets. As a consequence, of the normalization of  $\pi$ ,  $\min(N(A), N(A^c)) = 0$  and  $\max(\Pi(A), \Pi(A^c)) = 1$ , where  $A^c$  is the complement of  $A$ , or equivalently  $\Pi(A) = 1$  whenever  $N(A) > 0$ , which totally fits the intuition behind this formalism, namely that something somewhat certain should be fully possible, i.e., consistent with the available information.

### 3.2.4 Certainty Qualification

Human knowledge is often expressed in a declarative way using statements to which belief degrees are attached. Certainty-qualified pieces of uncertain information of the form  $A$  is *certain to degree*  $\alpha$  can then be modeled by the constraint  $N(A) \geq \alpha$ . It represents a family of possible epistemic states  $\pi$  that obey this constraints. The least specific possibility distribution among them exists and is defined by [3.3]

$$\pi_{(A,\alpha)}(s) = \begin{cases} 1 & \text{if } s \in A, \\ 1 - \alpha & \text{otherwise.} \end{cases} \quad (3.1)$$

If  $\alpha = 1$ , we get the characteristic function of  $A$ . If  $\alpha = 0$ , we get total ignorance. This possibility distribution is a key building block to construct possibility distributions from several pieces of uncertain knowledge. Indeed, e.g., in the finite case, any possibility distribution can be viewed as a collection of nested certainty-qualified statements. Let  $E_i = \{s : \pi(s) \geq \lambda_i \in L\}$  be the

$\lambda_i$ -cut of  $\pi$ . Then it is easy to check that  $\pi(s) = \min_{i:s \notin E_i} 1 - N(E_i)$  (with the convention  $\min_\emptyset = 1$ ).

We can also consider possibility-qualified statements of the form  $\Pi(A) \geq \beta$ ; however, the least specific epistemic state compatible with this constraint expresses total ignorance.

### 3.2.5 Joint Possibility Distributions

Possibility distributions over Cartesian products of attribute domains  $S_1 \times \dots \times S_m$  are called joint possibility distributions  $\pi(s_1, \dots, s_n)$ . The projection  $\pi_k^\downarrow$  of the joint possibility distribution  $\pi$  onto  $S_k$  is defined as

$$\begin{aligned} \pi_k^\downarrow(s_k) &= \Pi(S_1 \times \dots \times S_{k-1} \times \{s_k\} \times \dots \times S_{k+1} \times S_m) \\ &= \sup_{s_i \in S_i, i \neq k} \pi(s_1, \dots, s_n). \end{aligned}$$

Clearly,  $\pi(s_1, \dots, s_n) \leq \min_{k=1}^m \pi_k^\downarrow(s_k)$  that is, a joint possibility distribution is at least as specific as the Cartesian product of its projections. When the equality holds,  $\pi(s_1, \dots, s_n)$  is called *separable*.

### 3.2.6 Conditioning

Notions of conditioning exist in possibility theory. Conditional possibility can be defined similarly to probability theory using a Bayesian-like equation of the form [3.3]

$$\Pi(B \cap A) = \Pi(B | A) \star \Pi(A).$$

where  $\Pi(A) > 0$  and  $\star$  is a  $t$ -norm (A nondecreasing Abelian semigroup operation on the unit interval having identity 1 and absorbing element 0 [3.25].); moreover  $N(B | A) = 1 - \Pi(B^c | A)$ . The above equation makes little sense for necessity measures, as it becomes trivial when  $N(A) = 0$ , that is under lack of certainty, while in the above definition, the equation becomes problematic only if  $\Pi(A) = 0$ , which is natural as then  $A$  is considered impossible. If operation  $\star$  is the minimum, the equation  $\Pi(B \cap A) = \min(\Pi(B | A), \Pi(A))$  fails to characterize  $\Pi(B | A)$ , and we must resort to the minimal specificity principle to come up with the qualitative conditioning rule [3.3]

$$\Pi(B | A) = \begin{cases} 1 & \text{if } \Pi(B \cap A) = \Pi(A) > 0, \\ \Pi(B \cap A) & \text{otherwise.} \end{cases} \quad (3.2)$$

It is clear that  $N(B|A) > 0$  if and only if  $\Pi(B \cap A) > \Pi(B^c \cap A)$ . Moreover, if  $\Pi(B|A) > \Pi(B)$  then  $\Pi(B|A) = 1$ , which points out the limited expressiveness of this qualitative notion (no gradual positive reinforcement of possibility). However, it is possible to have that  $N(B) > 0, N(B^c|A_1) > 0, N(B|A_1 \cap A_2) > 0$  (i.e., oscillating beliefs). Extensive works on conditional possibility, especially qualitative, handling the case  $\Pi(A) = 0$ , have been recently carried out by *Colelli and Vantaggi* [3.26, 27] in the spirit of De Finetti's approach to subjective probabilities defined in terms of conditional measures and allowing for conditioning on impossible events.

In the numerical setting, due to the need of preserving for  $\Pi(B|A)$  continuity properties of  $\Pi$ , we must choose  $\star = \text{product}$ , so that

$$\Pi(B|A) = \frac{\Pi(B \cap A)}{\Pi(A)}$$

which makes possibilistic and probabilistic conditionings very similar [3.28] (now, gradual positive reinforcement of possibility is allowed). But there is yet another definition of numerical possibilistic conditioning, not based on the above equation as seen later in this chapter.

### 3.2.7 Independence

There are also several variants of possibilistic independence between events. Let us mention here the two basic approaches:

- *Unrelatedness*:  $\Pi(A \cap B) = \min(\Pi(A), \Pi(B))$ . When it does not hold, it indicates an epistemic form of mutual exclusion between  $A$  and  $B$ . It is symmetric but sensitive to negation. When it holds for all pairs made of  $A, B$  and their complements, it is an epistemic version of logical independence related to separability.
- *Causal independence*:  $\Pi(B|A) = \Pi(B)$ . This notion is different from the former one and stronger. It is a form of directed epistemic independence whereby learning  $A$  does not affect the plausibility of  $B$ . It is neither symmetric nor insensitive to negation: for instance, it is not equivalent to  $N(B|A) = N(B)$ .

Generally, independence in possibility theory is neither symmetric, nor insensitive to negation. For Boolean variables, independence between events is not equivalent to independence between variables. But

since the possibility scale can be qualitative or quantitative, and there are several forms of conditioning, there are also various possible forms of independence. For studies of various notions and their properties see [3.29–32]. More discussions and references appear in [3.4].

### 3.2.8 Fuzzy Interval Analysis

An important example of a possibility distribution is a fuzzy interval [3.3, 20]. A fuzzy interval is a fuzzy set of reals whose membership function is unimodal and upper-semi continuous. Its  $\alpha$ -cuts are closed intervals. The calculus of fuzzy intervals is an extension of interval arithmetics based on a possibilistic counterpart of a computation of random variable. To compute the addition of two fuzzy intervals  $A$  and  $B$  one has to compute the membership function of  $A \oplus B$  as the degree of possibility  $\mu_{A \oplus B}(z) = \Pi(\{(x, y) : x + y = z\})$ , based on the possibility distribution  $\min(\mu_A(x), \mu_B(y))$ . There is a large literature on possibilistic interval analysis; see [3.33] for a survey of 20th-century references.

### 3.2.9 Guaranteed Possibility

Possibility distributions originally represent negative information in the sense that their role is essentially to rule out impossible states. More recently, [3.34, 35] another type of possibility distribution has been considered where the information has a positive nature, namely it points out actually possible states, such as observed cases, examples of solutions, etc. Positively-flavored possibility distributions will be denoted by  $\delta$  and serve as evidential support functions. The conventions for interpreting them contrast with usual possibility distributions:

- $\delta(s) = 1$  means that state  $s$  is actually possible because of a high evidential support (for instance,  $s$  is a case that has been actually observed);
- $\delta(s) = 0$  means that state  $s$  has not been observed (yet: potential impossibility).

Note that  $\pi(s) = 1$  indicates *potential* possibility, while  $\delta(s) = 1$  conveys more information. In contrast,  $\delta(s) = 0$  expresses ignorance.

A measure of *guaranteed possibility* can be defined, that differs from functions  $\Pi$  and  $N$  [3.34, 35]

$$\Delta(A) = \inf_{s \in A} \delta(s).$$

It estimates to what extent *all* states in  $A$  are actually possible according to evidence.  $\Delta(A)$  can be used as a degree of evidential support for  $A$ . Of course, this function possesses a conjugate  $\nabla$  such that  $\nabla(A) = 1 - \Delta(A^c) = \sup_{s \notin A} 1 - \delta(s)$ . Function  $\nabla(A)$  evaluates the degree of potential necessity of  $A$ , as it is 1 only if some state  $s$  outside  $A$  is potentially impossible.

Uncertain statements of the form  $A$  is possible to degree  $\beta$  often mean that any realization of  $A$  is possible to degree  $\beta$  (e.g., *it is possible that the museum is open this afternoon*). They can then be modeled by a constraint of the form  $\Delta(A) \geq \beta$ . It corresponds to the idea of observed evidence.

This type of information is better exploited by assuming an informational principle opposite to the one of minimal specificity, namely, *any situation not yet observed is tentatively considered as impossible*. This is similar to the closed-world assumption. The most specific distribution  $\delta_{(A,\beta)}$  in agreement with  $\Delta(A) \geq \beta$  is

$$\delta_{(A,\beta)}(s) = \begin{cases} \beta & \text{if } s \in A, \\ 0 & \text{otherwise.} \end{cases}$$

Note that while possibility distributions induced from certainty qualified pieces of knowledge combine conjunctively, by discarding possible states, evidential support distributions induced by possibility-qualified pieces of evidence combine disjunctively, by accumulating possible states. Given several pieces of knowledge of the form  $x$  is  $F_i$  is possible, for  $i = 1, \dots, n$ , each of them translates into the constraint  $\delta \geq \mu_{F_i}$ ; hence, several constraints lead to the inequality  $\delta \geq \max_{i=1}^n \mu_{F_i}$  and on behalf of another minimal commitment principle based on maximal specificity, we get the possibility distribution

$$\delta = \max_{i=1}^n \pi_i,$$

where  $\delta_i$  is induced by the information item  $x$  is  $F_i$  is possible. It justifies the use of the maximum operation for combining evidential support functions. Acquiring pieces of possibility-qualified evidence leads to updating  $\delta_{(A,\beta)}$  into some wider distribution  $\delta > \delta_{(A,\beta)}$ . Any possibility distribution can be represented as a collection of nested possibility-qualified statements of the form  $(E_i, \Delta(E_i))$ , with  $E_i = \{s : \delta(s) \geq \lambda_i\}$ , since  $\delta(s) = \max_{i:s \in E_i} \Delta(E_i)$ , dually to the case of certainty-qualified statements.

### 3.2.10 Bipolar Possibility Theory

A bipolar representation of information using pairs  $(\delta, \pi)$  may provide a natural interpretation of interval-valued fuzzy sets [3.8]. Although positive and negative information are represented in separate and different ways via  $\delta$  and  $\pi$  functions, respectively, there is a coherence condition that should hold between positive and negative information. Indeed, observed information should not be impossible. Likewise, in terms of preferences, solutions that are preferred to some extent should not be unfeasible. This leads to enforce the coherence constraint  $\delta \leq \pi$  between the two representations.

This condition should be maintained when new information arrives and is combined with the previous one. This does not go for free since degrees  $\delta(s)$  tend to increase while degrees  $\pi(s)$  tend to decrease due to the disjunctive and conjunctive processes that, respectively, govern their combination. Maintaining this coherence requires a revision process that works as follows. If the current information state is represented by the pair  $(\delta, \pi)$ , receiving a new positive (resp. negative) piece of information represented by  $\delta^{\text{new}}$  (resp.  $\pi^{\text{new}}$ ) to be enforced, leads to revising  $(\delta, \pi)$  into  $(\max(\delta, \delta^{\text{new}}), \pi^{\text{rev}})$  (resp. into  $(\delta^{\text{rev}}, \min(\pi, \pi^{\text{new}}))$ ), using, respectively,

$$\pi^{\text{rev}} = \max(\pi, \delta^{\text{new}}); \quad (3.3)$$

$$\delta^{\text{rev}} = \min(\pi^{\text{new}}, \delta). \quad (3.4)$$

It is important to note that when both positive and negative pieces of information are collected, there are two options:

- Either priority is given to positive information over negative information: it means that (past) positive information cannot be ruled out by (future) negative information. This may be found natural when very reliable observations (represented by  $\delta$ ) contradict tentative knowledge (represented by  $\pi$ ). Then revising  $(\delta, \pi)$  by  $(\delta^{\text{new}}, \pi^{\text{new}})$  yields the new pair

$$(\delta^{\text{rev}}, \pi^{\text{rev}}) = (\max(\delta, \delta^{\text{new}}), \max(\min(\pi, \pi^{\text{new}}), \max(\delta, \delta^{\text{new}})))$$

- Priority is given to negative information over positive information. It makes sense when handling preferences. Indeed, then, positive information may be viewed as wishes, while negative informa-

tion reflects constraints. Then, revising  $(\delta, \pi)$  by  $(\delta^{\text{new}}, \pi^{\text{new}})$  would yield the new pair

$$(\delta^{\text{rev}}, \pi^{\text{rev}}) = (\min(\min(\pi, \pi^{\text{new}}), \max(\delta, \delta^{\text{new}})), \min(\pi, \pi^{\text{new}})).$$

It can be checked that the two latter revision rules generalize the two previous ones. With both revision options, it can be checked that if  $\delta \leq \pi$  and  $\delta^{\text{new}} \leq \pi^{\text{new}}$

hold, revising  $(\delta, \pi)$  by  $(\delta^{\text{new}}, \pi^{\text{new}})$  yields a new coherent pair. This revision process should not be confused with another one pertaining only to the negative part of the information, namely computing  $\min(\pi, \pi^{\text{new}})$  may yield a possibility distribution that is not normalized, in the case of inconsistency. If such an inconsistency takes place, it should be resolved (by some appropriate renormalization) before one of the two above bipolar revision mechanisms can be applied.

### 3.3 Qualitative Possibility Theory

This section is restricted to the case of a finite state space  $S$ , typically  $S$  is the set of interpretations of a formal propositional language  $\mathcal{L}$  based on a finite set of Boolean attributes  $\mathcal{V}$ . The usual connectives  $\wedge$  (conjunction),  $\vee$  (disjunction), and  $\neg$  (negation) are used. The possibility scale is then taken as a finite chain, or the unit interval understood as an ordinal scale, or even just a complete preordering of states. At the other end, one may use the set of natural integers (viewed as an impossibility scale) equipped with addition, which comes down to a countable subset of the unit interval, equipped with the product  $t$ -norm, instrumental for conditioning. However, the qualitative nature of the latter setting is questionable, even if authors using it do not consider it as genuinely quantitative.

#### 3.3.1 Possibility Theory and Modal Logic

In this section, the possibility scale is Boolean ( $L = \{0, 1\}$ ) and a possibility distribution reduces to a subset of states  $E$ , for instance the models of a set of formulas  $K$  representing the beliefs of an agent in propositional logic. The presence of a proposition  $p$  in  $K$  can be modeled by  $N([p]) = 1$ , or  $\Pi([\neg p]) = 0$  where  $[p]$  is the set of interpretations of  $p$ ; more generally the degrees of possibility and necessity can be defined by [3.36]:

- $N([p]) = \Pi([p]) = 1$  if and only if  $K \models p$  (the agent believes  $p$ )
- $N([\neg p]) = \Pi([\neg p]) = 0$  if and only if  $K \models \neg p$  (the agent believes  $\neg p$ )
- $N([p]) = 0$  and  $\Pi([p]) = 1$  if and only if  $K \not\models p$  and  $K \not\models \neg p$  (the agent is unsure about  $p$ )

However, in propositional logic, it cannot be syntactically expressed that  $N([p]) = 0$  nor  $\Pi([p]) = 1$ . To

do so, a modal language is needed [3.12], that prefixes propositions with modalities such as necessary ( $\Box$ ) and possible ( $\Diamond$ ). Then  $\Box p$  encodes  $N([p]) = 1$  (instead of  $p \in K$  in classical logic),  $\Diamond p$  encodes  $\Pi([p]) = 1$ . Only a very simple modal language  $\mathcal{L}^\Box$  is needed that encapsulates the propositional language  $\mathcal{L}$ . Atoms of this logic are of the form  $\Box p$ , where  $p$  is any propositional formula. Well-formed formulas in this logic are obtained by applying standard conjunction and negation to these atoms

$$\mathcal{L}^\Box = \Box p, p \in \mathcal{L} \mid \neg\phi \mid \phi \wedge \psi .$$

The well-known conjugateness between possibility and necessity reads:  $\Diamond p = \neg\Box\neg p$ . Maxitivity and minitivity axioms of possibility and necessity measure, respectively, read  $\Diamond(p \vee q) = \Diamond p \vee \Diamond q$  and  $\Box(p \wedge q) = \Box p \wedge \Box q$  and are well known to hold in regular modal logics, and the consistency of the epistemic state is ensured by axiom  $D : \Box p \rightarrow \Diamond p$ . This is the minimal epistemic logic (MEL) [3.37] needed to account for possibility theory. It corresponds to a small fragment of the logic KD without modality nesting and without objective formulas ( $\mathcal{L}^\Box \cap \mathcal{L} = \emptyset$ ). Models of such modal formulas are epistemic states: for instance,  $E$  is a model of  $\Box p$  means that  $E \subseteq [p]$  [3.37, 38]. This logic is sound and complete with respect to this semantics, and enables propositions whose truth status is explicitly unknown to be reasoned about.

#### 3.3.2 Comparative Possibility

A plausibility ordering is a complete preorder of states denoted by  $\geq_\pi$ , which induces a well-ordered partition  $\{E_1, \dots, E_n\}$  of  $S$ . It is the comparative counterpart of a possibility distribution  $\pi$ , i.e.,  $s \geq_\pi s'$  if and only if  $\pi(s) \geq \pi(s')$ . Indeed it is more natural to expect that

an agent will supply ordinal rather than numerical information about his beliefs. By convention,  $E_1$  contains the most normal states of fact,  $E_n$  the least plausible, or most surprising ones. Denoting by  $\max(A)$  any most plausible state  $s_0 \in A$ , ordinal counterparts of possibility and necessity measures [3.15] are then defined as follows:  $\{s\} \geq_{\Pi} \emptyset$  for all  $s \in S$  and

$$\begin{aligned} A \geq_{\Pi} B &\text{ if and only if } \max(A) \geq_{\pi} \max(B) \\ A \geq_N B &\text{ if and only if } \max(B^c) \geq_{\pi} \max(A^c). \end{aligned}$$

Possibility relations  $\geq_{\Pi}$  were proposed by Lewis [3.14] and they satisfy his characteristic property

$$A \geq_{\Pi} B \text{ implies } C \cup A \geq_{\Pi} C \cup B,$$

while necessity relations can also be defined as  $A \geq_N B$  if and only if  $B^c \geq_{\Pi} A^c$ , and they satisfy a similar axiom

$$A \geq_N B \text{ implies } C \cap A \geq_N C \cap B.$$

The latter coincides with epistemic entrenchment relations in the sense of belief revision theory [3.39] (provided that  $A >_{\Pi} \emptyset$ , if  $A \neq \emptyset$ ). Conditioning a possibility relation  $\geq_{\Pi}$  by a nonimpossible event  $C >_{\Pi} \emptyset$  means deriving a relation  $\geq_{\Pi}^C$  such that

$$A \geq_{\Pi}^C B \text{ if and only if } A \cap C \geq_{\Pi} B \cap C.$$

These results show that possibility theory is implicitly at work in the principal axiomatic approach to belief revision [3.40], and that conditional possibility obeys its main postulates [3.41]. The notion of independence for comparative possibility theory was studied by Dubois et al. [3.31], for independence between events, and Ben Amor et al. [3.32] between variables.

### 3.3.3 Possibility Theory and Nonmonotonic Inference

Suppose  $S$  is equipped with a plausibility ordering. The main idea behind qualitative possibility theory is that the state of the world is always believed to be as normal as possible, neglecting less normal states.  $A \geq_{\Pi} B$  really means that there is a normal state where  $A$  holds that is at least as normal as any normal state where  $B$  holds. The dual case  $A \geq_N B$  is intuitively understood as  $A$  is at least as certain as  $B$ , in the sense that there are states where  $B$  fails to hold that are at least as normal as the most normal state where  $A$  does not hold. In

particular, the events accepted as true are those which are true in all the most plausible states, namely the ones such that  $A >_{\Pi} \emptyset$ . These assumptions lead us to interpret the plausible inference  $A \approx B$  of a proposition  $B$  from another  $A$ , under a state of knowledge  $\geq_{\Pi}$  as follows:  $B$  should be true in all the most normal states were  $A$  is true, which means  $B >_{\Pi}^A B^c$  in terms of ordinal conditioning, that is,  $A \cap B$  is more plausible than  $A \cap B^c$ .  $A \approx B$  also means that the agent considers  $B$  as an accepted belief in the context  $A$ .

This kind of inference is nonmonotonic in the sense that  $A \approx B$  does not always imply  $A \cap C \approx B$  for any additional information  $C$ . This is similar to the fact that a conditional probability  $P(B | A \cap C)$  may be low even if  $P(B | A)$  is high. The properties of the consequence relation  $\approx$  are now well understood, and are precisely the ones laid bare by Lehmann and Magidor [3.42] for their so-called *rational inference*. Monotonicity is only partially restored:  $A \approx B$  implies  $A \cap C \approx B$  provided that  $A \approx C^c$  does not hold (i.e., that states were  $A$  is true do not typically violate  $C$ ). This property is called *rational monotony*, and, along with some more standard ones (like closure under conjunction), characterizes default possibilistic inference  $\approx$ . In fact, the set  $\{B, A \approx B\}$  of accepted beliefs in the context  $A$  is deductively closed, which corresponds to the idea that the agent reasons with accepted beliefs in each context as if they were true, until some event occurs that modifies this context. This closure property is enough to justify a possibilistic approach [3.43] and adding the rational monotonicity property ensures the existence of a single possibility relation generating the consequence relation  $\approx$  [3.44].

Plausibility orderings can be generated by a set of *if-then* rules tainted with unspecified exceptions. This set forms a knowledge base supplied by an agent. Each rule *if A then B* is modeled by a constraint of the form  $A \cap B >_{\Pi} A \cap B^c$  on possibility relations. There exists a single minimally specific element in the set of possibility relations satisfying all constraints induced by rules (unless the latter are inconsistent). It corresponds to the most compact plausibility ranking of states induced by the rules [3.44]. This ranking can be computed by an algorithm originally proposed by Pearl [3.45].

Qualitative possibility theory has been studied from the point of view of cognitive psychology. Experimental results [3.46] suggest that there are situations where people reason about uncertainty using the rules of possibility theory, rather than with those of probability theory, namely people jump to plausible conclusions based on assuming the current world is normal.

### 3.3.4 Possibilistic Logic

Qualitative possibility relations can be represented by (and only by) possibility measures ranging on any totally ordered set  $L$  (especially a finite one) [3.15]. This absolute representation on an ordinal scale is slightly more expressive than the purely relational one. For instance, one can express that a proposition is fully plausible ( $\Pi(A) = 1$ ), while using a possibility relation, one can only say that it is among the most plausible ones. When the finite set  $S$  is large and generated by a propositional language, qualitative possibility distributions can be efficiently encoded in possibilistic logic [3.47–49].

A possibilistic logic base  $K$  is a set of pairs  $(p_i, \alpha_i)$ , where  $p_i$  is an expression in classical (propositional or first-order) logic and  $\alpha_i > 0$  is an element of the value scale  $L$ . This pair encodes the constraint  $N(p_i) \geq \alpha_i$  where  $N(p_i)$  is the degree of necessity of the set of models of  $p_i$ . Each prioritized formula  $(p_i, \alpha_i)$  has a fuzzy set of models (via certainty qualification described in Sect. 3.2) and the fuzzy intersection of the fuzzy sets of models of all prioritized formulas in  $K$  yields the associated plausibility ordering on  $S$  encoded by a possibility distribution  $\pi_K$ . Namely, an interpretation  $s$  is all the less possible as it falsifies formulas with higher weights, i. e.,

$$\pi_K(s) = 1 \text{ if } s \models p_i, \forall (p_i, \alpha_i) \in K, \quad (3.5)$$

$$\begin{aligned} \pi_K(s) &= 1 - \max\{\alpha_i : (p_i, \alpha_i) \in K, s \not\models p_i\} \\ &\text{otherwise .} \end{aligned} \quad (3.6)$$

This distribution is obtained by applying the minimal specificity principle, since it is the largest one that satisfies the constraints  $N(p_i) \geq \alpha_i$ . If the classical logic base  $\{p_i : (p_i, \alpha_i) \in K\}$  is inconsistent,  $\pi_K$  is not normalized, and a level of inconsistency equal to  $\text{inc}(K) = 1 - \max \pi_K$  can be attached to the base  $K$ . However, the set of formulas  $\{p_i : (p_i, \alpha_i) \in K, \alpha_i > \text{inc}(K)\}$  is always consistent.

Syntactic deduction from a set of prioritized clauses is achieved by refutation using an extension of the standard resolution rule, whereby  $(p \vee q, \min(\alpha, \beta))$  can be derived from  $(p \vee r, \alpha)$  and  $(q \vee \neg r, \beta)$ . This rule, which evaluates the validity of an inferred proposition by the validity of the weakest premiss, goes back to Theophrastus, a disciple of Aristotle. Another way of presenting inference in possibilistic logic relies on the fact that  $K \vdash (p, \alpha)$  if and only if  $K_\alpha = \{p_i : (p_i, \alpha_i) \in K, \alpha_i \geq \alpha\} \vdash p$  in the sense of classical logic. In particular,  $\text{inc}(K) = \max\{\alpha : K_\alpha \vdash \perp\}$ . Inference in possibilistic logic can use this extended resolution rule and proceeds by refutation since  $K \vdash (p, \alpha)$  if and only if  $\text{inc}(\{(\neg p, 1)\} \cup K) \geq \alpha$ . Computational inference methods in possibilistic logic are surveyed in [3.50].

Possibilistic logic is an inconsistency-tolerant extension of propositional logic that provides a natural semantic setting for mechanizing nonmonotonic reasoning [3.51], with a computational complexity close to that of propositional logic. Namely, once a possibility distribution on models is generated by a set of *if-then* rules  $p_i \rightarrow q_i$  (as explained in Sect. 3.3.3 and modeled here using qualitative conditioning as  $N(q_i | p_i) > 0$ ), weights  $\alpha_i = N(\neg p_i \vee q_i)$  can be computed, and the corresponding possibilistic base built [3.51]. See [3.52] for an efficient method involving compilation.

Variants of possibilistic logic have been proposed in later works. A partially ordered extension of possibilistic logic has been proposed, whose semantic counterpart consists of partially ordered models [3.53]. Another approach for handling partial orderings between weights is to encode formulas with partially constrained weights in a possibilistic-like many-sorted propositional logic [3.54]. Namely, a formula  $(p, \alpha)$  is rewritten as a classical two-sorted clause  $p \vee ab_\alpha$ , where  $ab_\alpha$  means *the situation is  $\alpha$ -abnormal*, and thus the clause expresses that  $p$  is true or the situation is abnormal, while more generally  $(p, \min(\alpha, \beta))$  is rewritten as the clause  $p \vee ab_\alpha \vee ab_\beta$ . Then a known constraint between unknown weights such as  $\alpha \geq \beta$  is translated into a clause  $\neg ab_\alpha \vee ab_\beta$ . In this way, a possibilistic logic base, where only partial information about the relative ordering between the weights is available under the form of constraints, can be handled as a set of classical logic formulas that involve symbolic weights.

An efficient inference process has been proposed using the notion of forgetting variables. This approach provides a technique for compiling a standard possibilistic knowledge bases in order to process inference in polynomial time [3.55]. Let us also mention quasi-possibilistic logic [3.56], an extension of possibilistic logic based on the so-called *quasi-classical logic*, a paraconsistent logic whose inference mechanism is close to classical inference (except that it is not allowed to infer  $p \vee q$  from  $p$ ). This approach copes with inconsistency between formulas having the same weight. Other types of possibilistic logic can also handle constraints of the form  $\Pi(\phi) \geq \alpha$ , or  $\Delta(\phi) \geq \alpha$  [3.49].

There is a major difference between possibilistic logic and weighted many-valued logics [3.57]. Namely, in the latter, a weight  $\tau \in L$  attached to a (many valued, thus nonclassical) formula  $p$  acts as a truth-value

threshold, and  $(p, \tau)$  in a fuzzy knowledge base expresses the Boolean requirement that the truth value of  $p$  should be at least equal to  $\tau$  for  $(p, \tau)$  to be valid. So in such fuzzy logics, while truth of  $p$  is many-valued, the validity of a weighted formula is two-valued. On the contrary, in possibilistic logic, truth is two-valued (since  $p$  is Boolean), but the validity of a possibilistic formula  $(p, \alpha)$  is many-valued. In particular, it is possible to cast possibilistic logic inside a many-valued logic. The idea is to consider many-valued atomic sentences  $\phi$  of the form  $(p, \alpha)$ , where  $p$  is a formula in classical logic. Then, one can define well-formed formulas such as  $\phi \vee \psi$ ,  $\phi \wedge \psi$ , or yet  $\phi \rightarrow \psi$ , where the external connectives linking  $\phi$  and  $\psi$  are those of the chosen many-valued logic. From this point of view, possibilistic logic can be viewed as a fragment of a many-valued logic that uses only one external connective: conjunction interpreted as minimum. This approach involving a Boolean algebra embedded in a nonclassical one has been proposed by *Boldrin* and *Sossai* [3.58] with a view to augment possibilistic logic with fusion modes cast at the object level. It is also possible to replace classical logic by a many-valued logic inside possibilistic logic. For instance, possibilistic logic has been extended to Gödel many-valued logic [3.59]. A similar technique has been used by *Hájek* et al. to extend possibilistic logic to a many-valued modal setting [3.60].

*Lehmke* [3.61] has cast fuzzy logics and possibilistic logic inside the same framework, considering weighted many-valued formulas of the form  $(p, \theta)$ , where  $p$  is a many-valued formula with truth set  $T$ , and  $\theta$  is a *label* defined as a monotone mapping from the truth-set  $T$  to a *validity* set  $L$  (a set of possibility degrees).  $T$  and  $L$  are supposed to be complete lattices, and the set of labels has properties that make it a fuzzy extension of a filter. Labels encompass *fuzzy truth-values* in the sense of *Zadeh* [3.62], such as *very true*, *more or less true* that express uncertainty about (many-valued) truth in a graded way.

Rather than expressing statements such as *it is half true that John is tall*, which presupposes a state of complete knowledge about John's height, one may be interested in handling states of incomplete knowledge, namely assertions of the form *all we know is that John is tall*. One way to do it is to introduce fuzzy constants in a possibilistic first-ordered logic. *Dubois*, *Prade*, and *Sandri* [3.63] have noticed that an imprecise restriction on the scope of an existential quantifier can be handled in the following way. From the two premises  $\forall x \in A, \neg p(x, y) \vee q(x, y)$ , and  $\exists x \in B, p(x, a)$ , where  $a$  is a constant, we can conclude that  $\exists x \in B, q(x, a)$  pro-

vided that  $B \subseteq A$ . Thus, letting  $p(B, a)$  stand for  $\exists x \in B, p(x, a)$ , one can write

$$\forall x \in A, \neg p(x, y) \vee q(x, y), p(B, a) \vdash q(B, a)$$

if  $B \subseteq A$ ,  $B$  being an imprecise constant. Letting  $A$  and  $B$  be fuzzy sets, the following pattern can be validated in possibilistic logic

$$\begin{aligned} & (\neg p(x, y) \vee q(x, y), \min(\mu_A(x), \alpha)), (p(B, a), \beta) \\ & \vdash (q(B, a), \min(N_B(A), \alpha, \beta)), \end{aligned}$$

where  $N_B(A) = \inf_t \max(\mu_A(t), 1 - \mu_B(t))$  is the necessity measure of the fuzzy event  $A$  based on fuzzy information  $B$ . Note that  $A$ , which appears in the weight slot of the first possibilistic formula plays the role of a fuzzy predicate, since the formula expresses that *the more x is A, the more certain (up to level α) if p is true for (x, y), q is true for them as well*.

*Alsinet* and *Godo* [3.64, 65] have applied possibilistic logic to logic programming that allows for fuzzy constants [3.65, 66]. They have developed programming environments based on possibility theory. In particular, the above inference pattern can be strengthened, replacing  $B$  by its cut  $B_\beta$  in the expression of  $N_B(A)$  and extended to a sound resolution rule. They have further developed possibilistic logic programming with similarity reasoning [3.67] and more recently argumentation [3.68, 69].

Lastly, in order to improve the knowledge representation power of the answer-set programming (**ASP**) paradigm, the stable model semantics has been extended by taking into account a certainty level, expressed in terms of necessity measure, on each rule of a normal logic program. It leads to the definition of a possibilistic stable model for weighted answer-set programming [3.70]. *Bauters* et al. [3.71] introduce a characterization of answer sets of classical and possibilistic **ASP** programs in terms of possibilistic logic where an **ASP** program specifies a set of constraints on possibility distributions.

### 3.3.5 Ranking Function Theory

A theory that parallels possibility theory to a large extent and that has been designed for handling issues in belief revision, nonmonotonic reasoning and causation, just like qualitative possibility theory is the one of ranking functions by *Spohn* [3.9, 10, 72]. The main difference is that it is not really a qualitative theory as it uses the set of integers including  $\infty$  (denoted by  $\mathbb{N}^+$ )

as a value scale. Hence, it is more expressive than qualitative possibility theory, but it is applied to the same problems.

Formally [3.10], a ranking function is a mapping  $\kappa : 2^S \rightarrow \mathbb{N}^+$  such that:

- $\kappa(\{s\}) = 0$  for some  $s \in S$ ;
- $\kappa(A) = \min_{s \in A} \kappa(\{s\})$ ;
- $\kappa(\emptyset) = \infty$ .

It is immediate to verify that the set function  $\Pi(A) = 2^{-\kappa(A)}$  is a possibility measure. So a ranking function is an integer-valued measure of impossibility (disbelief). The function  $\beta(A) = \kappa(A^c)$  is an integer-valued necessity measure used by Spohn for measuring belief, and it is clear that the rescaled necessity measure is  $N(A) = 1 - 2^{-\beta(A)}$ . Interestingly, ranking functions also bear close connection to probability theory [3.72], viewing  $\kappa(A)$  as the exponent of an infinitesimal probability, of the form  $P(A) = e^{\kappa(A)}$ . Indeed the order of magnitude of  $P(A \cup B)$  is then  $e^{\min(\kappa(A), \kappa(B))}$ . Integers also come up naturally if we consider Hamming distances between models in the Boolean logic context, if for instance, the degree of possibility of an interpretation is a function of its Hamming distance to the closest model of a classical knowledge base.

Spohn [3.9] also introduces conditioning concepts, especially:

- The so-called  $A$ -part of  $\kappa$ , which is a conditioning operation by event  $A$  defined by  $\kappa(B | A) = \kappa(B \cap A) - \kappa(A)$ ;
- The  $(A, n)$ -conditionalization of  $\kappa$ ,  $\kappa(\cdot | (A \rightarrow n))$  which is a revision operation by an uncertain input enforcing  $\kappa'(A^c) = n$ , and defined by

$$\kappa(s | (A \rightarrow n)) = \begin{cases} \kappa(s | A) & \text{if } s \in A \\ n + \kappa(s | A^c) & \text{otherwise.} \end{cases} \quad (3.7)$$

This operation makes  $A$  more believed than  $A^c$  by  $n$  steps, namely,

$$\beta(A | (A \rightarrow n)) = 0; \quad \beta(A^c | (A \rightarrow n)) = n.$$

It is easy to see that the conditioning of ranking functions comes down to the product-based conditioning of numerical possibility measures, and to the infinitesimal counterpart of usual Bayesian conditioning of probabilities. The other conditioning rule can be obtained by means of Jeffrey's rule of conditioning [3.73]  $P(B | (A, \alpha)) = \alpha P(B | A) + (1 - \alpha)P(B | A^c)$

by a constraint of the form  $P(A) = \alpha$ . Both qualitative and quantitative counterparts of this revision rule in possibility theory have been studied in detail [3.74, 75]. In fact, ranking function theory is formally encompassed by numerical possibility theory. Moreover, there is no fusion rule in Spohn theory, while fusion is one of the main applications of possibility theory (see Sect. 3.5).

### 3.3.6 Possibilistic Belief Networks

Another compact representation of qualitative possibility distributions is the possibilistic directed graph, which uses the same conventions as Bayesian nets, but relies on conditional possibility [3.76]. The qualitative approach is based on a symmetric notion of qualitative independence  $\Pi(B \cap A) = \min(\Pi(A), \Pi(B))$  that is weaker than the causal-like condition  $\Pi(B | A) = \Pi(B)$  [3.31]. Like joint probability distributions, joint possibility distributions can be decomposed into a conjunction of conditional possibility distributions (using minimum or product) in a way similar to Bayes nets [3.76]. A joint possibility distribution associated with variables  $X_1, \dots, X_n$ , decomposed by the chain rule

$$\pi(X_1, \dots, X_n) = \min(\pi(X_n | X_1, \dots, X_{n-1}), \dots, \pi(X_2 | X_1), \pi(X_1)).$$

Such a decomposition can be simplified by assuming conditional independence relations between variables, as reflected by the structure of the graph. The form of independence between variables at work here is conditional noninteractivity: Two variables  $X$  and  $Y$  are independent in the context  $Z$ , if for each instance  $(x, y, z)$  of  $(X, Y, Z)$  we have:  $\pi(x, y | z) = \min(\pi(x | z), \pi(y | z))$ .

Ben Amor and Benferhat [3.77] investigate the properties of qualitative independence that enable local inferences to be performed in possibilistic nets. Uncertainty propagation algorithms suitable for possibilistic graphical structures have been studied in [3.78]. It is also possible to propagate uncertainty in nondirected decompositions of joint possibility measures as done quite early by Borgelt et al. [3.79]. Counterparts of product-based numerical possibilistic nets using ranking functions exist as well [3.10]. Qualitative possibilistic counterparts of decision trees and influence diagrams for decision trees have been recently investigated [3.80, 81]. Compilation techniques for inference in possibilistic networks have been devised [3.82]. Finally, the study of possibilistic networks from the standpoint of causal reasoning has been invest-

tigated, using the concept of intervention, that comes down to enforcing the values of some variables so as to lay bare their influence on other ones [3.83, 84].

### 3.3.7 Fuzzy Rule-Based and Case-Based Approximate Reasoning

A typology of fuzzy rules has been devised in the setting of possibility theory, distinguishing rules whose purpose is to propagate uncertainty through reasoning steps, from rules whose main purpose is similarity-based interpolation [3.85], depending on the choice of a many-valued implication connective that models a rule. The bipolar view of information based on  $(\delta, \pi)$  pairs sheds new light on the debate between conjunctive and implicative representation of rules [3.86]. Representing a rule as a material implication focuses on counterexamples to rules, while using a conjunction between antecedent and consequent points out examples of the rule and highlights its positive content. Traditionally in fuzzy control and modeling, the latter representation is adopted, while the former is the logical tradition. Introducing fuzzy implicative rules in modeling accounts for constraints or landmark points the model should comply with (as opposed to observed data) [3.87]. The bipolar view of rules in terms of examples and counterexamples may turn out to be very useful when extracting fuzzy rules from data [3.88].

Fuzzy rules have been applied to case-based reasoning (CBR). In general, CBR relies on the following implicit principle: *similar situations may lead to similar outcomes*. Thus, a similarity relation  $S$  between problem descriptions or situations, and a similarity measure  $T$  between outcomes are needed. This implicit CBR principle can be expressed in the framework of fuzzy rules as: “the more similar (in the sense of  $S$ ) are the attribute values describing two situations, the more possible the similarity (in the sense of  $T$ ) of the values of the corresponding outcome attributes.” Given a situation  $s_0$  associated to an unknown outcome  $t_0$  and a current case  $(s, t)$ , this principle enables us to conclude on the possibility of  $t_0$  being equal to a value similar to  $t$  [3.89]. This acknowledges the fact that, often in practice, a database may contain cases that are rather similar with respect to the problem description attributes, but which may be distinct with respect to outcome attribute(s). This emphasizes that case-based reasoning can only lead to cautious conclusions.

The possibility rule *the more similar  $s$  and  $s_0$ , the more possible  $t$  and  $t_0$  are similar*, is modeled in terms of a guaranteed possibility measure [3.90]. This leads

to enforce the inequality  $\Delta_0(T(t, \cdot)) \geq \mu_S(s, s_0)$ , which expresses that the guaranteed possibility that  $t_0$  belongs to a high degree to the fuzzy set of values that are  $T$ -similar to  $t$ , is lower bounded by the  $S$ -similarity of  $s$  and  $s_0$ . Then the fuzzy set  $F$  of possible values  $t'$  for  $t_0$  with respect to case  $(s, t)$  is given by

$$F_{t_0}(t') = \min(\mu_T(t, t'), \mu_S(s, s_0)),$$

since the maximally specific distribution such that  $\Delta(A) \geq \alpha$  is  $\delta = \min(\mu_A, \alpha)$ . What is obtained is the fuzzy set  $T(t, \cdot)$  of values  $t'$  that are  $T$ -similar to  $t$ , whose possibility level is truncated at the global degree  $\mu_S(s, s_0)$  of similarity of  $s$  and  $s_0$ . The max-based aggregation of the various contributions obtained from the comparison with each case  $(s, t)$  in the memory  $M$  of cases acknowledges the fact that each new comparison may suggest new possible values for  $t_0$  and agrees with the positive nature of the information in the repository of cases. Thus, we obtain the following fuzzy set  $E_{s_0}$  of the possible values  $t'$  for  $t_0$

$$E_{s_0}(t') = \max_{(s,t) \in M} \min(S(s, s_0), T(t, t')).$$

This latter expression can be put in parallel with the evaluation of a flexible query [3.91]. This approach has been generalized to imprecisely or fuzzily described situations, and has been related to other approaches to instance-based prediction [3.92, 93].

### 3.3.8 Preference Representation

Possibility theory also offers a framework for preference modeling in constraint-directed reasoning. Both prioritized and soft constraints can be captured by possibility distributions expressing degrees of feasibility rather than plausibility [3.6]. Possibility theory offers a natural setting for fuzzy optimization whose aim is to balance the levels of satisfaction of multiple fuzzy constraints (instead of minimizing an overall cost) [3.94]. In such problems, some possibility distributions represent soft constraints on decision variables, other ones can represent incomplete knowledge about uncontrollable state variables. Qualitative decision criteria are particularly adapted to the handling of uncertainty in this setting. Possibility distributions can also model ill-known constraint coefficients in linear and nonlinear programming, thus leading to variants of chance-constrained programming [3.95].

Optimal solutions of fuzzy constraint-based problems maximize the satisfaction of the most violated constraint, which does not ensure the Pareto dominance

of all such solutions. More demanding optimality notions have been defined, by canceling equally satisfied constraints (the so-called *discrimin* ordering) or using a leximin criterion [3.94, 96, 97].

Besides, the probabilistic logic setting provides a compact representation framework for preferences, where probabilistic logic formulas represent prioritized constraints on Boolean domains. This approach has been compared to qualitative conditional preference networks (**CP nets**), based on a systematic ceteris paribus assumption (preferential independence between decision variables). **CP nets** induce partial orders of solutions rather than complete preorders, as probabilistic logic does [3.98]. Probabilistic networks can also model preference on the values of variables, conditional to the value of other ones, and offer an alternative to conditional preference networks [3.98].

Bipolar possibility theory has been applied to preference problems where it can be distinguished between imperative constraints (modeled by propositions with a degree of necessity), and nonimperative wishes (modeled by propositions with a degree of guaranteed possibility level) [3.99]. Another kind of bipolar approach to qualitative multifactorial evaluation based on possibility theory, is when comparing objects in terms of their pros and cons where the decision maker focuses on the most important assets or defects. Such qualitative multifactorial bipolar decision criteria have been defined, axiomatized [3.100], and empirically tested [3.101]. They are qualitative counterparts of cumulative prospect theory criteria of *Kahneman* and *Tverski* [3.102].

Two issues in preference modeling based on possibility theory in a logic format are as follows:

- Preference statements of the form  $\Pi(p) > \Pi(q)$  provide an incomplete description of a preference relation. One question is then how to complete this description by default. The principle of minimal specificity then means that a solution not explicitly rejected is satisfactory by default. The dual maximal specificity principle, says that a solution not supported is rejected by default. It is not always clear which principle is the most natural.
- A statement according to which it is better to satisfy a formula  $p$  than a formula  $q$  can in fact be interpreted in several ways. For instance, it may mean that the best solution satisfying  $p$  is better than the best solution satisfying  $q$ , which reads  $\Pi(p) > \Pi(q)$  and can be encoded in probabilistic logic under minimal specificity assumption; a stronger statement is that the worst solution satisfying  $p$  is

better than the best solution satisfying  $q$ , which reads  $\Delta(p) > \Pi(q)$ . Other possibilities are  $\Delta(p) > \Delta(q)$ , and  $\Pi(p) > \Delta(q)$ . This question is studied in some detail by *Kaci* [3.103].

### 3.3.9 Decision-Theoretic Foundations

*Zadeh* [3.1] hinted that *since our intuition concerning the behavior of possibilities is not very reliable*, our understanding of them

*would be enhanced by the development of an axiomatic approach to the definition of subjective possibilities in the spirit of axiomatic approaches to the definition of subjective probabilities.*

Decision-theoretic justifications of qualitative possibility were devised, in the style of Von Neumann and Morgenstern, and *Savage* [3.104] more than 15 years ago [3.105, 106].

On top of the set of states, assume there is a set  $X$  of consequences of decisions. A decision, or act, is modeled as a mapping  $f$  from  $S$  to  $X$  assigning to each state  $s$  its consequence  $f(s)$ . The axiomatic approach consists in proposing properties of a preference relation  $\geq$  between acts so that a representation of this relation by means of a preference functional  $W(f)$  is ensured, that is, act  $f$  is as good as act  $g$  (denoted by  $f \geq g$ ) if and only if  $W(f) \geq W(g)$ .  $W(f)$  depends on the agent's knowledge about the state of affairs, here supposed to be a possibility distribution  $\pi$  on  $S$ , and the agent's goal, modeled by a utility function  $u$  on  $X$ . Both the utility function and the possibility distribution map to the same finite chain  $L$ . A pessimistic criterion  $W_\pi^-(f)$  is of the form

$$W_\pi^-(f) = \min_{s \in S} \max(n(\pi(s)), u(f(s))),$$

where  $n$  is the order-reversing map of  $L$ .  $n(\pi(s))$  is the degree of certainty that the state is not  $s$  (hence the degree of surprise of observing  $s$ ),  $u(f(s))$  the utility of choosing act  $f$  in state  $s$ .  $W_\pi^-(f)$  is all the higher as all states are either very surprising or have high utility. This criterion is actually a prioritized extension of the Wald maximin criterion. The latter is recovered if  $\pi(s) = 1$  (top of  $L$ )  $\forall s \in S$ . According to the pessimistic criterion, acts are chosen according to their worst consequences, restricted to the most plausible states  $S^* = \{s, \pi(s) \geq n(W_\pi^-(f))\}$ . The optimistic counterpart of this criterion is

$$W_\pi^+(f) = \max_{s \in S} \min(\pi(s), u(f(s))).$$

$W_\pi^+(f)$  is all the higher as there is a very plausible state with high utility. The optimistic criterion was first proposed by Yager [3.107] and the pessimistic criterion by Whalen [3.108]. See Dubois et al. [3.109] for the resolution of decision problems under uncertainty using the above criterion, and cast in the possibilistic logic framework. Such criteria can be refined by the classical expected utility criterion [3.110].

These optimistic and pessimistic possibilistic criteria are particular cases of a more general criterion based on the Sugeno integral [3.111] specialized to possibility and necessity of fuzzy events [3.1, 20]

$$S_{\gamma,u}(f) = \max_{\lambda \in L} \min(\lambda, \gamma(F_\lambda)),$$

where  $F_\lambda = \{s \in S, u(f(s)) \geq \lambda\}$ ,  $\gamma$  is a monotonic set function that reflects the decision-maker attitude in front of uncertainty:  $\gamma(A)$  is the degree of confidence in event  $A$ . If  $\gamma = \Pi$ , then  $S_{\Pi,u}(f) = W_\pi^+(f)$ . Similarly, if  $\gamma = N$ , then  $S_{N,u}(f) = W_\pi^-(f)$ .

For any acts  $f, g$ , and any event  $A$ , let  $fAg$  denote an act consisting of choosing  $f$  if  $A$  occurs and  $g$  if its complement occurs. Let  $f \wedge g$  (resp.  $f \vee g$ ) be the act whose results yield the worst (resp. best) consequence of the two acts in each state. Constant acts are those whose consequence is fixed regardless of the state. A result in [3.112, 113] provides an act-driven axiomatization of these criteria, and enforces possibility theory as a *rational* representation of uncertainty for a finite state space  $S$ :

### Theorem 3.1

Suppose the preference relation  $\succeq$  on acts obeys the following properties:

1.  $(X^S, \succeq)$  is a complete preorder.
2. There are two acts such that  $f \succ g$ .

3.  $\forall A, \forall g$  and  $h$  constant,  $\forall f, g \succeq h$  implies  $gAf \succeq hAf$ .
4. If  $f$  is constant,  $f \succ h$  and  $g \succ h$  imply  $f \wedge g \succ h$ .
5. If  $f$  is constant,  $h \succ f$  and  $h \succ g$  imply  $h \succ f \vee g$ .

Then there exists a finite chain  $L$ , an  $L$ -valued monotonic set function  $\gamma$  on  $S$  and an  $L$ -valued utility function  $u$ , such that  $\succeq$  is representable by a Sugeno integral of  $u(f)$  with respect to  $\gamma$ . Moreover,  $\gamma$  is a necessity (resp. possibility) measure as soon as property (4) (resp. (5)) holds for all acts. The preference functional is then  $W_\pi^-(f)$  (resp.  $W_\pi^+(f)$ ).

Axioms (4 and 5) contradict expected utility theory. They become reasonable if the value scale is finite, decisions are one-shot (no compensation) and provided that there is a big step between any level in the qualitative value scale and the adjacent ones. In other words, the preference pattern  $f \succ h$  always means that  $f$  is significantly preferred to  $h$ , to the point of considering the value of  $h$  negligible in front of the value of  $f$ . The above result provides decision-theoretic foundations of possibility theory, whose axioms can thus be tested from observing the choice behavior of agents. See [3.114] for another approach to comparative possibility relations, more closely relying on Savage axioms, but giving up any comparability between utility and plausibility levels. The drawback of these and other qualitative decision criteria is their lack of discrimination power [3.115]. To overcome it, refinements of possibilistic criteria were recently proposed, based on lexicographic schemes. These refined criteria turn out to be by a classical (but big-stepped) expected utility criterion [3.110], and Sugeno integral can be refined by a Choquet integral [3.116]. For extension of this qualitative decision-making framework to multiple-stage decision, see [3.117].

## 3.4 Quantitative Possibility Theory

The phrase *quantitative possibility* refers to the case when possibility degrees range in the unit interval, and are considered in connection with belief function and imprecise probability theory. Quantitative possibility theory is the natural setting for a reconciliation between probability and fuzzy sets. In that case, a precise articulation between possibility and probability theories is useful to provide an interpretation to possibility and necessity degrees. Several such interpretations can

be consistently devised: a degree of possibility can be viewed as an upper probability bound [3.118], and a possibility distribution can be viewed as a likelihood function [3.119]. A possibility measure is also a special case of a Shafer plausibility function [3.120]. Following a very different approach, possibility theory can account for probability distributions with extreme values, infinitesimal [3.72] or having big steps [3.121]. There are finally close connections between possibility theory

and idempotent analysis [3.122]. The theory of large deviations in probability theory [3.123] also handles set functions that look like possibility measures [3.124]. Here we focus on the role of possibility theory in the theory of imprecise probability.

### 3.4.1 Possibility as Upper Probability

Let  $\pi$  be a possibility distribution where  $\pi(s) \in [0, 1]$ . Let  $\mathbf{P}(\pi)$  be the set of probability measures  $P$  such that  $P \leq \Pi$ , i.e.,  $\forall A \subseteq S, P(A) \leq \Pi(A)$ . Then the possibility measure  $\Pi$  coincides with the upper probability function  $P^*$  such that  $P^*(A) = \sup\{P(A), P \in \mathbf{P}(\pi)\}$  while the necessity measure  $N$  is the lower probability function  $P_*$  such that  $P_*(A) = \inf\{P(A), P \in \mathbf{P}(\pi)\}$ ; see [3.118, 125] for details.  $P$  and  $\pi$  are said to be consistent if  $P \in \mathbf{P}(\pi)$ . The connection between possibility measures and imprecise probabilistic reasoning is especially promising for the efficient representation of nonparametric families of probability functions, and it makes sense even in the scope of modeling linguistic information [3.126].

A possibility measure can be computed from nested confidence subsets  $\{A_1, A_2, \dots, A_m\}$  where  $A_i \subset A_{i+1}, i = 1, \dots, m-1$ . Each confidence subset  $A_i$  is attached a positive confidence level  $\lambda_i$  interpreted as a lower bound of  $P(A_i)$ , hence a necessity degree. It is viewed as a certainty qualified statement that generates a possibility distribution  $\pi_i$  according to Sect. 3.2. The corresponding possibility distribution is

$$\begin{aligned}\pi(s) &= \min_{i=1, \dots, m} \pi_i(s) \\ &= \begin{cases} 1 & \text{if } s \in A_1 \\ 1 - \lambda_{j-1} & \text{if } j = \max\{i : s \notin A_i\} > 1 \end{cases}.\end{aligned}$$

The information modeled by  $\pi$  can also be viewed as a nested random set  $\{(A_i, v_i), i = 1, \dots, m\}$ , where  $v_i = \lambda_i - \lambda_{i-1}$ . This framework allows for imprecision (reflected by the size of the  $A_i$ 's) and uncertainty (the  $v_i$ 's). And  $v_i$  is the probability that the agent only knows that  $A_i$  contains the actual state (it is not  $P(A_i)$ ). The random set view of possibility theory is well adapted to the idea of imprecise statistical data, as developed in [3.127, 128]. Namely, given a bunch of imprecise (not necessarily nested) observations (called focal sets),  $\pi$  supplies an approximate representation of the data, as  $\pi(s) = \sum_{i: s \in A_i} v_i$ .

In the continuous case, a fuzzy interval  $M$  can be viewed as a nested set of  $\alpha$ -cuts, which are intervals  $M_\alpha = \{x : \mu_M(x) \geq \alpha, \forall \alpha > 0\}$ . In the continuous case,

note that the degree of necessity is  $N(M_\alpha) = 1 - \alpha$ , and the corresponding probability set  $\mathbf{P}(\mu_M) = \{P : P(M_\alpha) \geq 1 - \alpha, \forall \alpha > 0\}$ . Representing uncertainty by the family of pairs  $\{(M_\alpha, 1 - \alpha) : \forall \alpha > 0\}$  is very similar to the basic approach of info-gap theory [3.129].

The set  $\mathbf{P}(\pi)$  contains many probability distributions, arguably too many. Neumaier [3.130] has recently proposed a related framework, in a different terminology, for representing smaller subsets of probability measures using two possibility distributions instead of one. He basically uses a pair of distributions  $(\delta, \pi)$  (in the sense of Sect. 3.2) of distributions, he calls *cloud*, where  $\delta$  is a guaranteed possibility distribution (in our terminology) such that  $\pi \geq \delta$ . A cloud models the (generally nonempty) set  $\mathbf{P}(\pi) \cap \mathbf{P}(1 - \delta)$ , viewing  $1 - \delta$  as a standard possibility distribution. The precise connections between possibility distributions, clouds and other simple representations of numerical uncertainty is studied in [3.131].

### 3.4.2 Conditioning

There are two kinds of conditioning that can be envisaged upon the arrival of new information  $E$ . The first method presupposes that the new information alters the possibility distribution  $\pi$  by declaring all states outside  $E$  impossible. The conditional measure  $\pi(\cdot | E)$  is such that  $\Pi(B | E) \cdot \Pi(E) = \Pi(B \cap E)$ . This is formally Dempster rule of conditioning of belief functions, specialized to possibility measures. The conditional possibility distribution representing the weighted set of confidence intervals is

$$\pi(s | E) = \begin{cases} \frac{\pi(s)}{\Pi(E)} & \text{if } s \in E \\ 0 & \text{otherwise.} \end{cases}$$

De Baets et al. [3.28] provide a mathematical justification of this notion in an infinite setting, as opposed to the min-based conditioning of qualitative possibility theory. Indeed, the maxitivity axiom extended to the infinite setting is not preserved by the min-based conditioning. The product-based conditioning leads to a notion of independence of the form  $\Pi(B \cap E) = \Pi(B) \cdot \Pi(E)$  whose properties are very similar to the ones of probabilistic independence [3.30].

Another form of conditioning [3.132, 133], more in line with the Bayesian tradition, considers that the possibility distribution  $\pi$  encodes imprecise statistical information, and event  $E$  only reflects a feature of the current situation, not of the state in general. Then

the value  $\Pi(B \parallel E) = \sup\{P(B | E), P(E) > 0, P \leq \Pi\}$  is the result of performing a sensitivity analysis of the usual conditional probability over  $\mathbf{P}(\pi)$  [3.134]. Interestingly, the resulting set function is again a possibility measure, with distribution

$$\pi(s \parallel E) = \begin{cases} \max\left(\pi(s), \frac{\pi(s)}{\pi(s) + N(E)}\right), & \text{if } s \in E \\ 0 & \text{otherwise.} \end{cases}$$

It is generally less specific than  $\pi$  on  $E$ , as clear from the above expression, and becomes noninformative when  $N(E) = 0$  (i.e., if there is no information about  $E$ ). This is because  $\pi(\cdot \parallel E)$  is obtained from the focusing of the generic information  $\pi$  over the reference class  $E$ . On the contrary,  $\pi(\cdot | E)$  operates a revision process on  $\pi$  due to additional knowledge asserting that states outside  $E$  are impossible. See *De Cooman* [3.133] for a detailed study of this form of conditioning.

### 3.4.3 Probability–Possibility Transformations

The problem of transforming a possibility distribution into a probability distribution and conversely is meaningful in the scope of uncertainty combination with heterogeneous sources (some supplying statistical data, other linguistic data, for instance). It is useful to cast all pieces of information in the same framework. The basic requirement is to respect the consistency principle  $\Pi \geq P$ . The problem is then either to pick a probability measure in  $\mathbf{P}(\pi)$ , or to construct a possibility measure dominating  $P$ .

There are two basic approaches to possibility/probability transformations, which both respect a form of probability–possibility consistency. One, due to *Klir* [3.135, 136] is based on a principle of information invariance, the other [3.137] is based on optimizing information content. Klir assumes that possibilistic and probabilistic information measures are commensurate. Namely, the choice between possibility and probability is then a mere matter of translation between languages *neither of which is weaker or stronger than the other* (quoting *Klir* and *Parviz* [3.138]). It suggests that entropy and imprecision capture the same facet of uncertainty, albeit in different guises. The other approach, recalled here, considers that going from possibility to probability leads to increase the precision of the considered representation (as we go from

a family of nested sets to a random element), while going the other way around means a loss of specificity.

#### From Possibility to Probability

The most basic example of transformation from possibility to probability is the Laplace principle of insufficient reason claiming that what is equally possible should be considered as equally probable. A generalized Laplacean indifference principle is then adopted in the general case of a possibility distribution  $\pi$ : the weights  $v_i$  bearing on the sets  $A_i$  from the nested family of levels cuts of  $\pi$  are uniformly distributed on the elements of these cuts  $A_i$ . Let  $P_i$  be the uniform probability measure on  $A_i$ . The resulting probability measure is  $P = \sum_{i=1, \dots, m} v_i \cdot P_i$ . This transformation, already proposed in 1982 [3.139] comes down to selecting the center of gravity of the set  $\mathbf{P}(\pi)$  of probability distributions dominated by  $\pi$ . This transformation also coincides with Smets' pignistic transformation [3.140] and with the Shapley value of the *unanimity game* (another name of the necessity measure) in game theory. The rationale behind this transformation is to minimize arbitrariness by preserving the symmetry properties of the representation. This transformation from possibility to probability is one-to-one. Note that the definition of this transformation does not use the nestedness property of cuts of the possibility distribution. It applies all the same to nonnested random sets (or belief functions) defined by pairs  $\{(A_i, v_i), i = 1, \dots, m\}$ , where  $v_i$  are nonnegative reals such that  $\sum_{i=1, \dots, m} v_i = 1$ .

#### From Objective Probability to Possibility

From probability to possibility, the rationale of the transformation is not the same according to whether the probability distribution we start with is subjective or objective [3.106]. In the case of a statistically induced probability distribution, the rationale is to preserve as much information as possible. This is in line with the handling of  $\Delta$ -qualified pieces of information representing observed evidence, considered in Sect. 3.2; hence we select as the result of the transformation of a probability measure  $P$ , the most specific possibility measure in the set of those dominating  $P$  [3.137]. This most specific element is generally unique if  $P$  induces a linear ordering on  $S$ . Suppose  $S$  is a finite set. The idea is to let  $\Pi(A) = P(A)$ , for these sets  $A$  having minimal probability among other sets having the same cardinality as  $A$ . If  $p_1 > p_2 > \dots > p_n$ , then  $\Pi(A) = P(A)$  for sets  $A$  of the form  $\{s_i, \dots, s_n\}$ , and the possibility distribution is defined

as  $\pi_P(s_i) = \sum_{j=i,\dots,m} p_j$ , with  $p_j = P(\{s_j\})$ . Note that  $\pi_P$  is a kind of cumulative distribution of  $P$ , already known as a Lorentz curve in the mathematical literature [3.141]. If there are equiprobable elements, the unicity of the transformation is preserved if equipossibility of the corresponding elements is enforced. In this case it is a bijective transformation as well. Recently, this transformation was used to prove a rather surprising agreement between probabilistic indeterminateness as measured by Shannon entropy, and possibilistic non-specificity. Namely it is possible to compare probability measures on finite sets in terms of their relative *peakedness* (a concept adapted from Birnbaum [3.142]) by comparing the relative specificity of their possibilistic transforms. Namely let  $P$  and  $Q$  be two probability measures on  $S$  and  $\pi_P, \pi_Q$  the possibility distributions induced by our transformation. It can be proved that if  $\pi_P \geq \pi_Q$  (i.e.,  $P$  is less peaked than  $Q$ ) then the Shannon entropy of  $P$  is higher than the one of  $Q$  [3.143]. This result give some grounds to the intuitions developed by Klir [3.135], without assuming any commensurability between entropy and specificity indices.

### Possibility Distributions Induced by Prediction Intervals

In the continuous case, moving from objective probability to possibility means adopting a representation of uncertainty in terms of prediction intervals around the mode viewed as the *most frequent value*. Extracting a prediction interval from a probability distribution or devising a probabilistic inequality can be viewed as moving from a probabilistic to a possibilistic representation. Namely suppose a nonatomic probability measure  $P$  on the real line, with unimodal density  $\phi$ , and suppose one wishes to represent it by an interval  $I$  with a prescribed level of confidence  $P(I) = \gamma$  of hitting it. The most natural choice is the most precise interval ensuring this level of confidence. It can be proved that this interval is of the form of a cut of the density, i.e.,  $I_\gamma = \{s, \phi(s) \geq \theta\}$  for some threshold  $\theta$ . Moving the degree of confidence from 0 to 1 yields a nested family of prediction intervals that form a possibility distribution  $\pi$  consistent with  $P$ , the most specific one actually, having the same support and the same mode as  $P$  and defined by [3.137]

$$\pi(\inf I_\gamma) = \pi(\sup I_\gamma) = 1 - \gamma = 1 - P(I_\gamma).$$

This kind of transformation again yields a kind of cumulative distribution according to the ordering in-

duced by the density  $\phi$ . Similar constructs can be found in the statistical literature (Birnbaum [3.142]). More recently Mauris et al. [3.144] noticed that starting from any family of nested sets around some characteristic point (the mean, the median,...), the above equation yields a possibility measure dominating  $P$ . Well-known inequalities of probability theory, such as those of Chebyshev and Camp-Meidel, can also be viewed as possibilistic approximations of probability functions. It turns out that for symmetric unimodal densities, each side of the optimal possibilistic transform is a convex function. Given such a probability density on a bounded interval  $[a, b]$ , the triangular fuzzy number whose core is the mode of  $\phi$  and the support is  $[a, b]$  is thus a possibility distribution dominating  $P$  regardless of its shape (and the tightest such distribution). These results justify the use of symmetric triangular fuzzy numbers as fuzzy counterparts to uniform probability distributions. They provide much tighter probability bounds than Chebyshev and Camp-Meidel inequalities for symmetric densities with bounded support. This setting is adapted to the modeling of sensor measurements [3.145]. These results are extended to more general distributions by Baudrit et al. [3.146], and provide a tool for representing poor probabilistic information. More recently, Mauris [3.147] unifies, by means of possibility theory, many old techniques independently developed in statistics for one-point estimation, relying on the idea of dispersion of an empirical distribution. The efficiency of different estimators can be compared by means of fuzzy set inclusion applied to optimal possibility transforms of probability distributions. This unified approach does not presuppose a finite variance.

### Subjective Possibility Distributions

The case of a subjective probability distribution is different. Indeed, the probability function is then supplied by an agent who is in some sense forced to express beliefs in this form due to rationality constraints, and the setting of exchangeable bets. However his actual knowledge may be far from justifying the use of a single well-defined probability distribution. For instance in case of total ignorance about some value, apart from its belonging to an interval, the framework of exchangeable bets enforces a uniform probability distribution, on behalf of the principle of insufficient reason. Based on the setting of exchangeable bets, it is possible to define a subjectivist view of numerical possibility theory, that differs from the proposal of Walley [3.134]. The approach developed by Dubois et al. [3.148] re-

lies on the assumption that when an agent constructs a probability measure by assigning prices to lotteries, this probability measure is actually induced by a belief function representing the agent's actual state of knowledge. We assume that going from an underlying belief function to an elicited probability measure is achieved by means of the above mentioned pignistic transformation, changing focal sets into uniform probability distributions. The task is to reconstruct this underlying belief function under a minimal commitment assumption. In the paper [3.148], we pose and solve the problem of finding the least informative belief function having a given pignistic probability. We prove that it is unique and consonant, thus induced by a possibility distribution. The obtained possibility distribution can be defined as the converse of the pignistic transformation (which is one-to-one for possibility distributions). It is subjective in the same sense as in the subjectivist school in probability theory. However, it is the least biased representation of the agent's state of knowledge compatible with the observed betting behavior. In particular, it is less specific than the one constructed from the prediction intervals of an objective probability. This transformation was first proposed in [3.149] for objective probability, interpreting the empirical necessity of an event as summing the excess of probabilities of realizations of this event with respect to the probability of the most likely realization of the opposite event.

### Possibility Theory and Defuzzification

Possibilistic mean values can be defined using Choquet integrals with respect to possibility and necessity measures [3.133, 150], and come close to defuzzification methods [3.151]. Interpreting a fuzzy interval  $M$ , associated with a possibility distribution  $\mu_M$ , as a family of

probabilities, upper and lower mean values  $E^*(M)$  and  $E_*(M)$ , can be defined as [3.152]

$$E_*(M) = \int_0^1 \inf M_\alpha \, d\alpha; \quad E^*(M) = \int_0^1 \sup M_\alpha \, d\alpha,$$

where  $M_\alpha$  is the  $\alpha$ -cut of  $M$ .

Then the mean interval  $E(M) = [E_*(M), E^*(M)]$  of  $M$  is the interval containing the mean values of all random variables consistent with  $M$ , that is  $E(M) = \{E(P) \mid P \in \mathbf{P}(\mu_M)\}$ , where  $E(P)$  represents the expected value associated with the probability measure  $P$ . That the *mean value* of a fuzzy interval is an interval seems to be intuitively satisfactory. Particularly the mean interval of a (regular) interval  $[a, b]$  is this interval itself. The upper and lower mean values are linear with respect to the addition of fuzzy numbers. Define the addition  $M + N$  as the fuzzy interval whose cuts are  $M_\alpha + N_\alpha = \{s + t \mid s \in M_\alpha, t \in N_\alpha\}$  defined according to the rules of interval analysis. Then  $E(M + N) = E(M) + E(N)$ , and similarly for the scalar multiplication  $E(aM) = aE(M)$ , where  $aM$  has membership grades of the form  $\mu_M(s/a)$  for  $a \neq 0$ . In view of this property, it seems that the most natural defuzzification method is the middle point  $\hat{E}(M)$  of the mean interval (originally proposed by Yager [3.153]). Other defuzzification techniques do not generally possess this kind of linearity property.  $\hat{E}(M)$  has a natural interpretation in terms of simulation of a fuzzy variable [3.154], and is the mean value of the pignistic transformation of  $M$ . Indeed it is the mean value of the empirical probability distribution obtained by the random process defined by picking an element  $\alpha$  in the unit interval at random, and then an element  $s$  in the cut  $M_\alpha$  at random.

## 3.5 Some Applications

Possibility theory has not been the main framework for engineering applications of fuzzy sets in the past. However, on the basis of its connections to symbolic artificial intelligence, to decision theory and to imprecise statistics, we consider that it has significant potential for further applied developments in a number of areas, including some where fuzzy sets are not yet always accepted. Only some directions are pointed out here.

### 3.5.1 Uncertain Database Querying and Preference Queries

The evaluation of a flexible query in the face of incomplete or fuzzy information amounts to computing the possibility and the necessity of the fuzzy event expressing the gradual satisfaction of the query [3.155]. This evaluation, known as fuzzy pattern matching [3.156, 157], corresponds to the extent to which fuzzy sets

(representing the query) overlap, or include the possibility distributions (representing the available information). Such an evaluation procedure has been extended to symbolic labels that are no longer represented by possibility distributions, but which belong to possibilistic ontologies where approximate similarity and subsumption between labels are estimated in terms of possibility and necessity degrees, respectively [3.158]. These approaches presuppose a total lack of dependencies between ill-known attributes. A more general approach based on possible world semantics has been envisaged [3.159]. However, as for the probabilistic counterpart of this latter view, evaluating queries has a high computational cost [3.160]. This is why it has been proposed to only use certainty qualified values (or disjunctions of values), as in possibilistic logic, rather than general possibility distributions, for representing attribute values pervaded with uncertainty. It has been shown that it leads to a tractable extension of relational algebra operations [3.161, 3.162].

Besides, possibility theory is not only useful for representing qualitative uncertainty, but it may also be of interest for representing preferences, and as such may be applied to the handling of preferences queries [3.163]. Thus, requirements of the form *A and preferably B* (i.e., it is more satisfactory to have *A* and *B* than *A* alone), or *A or at least B* can be expressed using appropriate priority orderings, as in possibilistic logic [3.164]. Lastly, in bipolar queries [3.165–3.167], flexible constraints that are more or less compulsory are distinguished from additional wishes that are optional, as for instance in the request find the apartments that are cheap and maybe near the train station. Indeed, negative preferences express what is (more or less, or completely) impossible or undesirable, and by complementation state flexible constraints restricting the possible or acceptable values. Positive preferences are not compulsory, but rather express wishes; they state what attribute values would be really satisfactory.

### 3.5.2 Description Logics

Description logics (initially named terminological logics) are tractable fragments of first-order logic representation languages that handle notions of concepts, roles and instances, referring at the semantic level to the respective notions of set, binary relations, membership, and cardinality. They are useful for describing ontologies that consist in hierarchies of concepts in a particular domain, for the semantic web. Two ideas that, respectively, come from fuzzy sets and possibil-

ity theory, and that may be combined, may be used for extending the expressive power of description logics. On one hand, vague concepts can be approximated in practice by pairs of nested sets corresponding to the cores and the supports of fuzzy sets, thus sorting out the typical elements, in a way that agrees with fuzzy set operations and inclusions. On the other hand, a possibilistic treatment of uncertainty and exceptions can be performed on top of a description logic in a possibilistic logic style [3.168]. In both cases, the underlying principle is to remain as close as possible to classical logic for preserving computational efficiency as much as possible. Thus, formal expressions such as  $(P \supseteq_{\alpha}^X Q, \beta)$  intend to mean that *it is certain at least at level  $\beta$  that the degree of subsumption of concept  $P$  in  $Q$  is at least  $\alpha$* , in the sense of some  $X$ -implication (e.g., Gödel, or Kleene–Dienes implication). In particular, it can be expressed that *typical Ps are Qs*, or that *typical Ps are typical Qs*, or that an instance is typical of a concept. Such ideas have been developed by Qi et al. [3.169] toward implemented systems in connection with web research.

### 3.5.3 Information Fusion

Possibility theory offers a simple, flexible framework for information fusion that can handle incompleteness and conflict. For instance, intervals or fuzzy intervals can be merged, coming from several sources. The basic fusion modes are the conjunctive and disjunctive modes, presupposing, respectively, that all sources of information are reliable and that at least one is [3.170, 3.171]. In the conjunctive mode, the use of the minimum operation avoids assuming sources are independent. If they are, the product rule can be applied, whereby low plausibility degrees reinforce toward impossibility. Quite often, the results of a conjunctive aggregation are subnormalized, this indicating a conflict. Then, it is common to apply a renormalization step that makes this mode of combination brittle in case of strong conflict, and anyway the more numerous the sources the more conflicting they become. Weighted average of possibility degrees can be used but it does not preserve the properties of possibility measure. The use of the disjunctive mode is more cautious: it avoids the conflict at the expense of losing information. When many sources are involved the result becomes totally uninformative.

To cope with this problem, some ad hoc adaptive combination rules have been proposed that focus on maximal subsets of sources that are either

fully consistent or not completely inconsistent [3.170]. This scheme has been further improved by Oussalah et al. [3.172]. Oussalah [3.173] has proposed a number of postulates a possibilistic fusion rule should satisfy. Another approach is to merge the set of cuts of the possibility distributions based on the maximal consistent subsets of sources (consistent subsets of cuts are merged using conjunction, and the results are merged disjunctively). The result is then a belief function [3.174]. Another option is to make a guess on the number of reliable sources and merge information inside consistent subsets of sources having this cardinality.

Possibilistic information fusion can be performed syntactically on more compact representations such as possibilistic logic bases [3.175] (the merging of possibilistic networks [3.176] has also been recently considered). The latter type of fusion may be of interest both from a computational and from representational point of view. Still it is important to make sure that the syntactic operations are counterparts of semantic ones. Fusion should be performed both at the semantic and at the syntactic levels equivalently. For instance, the conjunctive merging of two possibility distributions corresponds to the mere union of the possibilistic bases that represent them. More details for other operations can be found in [3.175, 177], and in the bipolar case in [3.99]. This line of research is pursued by Qi et al. [3.178]. They also proposed an approach to measuring conflict between possibilistic knowledge bases [3.179].

The distance-based approach [3.180] that applies to the fusion of classical logic bases can be embedded in the possibilistic fusion setting as well [3.177]. The distance between an interpretation  $s$  and each classical base  $K$  is usually defined as  $d(s, K) = \min\{H(s, s^*) : s^* \models K\}$  where  $H(s, s^*)$  is the Hamming distance that evaluates the number of literals with different signs in  $s$  and  $s^*$ ). It is then easy to encode the distance  $d(s, K)$  into a possibilistic knowledge base (interpreting possibility as Hamming-distance-based similarity to the models of  $K$ , i.e.,  $\pi(s) = a^{d(s,K)}, a \in (0, 1)$ ). The result of the possibilistic fusion is a possibilistic knowledge base, the highest weight layer of which is the classical database that is searched for, provided that the distance merging operation is suitably translated to a possibilistic merging operation.

A similar problem exists in belief revision where an epistemic state, represented either by a possibility distribution or by a possibilistic logic base, is revised by an input information  $p$  [3.181]. Revision can be viewed as prioritized fusion, using for instance conditioning,

or other operations, depending if in the revised epistemic state one wants to enforce  $N(p) = 1$ , or  $N(p) > 0$  only, or if we are dealing with an uncertain input  $(p, \alpha)$ . Then, the uncertain input may be understood as enforcing  $N(p) \geq \alpha$  in any case, or as taking it into account only if it is sufficiently certain w.r.t. the current epistemic state.

### 3.5.4 Temporal Reasoning and Scheduling

Temporal reasoning may refer to time intervals or to time points. When handling time intervals, the basic building block is the one provided by Allen relations between time intervals. There are 13 relations that describe the possible relative locations of two intervals. For instance, given the two intervals  $A = [a, a']$  and  $B = [b, b']$ ,  $A$  is before (resp. after)  $B$  means  $a' < b$  (resp.  $b' < a$ ),  $A$  meets (resp. is met by)  $B$  means  $a' = b$  (resp.  $b' = a$ ),  $A$  overlaps (resp. is overlapped by)  $B$  iff  $b > a$  and  $a' > b$  and  $b' > a'$  (resp.  $a > b$  and  $b' > a$ , and  $a' > b'$ ). The introduction of fuzzy features in temporal reasoning can be related to two different issues:

- First, it can be motivated by the need of a gradual, linguistic-like description of temporal relations even in the face of complete information. Then an extension of Allen relational calculus has been proposed, which is based on fuzzy comparators expressing linguistic tolerance, which are used in place of the exact relations  $>$ ,  $='$ , and  $<$ . Fuzzy Allen relations are thus defined from three fuzzy relations between dates that can be, for instance *approximately equal*, *clearly greater*, and *clearly smaller*, where, e.g., the extent to which  $x$  is *approximately equal to*  $y$  is the degree of membership of  $x - y$  to some fuzzy set expressing something like *small* [3.182, 183].
- Second, the possibilistic handling of fuzzy or incomplete information leads to pervade classical Allen relations, and more generally fuzzy Allen relations, with uncertainty. Then patterns for propagating uncertainty and composing the different (fuzzy) Allen relations in a possibilistic way have been laid bare [3.184, 185].

Besides, the handling of temporal reasoning in terms of relations between time points can also be extended in case of uncertain information [3.186]. Uncertain relations between temporal points are represented by means of possibility distributions over the three basic relations  $>$ ,  $='$ , and  $<$ . Operations for computing in-

verse relations, for composing relations, for combining relations coming from different sources and pertaining to the same temporal points, or for handling negation, have been defined. This shows that possibilistic temporal uncertainty can be handled in the setting of point algebra. The possibilistic approach can then be favorably compared with a probabilistic approach previously proposed (first, the approach can be purely qualitative, thus avoiding the necessity of quantifying uncertainty if information is poor, and second, it is capable of modeling ignorance in a nonbiased way). Possibilistic logic has also been extended to a timed version where time intervals where a proposition is more or less certainly true is attached to classical propositional formulas [3.187].

Applications of possibility theory-based decision-making can be found in scheduling. One issue is to handle fuzzy due dates of jobs using the calculus of fuzzy constraints [3.188]. Another issue is to handle uncertainty in task durations in basic scheduling problems such as program evaluation and review technique (PERT) networks. A large literature exists on this topic [3.189, 190] where the role of fuzzy sets is not always very clear. Convincing solutions on this problem start with the works of Chanas and Zielinski [3.191, 192], where the problem is posed in terms of projecting a joint possibility theory on quantities of interest (earliest finishing times, or slack times) and where tasks can be possibly or certainly critical. A full solution applying Boolean possibility theory to interval uncertainty of tasks durations is described in [3.193], and its fuzzy extension in [3.194]. Other scheduling problems are solved in the same possibilistic framework by Kasperski and colleagues [3.195, 196], as well as more general optimization problems [3.197, 198].

### 3.5.5 Risk Analysis

The aim of risk analysis studies is to perform uncertainty propagation under poor data and without independence assumptions (see the papers in the special issue [3.199]). Finding the potential of possibilistic representations in computing conservative bounds for such probabilistic calculations is certainly a major challenge [3.200]. An important research direction is the comparison between fuzzy interval analysis [3.33] and random variable calculations with

a view to unifying them [3.201]. Methods for joint propagation of possibilistic and probabilistic information have been devised [3.202], based on casting both in a random set setting [3.203]; the case of probabilistic models with fuzzy interval parameters has also been dealt with [3.204]. The active area of fuzzy random variables is also connected to this question [3.205].

### 3.5.6 Machine Learning

Applications of possibility theory to learning have started to be investigated rather recently in different directions. For instance, taking advantage of the proximity between reinforcement learning and partially observed Markov decision processes, a possibilistic counterpart of reinforcement learning has been proposed after developing the possibilistic version of the latter [3.206]. Besides, by looking for big-stepped probability distributions, defined by discrete exponential distributions, one can mine data bases for discovering default rules [3.207]. Big-stepped probabilities mimic possibility measures in the sense that  $P(A) > P(B)$  if and only if  $\max_{s \in A} p(s) > \max_{s \in B} p(s)$ . The version space approach to learning presents interesting similarities with the binary bipolar possibilistic representation setting, thinking of examples as positive information and of counterexamples as negative information [3.208]. The general bipolar setting, where intermediary degrees of possibility are allowed, provides a basis for extending version space approach in a graded way, where examples and counter examples can be weighted according to their importance. The graded version space approach agrees with the possibilistic extension of inductive logic programming [3.209]. Indeed, where the background knowledge may be associated with certainty levels, the examples may be more or less important to cover, and the set of rules that is learnt may be stratified in order to have a better management of exceptions in multiple-class classification problems, in agreement with the possibilistic approach to nonmonotonic reasoning.

Other applications of possibility theory can be found in fields such as data analysis [3.79, 210, 211], diagnosis [3.212, 213], belief revision [3.181], argumentation [3.68, 214, 215], etc.

## 3.6 Some Current Research Lines

A number of ongoing works deal with new research lines where possibility theory is central. In the following, we outline a few of those:

- *Formal concept analysis:* Formal concept analysis ([FCA](#)) studies Boolean data tables relating objects and attributes. The key issue of [FCA](#) is to extract so-called concepts from such tables. A concept is a maximal set of objects sharing a maximal number of attributes. The enumeration of such concepts can be carried out via a Galois connection between objects and attributes, and this Galois connection uses operators similar to the  $\Delta$  function of possibility theory. Based on this analogy, other correspondences can be laid bare using the three other set functions of possibility theory [[3.216](#), [217](#)]. In particular, one of these correspondences detects independent subtables [[3.22](#)]. This approach can be systematized to fuzzy or uncertain versions of formal concept analysis.
- *Generalized possibilistic logic:* Possibilistic logic, in its basic version, attaches degrees of necessity to formulas, which turn them into graded modal formulas of the necessity kind. However only conjunction of weighted formulas are allowed. Yet very early we noticed that it makes sense to extend the language toward handing constraints on the degree of possibility of a formula. This requires allowing for negation and disjunctions of necessity-qualified proposition. This extension, still under study [[3.218](#)], puts together the KD modal logic and basic possibilistic logic. Recently it has been shown that nonmonotonic logic programming languages can be translated into generalized possibilistic logic, making the meaning of negation by default in rules much more transparent [[3.219](#)]. This move from basic to generalized possibilistic logic also enables further extensions to the multiagent and the multisource case [[3.220](#)] to be considered. Besides, it has been recently shown that a Sugeno integral can also be represented in terms of possibilistic logic, which enables us to lay bare the logical description of an aggregation process [[3.221](#)].
- *Qualitative capacities and possibility measures:* While a numerical possibility measure is equivalent to a convex set of probability measures, it turns out that in the qualitative setting, a monotone set function can be represented by means of a family of possibility measures [[3.222](#), [223](#)]. This line of research enables qualitative counterparts of results in the study of Choquet capacities in the numerical settings to be established. Especially, a monotone set function can be seen as the counterpart of a belief function, and various concepts of evidence theory can be adapted to this setting [[3.224](#)]. Sugeno integral can be viewed as a lower possibilistic expectation in the sense of Sect. [3.3.9](#) [[3.223](#)]. These results enable the structure of qualitative monotonic set functions to be laid bare, with possible connection with neighborhood semantics of nonregular modal logics [[3.225](#)].
- *Regression and kriging:* Fuzzy regression analysis is seldom envisaged from the point of view of possibility theory. One exception is the possibilistic regression initiated by *Tanaka and Guo* [[3.211](#)], where the idea is to approximate precise or set-valued data in the sense of inclusion by means of a set-valued or fuzzy set-valued linear function obtained by making the linear coefficients of a linear function fuzzy. The alternative approach is the fuzzy least squares of *Diamond* [[3.226](#)] where fuzzy data are interpreted as functions and a crisp distance between fuzzy sets is often used. However, in this approach, fuzzy data are questionably seen as objective entities [[3.227](#)]. The introduction of possibility theory in regression analysis of fuzzy data comes down to an epistemic view of fuzzy data whereby one tries to construct the envelope of all linear regression results that could have been obtained, had the data been precise [[3.228](#)]. This view has been applied to the kriging problem in geostatistics [[3.229](#)]. Another use of possibility theory consists in exploiting possibility–probability transforms to develop a form of quantile regression on crisp data [[3.230](#)], yielding a fuzzy function that is much more faithful to the data set than what a fuzzified linear function can offer.

# Aggregation

Radko Mesiar, Anna Kolesárová, Magda Komorníková

After a brief presentation of the history of aggregation, we recall the concept of aggregation functions on  $[0, 1]$  and on a general interval  $I \subseteq [-\infty, \infty]$ . We give a list of basic examples as well as some peculiar examples of aggregation functions. After discussing the classification of aggregation functions on  $[0, 1]$  and presenting the prototypical examples for each introduced class, we also recall several construction methods for aggregation functions, including optimization methods, extension methods, constructions based on given

aggregation functions, and introduction of weights. Finally, a remark on aggregation of more general inputs, such as intervals, distribution functions, or fuzzy sets, is added.

Part A | 4.1

Aggregation (fusion, joining) of several input values into one, in some sense the most informative value, is a basic processing method in any field dealing with quantitative information. We only recall mathematics, physics, economy, sociology or finance, among others.

Basic arithmetical operations of addition and multiplication on  $[0, \infty]$  are typical examples of aggregation functions. As another example let us recall integration and its application to geometry allowing us to compute areas, surfaces, volumes, etc.

## 4.1 Historical and Introductory Remarks

Just in the field of integration one can find the first historical traces of aggregation known in the written form. Recall the Moscow *mathematical* papyrus and its problem no. 14, dating back to 1850 BC, concerning the computation of the volume of a pyramidal frustum [4.1], or the exhaustive method allowing to compute several types of areas proposed by Eudoxus of Cnidos around 370 BC [4.2]. The roots of a recent penalty-based method of constructing aggregation functions [4.3] can be found in books of Appolonius of Perga (living in the period about 262–190 BC) who (motivated by the center of gravity problems) proposed an approach leading to the centroid, i.e., to the arithmetic mean, minimizing the sum of squares of the Euclidean distances of the given  $n$  points from an unknown but fixed one. Generalization of the Appolonius

of Perga method based on a general norm is known as the Fréchet mean, or also as the *Karcher* mean, and it was deeply discussed in [4.4].

Another type of mean, the Heronian mean of two nonnegative numbers  $x$  and  $y$  is given by the formula

$$\text{He}(x, y) = \frac{1}{3} (x + \sqrt{xy} + y) . \quad (4.1)$$

It is named after Hero of Alexandria (10–70 AD) who used this aggregation function for finding the volume of a conical or pyramidal frustum. He showed that this volume is equal to the product of the height of the frustum and the Heronian mean of areas of parallel bases.

Another interesting historical example can be found in multivalued logic. Already Aristotle (384–322 BC)

was a classical logician who did not fully accept the law of excluded middle, but he did not create a system of multivalued logic to explain this isolated remark (in the work *De Interpretatione*, chapter IX). Systems of multivalued logics considering  $3, n$  (finitely many), and later also infinitely many truth degrees were introduced by *Lukasiewicz* [4.5], *Post* [4.6], *Gödel* [4.7], respectively, and in each of these systems the aggregation of truth values was considered (conjunction, disjunction).

Though several particular aggregation functions (or classes of aggregation functions) were discussed in many earlier works (we only recall means discussed around 1930 by *Kolmogorov* [4.8] and *Nagumo* [4.9], or later by *Aczél* [4.10], triangular norms and copulas studied by *Schweizer* and *Sklar* in 1960s of the previous century and summarized in [4.11]), an independent theory of aggregation can be dated only about 20 years back and the roots of its axiomatization can be found in [4.12–14]. Probably the first monograph devoted purely to aggregation is the monograph by *Calvo et al.* [4.15]. As a basic literature for any scientist interested in aggregation we recommend the monographs [4.16–18].

In this chapter, not only we summarize some earlier, but also some recent results concerning aggregation, including classification, construction methods, and several examples. We will deal with inputs and outputs from the unit interval  $[0, 1]$ . Note that though, in general, we can consider an arbitrary interval  $I \subseteq [-\infty, \infty]$ , there is no loss of generality (up to the isomorphism) when restricting our considerations to  $I = [0, 1]$ . As an example, consider the aggregation of nonnegative inputs, i. e., fix  $I = [0, \infty[$ . Then any aggregation function  $A$  on  $[0, \infty[$  can be seen as an isomorphic transform of some aggregation function  $B$  on  $[0, 1]$ , restricted to  $[0, 1[$  and satisfying two constraints:

- i)  $B(x) = 1$  if and only if  $x = (1, \dots, 1)$ ,
- ii)  $\sup \{B(x) \mid x \in [0, 1]^n\} = 1, n \in \mathbb{N}$ .

Note that any increasing bijection  $\varphi : [0, 1[ \rightarrow [0, \infty[$  can be applied as the considered isomorphism. For more details about aggregation on a general interval  $I \subseteq [-\infty, \infty]$  refer to [4.17].

We can consider either aggregation functions with a fixed number  $n \in \mathbb{N}, n \geq 2$ , of inputs or extended aggregation functions defined for any number  $n \in \mathbb{N}$  of inputs. The number  $n$  is called the arity of the aggregation function.

### Definition 4.1

For a fixed  $n \in \mathbb{N}, n \geq 2$ , a function  $A : [0, 1]^n \rightarrow [0, 1]$  is called an ( $n$ -ary) aggregation function whenever it is increasing in each variable and satisfies the boundary conditions

$$A(0, \dots, 0) = 0 \quad \text{and} \quad A(1, \dots, 1) = 1.$$

A mapping  $A : \bigcup_{n \in \mathbb{N}} [0, 1]^n \rightarrow [0, 1]$  is called an extended aggregation function whenever  $A(x) = x$  for each  $x \in [0, 1]$ , and for each  $n \in \mathbb{N}, n \geq 2$ ,  $A \mid [0, 1]^n$  is an  $n$ -ary aggregation function.

The framework of extended aggregation functions is rather general, not relating different arities, and thus some additional constraints are often considered, such as associativity, decomposability, neutral element, etc.

The Heronian mean  $H_e$  given in (4.1) is an example of a binary aggregation function. Prototypical examples of extended aggregation functions on  $[0, 1]$  are:

- The smallest extended aggregation function  $A_s$  given by

$$A_s(x) = \begin{cases} 1 & \text{if } x = (1, \dots, 1) \\ 0 & \text{else.} \end{cases}$$

- The greatest extended aggregation function  $A_g$  given by

$$A_g(x) = \begin{cases} 0 & \text{if } x = (0, \dots, 0) \\ 1 & \text{else.} \end{cases}$$

- The arithmetic mean  $M$  given by

$$M(x_1, \dots, x_n) = \frac{1}{n} \sum_{i=1}^n x_i.$$

- The geometric mean  $G$  given by

$$G(x_1, \dots, x_n) = \left( \prod_{i=1}^n x_i \right)^{\frac{1}{n}}.$$

- The product  $\Pi$  given by

$$\Pi(x_1, \dots, x_n) = \prod_{i=1}^n x_i.$$

- The minimum  $\text{Min}$  given by

$$\text{Min}(x_1, \dots, x_n) = \min \{x_1, \dots, x_n\}.$$

- The maximum Max given by

$$\text{Max}(x_1, \dots, x_n) = \max \{x_1, \dots, x_n\} .$$

- The truncated sum  $S_L$  (also known as the Łukasiewicz  $t$ -conorm) given by

$$S_L(x_1, \dots, x_n) = \min \left\{ 1, \sum_{i=1}^n x_i \right\} ,$$

- The 3- $\Pi$ -operator  $E$  introduced in [4.19] and given by

$$E(x_1, \dots, x_n) = \frac{\prod_{i=1}^n x_i}{\prod_{i=1}^n x_i + \prod_{i=1}^n (1-x_i)} ,$$

with some convention covering the case  $\frac{0}{0}$ ,

- The Pascal weighted arithmetic mean  $W_P$  given by

$$W_P(x_1, \dots, x_n) = \frac{1}{2^{n-1}} \sum_{i=1}^n \binom{n-1}{i-1} x_i .$$

As distinguished examples of  $n$ -ary aggregation functions for a fixed arity  $n \geq 2$ , recall the projections  $P_i$  and order statistics  $\text{OS}_i$ ,  $i = 1, \dots, n$ , given by

$$P_i(x_1, \dots, x_n) = x_i$$

and

$$\text{OS}_i(x_1, \dots, x_n) = x_{\sigma(i)} ,$$

where  $\sigma$  is an arbitrary permutation of  $(1, \dots, n)$  such that  $x_{\sigma(1)} \leq x_{\sigma(2)} \leq \dots \leq x_{\sigma(n)}$ . Observe that the first projection  $P_F = P_1$  and the last projection  $P_L = P_n$  can be seen as instances of extended aggregation functions  $P_F$  and  $P_L$ , respectively. On the other hand, for any fixed  $n \geq 2$ ,  $\text{OS}_1$  is just  $\text{Min} | [0, 1]^n$  and  $\text{OS}_n = \text{Max} | [0, 1]^n$ .

As a peculiar example of an extended aggregation function we can introduce the mapping  $V : \bigcup_{n \in \mathbb{N}} [0, 1]^n \rightarrow [0, 1]$  given by

$$V(x_1, \dots, x_n) = \min \left\{ \left( \sum_{i=1}^n x_i^n \right)^{\frac{1}{n}}, 1 \right\} . \quad (4.2)$$

## 4.2 Classification of Aggregation Functions

Let us denote by  $\mathcal{A}$  the class of all extended aggregation functions, and by  $\mathcal{A}_n$  (for a fixed  $n \geq 2$ ) the class of all  $n$ -ary aggregation functions. Several classifications of  $n$ -ary aggregation functions can be straightforwardly extended to the class  $\mathcal{A}$ . The basic classification proposed by Dubois and Prade [4.20] distinguishes (both for  $n$ -ary and extended aggregation functions):

- *Conjunctive* aggregation functions,  $C = \{A \in \mathcal{A} \mid A \leq \text{Min}\}$ ,
- *Disjunctive* aggregation functions,  $D = \{A \in \mathcal{A} \mid A \geq \text{Max}\}$ ,
- *Averaging* aggregation functions,  $\mathcal{Av} = \{A \in \mathcal{A} \mid \text{Min} \leq A \leq \text{Max}\}$ ,
- *Mixed* aggregation functions,  $\mathcal{M} = \mathcal{A} \setminus (C \cup D \cup \mathcal{Av})$ .

Considering purely averaging aggregation functions  $\mathcal{Av}^p = \mathcal{Av} \setminus \{\text{Min}, \text{Max}\}$ , we can see that the set  $\{C, D, \mathcal{Av}^p, \mathcal{M}\}$  forms a partition of  $\mathcal{A}$ . Note that the classes  $\mathcal{A}, C, D, \mathcal{Av}, \mathcal{Av}^p$  are convex, which is not the case of the class  $\mathcal{M}$ . For the previously introduced ex-

amples it holds:

- $M, G, W_P, P_F, P_L \in \mathcal{Av}^p$ ,
- $\Pi \in C$ ,
- $S_L, V \in D$ ,
- $E \in \mathcal{M}$ .

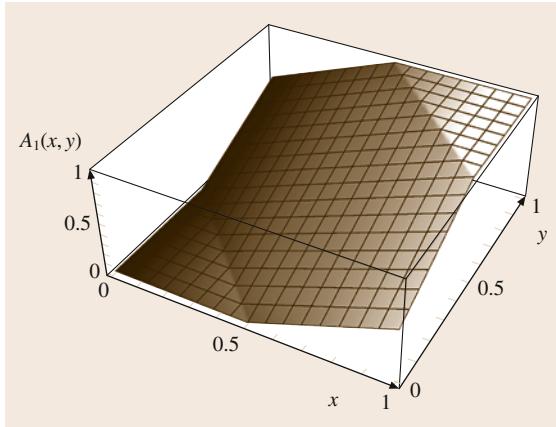

Observe that  $n$ -ary aggregation functions  $P_i$  and  $\text{OS}_i$ ,  $i = 1, \dots, n$ , are averaging, so are their convex sums, i.e., weighted arithmetic means

$$W = \sum_{i=1}^n w_i P_i ,$$

and ordered weighted averages (OWA operators) [4.21],

$$\text{OWA} = \sum_{i=1}^n w_i \text{OS}_i ,$$

with  $w_i \geq 0$  and  $\sum_{i=1}^n w_i = 1$ . The binary Heronian mean  $\text{He}$  given in (4.1) is a convex combination of

**Fig. 4.1** 3D plot of the aggregation function  $A_1$  defined by (4.3)

the arithmetic mean  $M$  and the geometric mean  $G$ ,  $\text{He} = \frac{2}{3}M + \frac{1}{3}G$ , and thus it is also averaging.

Consider two binary aggregation functions  $A_1, A_2 : [0, 1]^2 \rightarrow [0, 1]$  given by

$$A_1(x, y) = \text{Med}(0, 1, x + y - 0.5) \quad (4.3)$$

and

$$A_2(x, y) = \text{Med}(x + y, 0.5, x + y - 1), \quad (4.4)$$

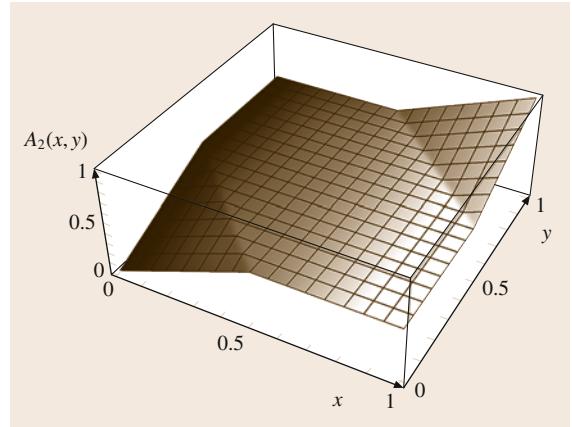

where  $\text{Med}$  is the standard median operator. Then  $A_1, A_2 \in \mathcal{M}$  but  $\frac{1}{2}A_1 + \frac{1}{2}A_2 = M \in \mathcal{Av}$ . The 3D plots of aggregation functions  $A_1, A_2$  and  $M$  are depicted in Figs. 4.1–4.3.

More refined classifications of  $n$ -ary aggregation functions are related to order statistics  $\text{OS}_i$ ,  $i = 1, \dots, n$ . The conjunctive classification [4.22] deals with the partition of the class  $\mathcal{A}_n$  given by  $\{C_1, \dots, C_n, R_C\}$ , where the class of  $i$ -conjunctive aggregation functions,  $i = 1, \dots, n$ , is defined by

$$\begin{aligned} C_i &= \{A \in \mathcal{A}_n \mid \min\{\text{card}\{j \mid x_j \geq A(x)\} \\ &\quad \mid x \in [0, 1]^n\} = i\} \\ &= \{A \in \mathcal{A}_n \mid A \leq \text{OS}_{n-i+1} \text{ but not } A \leq \text{OS}_{n-i}\}, \end{aligned}$$

where formally  $\text{OS}_0 \equiv 0$ .

In other words,  $A$  is  $i$ -conjunctive if and only if the aggregated value  $A(\mathbf{x})$  is dominated by at least  $i$  input values independently of  $\mathbf{x} \in [0, 1]^n$ , but not by  $(i+1)$  values, in general.

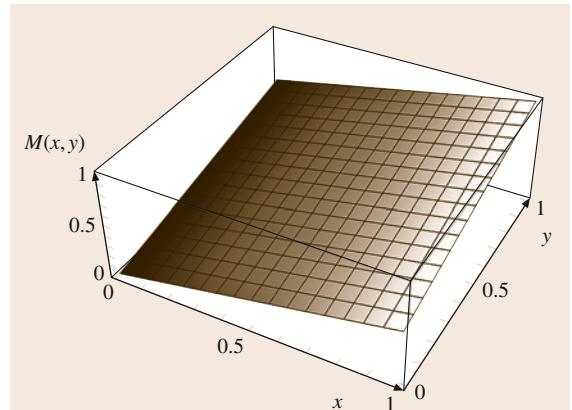

**Fig. 4.2** 3D plot of the aggregation function  $A_2$  defined by (4.4)

Clearly, the classes  $C_1, \dots, C_n$  are pairwise disjoint and the remaining aggregation functions are members of the class  $R_C = \mathcal{A}_n \setminus \bigcup_{i=1}^n C_i$ . If we come back to the above-mentioned basic classification of aggregation functions (applied to  $\mathcal{A}_n$ ), we obtain  $C = C_n$  and  $\mathcal{W}_C = \bigcup_{i=1}^{n-1} C_i = \mathcal{Av} \setminus \{\text{Min}\}$ . The class  $\mathcal{W}_C$  is called *weakly conjunctive* [4.22].

Similarly, we have a disjunctive type of classification of  $\mathcal{A}_n$  related to the partition  $\{\mathcal{D}_1, \dots, \mathcal{D}_n, R_D\}$ , with

$$\mathcal{D}_i = \{A \in \mathcal{A}_n \mid A \geq \text{OS}_i \text{ but not } A \geq \text{OS}_{i+1}\}, \quad i = 1, \dots, n.$$

**Fig. 4.3** 3D plot of the aggregation function  $\frac{1}{2}A_1 + \frac{1}{2}A_2 = M$

Then  $\mathcal{D}_n = \mathcal{D}$  and for the class of *weakly disjunctive* aggregation functions  $\mathcal{W}_{\mathcal{D}} = \bigcup_{i=1}^{n-1} \mathcal{D}_i$  we have  $\mathcal{W}_{\mathcal{D}} = \mathcal{A}^p \setminus \{\text{Max}\}$ . Hence  $\mathcal{W}_{\mathcal{C}} \cap \mathcal{W}_{\mathcal{D}} = \mathcal{A}^{p^p}$ , and  $A \in \bigcup_{i=1}^n C_i$  if and only if  $A \leq \text{Max}$ , while  $A \in \bigcup_{i=1}^n \mathcal{D}_i$  if and only if  $A \geq \text{Min}$ .

Note that the conjunctive and disjunctive classifications can be applied to aggregation functions defined on posets, too [4.22], and that this approach to the classification of aggregation functions on  $[0, 1]$  was already proposed by *Marichal* in [4.23] as  $i$ -tolerant and  $i$ -intolerant aggregation functions (Marichal's approach based on order statistics is applicable when considering chains only).

Observe that this approach to classification has no direct extension to extended aggregation functions. On the other hand, we have the next classification valid for extended aggregation functions only. We distinguish:

- *Dimension decreasing* aggregation functions forming the class  $\mathcal{A}_{\searrow}$ , satisfying  $A(x_1, \dots, x_n, x_{n+1}) \leq A(x_1, \dots, x_n)$  for any  $n \in \mathbb{N}$ ,  $x_1, \dots, x_{n+1} \in [0, 1]$ , but violating the equality, in general.
- *Dimension increasing* aggregation functions forming the class  $\mathcal{A}_{\nearrow}$ , satisfying  $A(x_1, \dots, x_n, x_{n+1}) \geq A(x_1, \dots, x_n)$  for any  $n \in \mathbb{N}$ ,  $x_1, \dots, x_{n+1} \in [0, 1]$ , but violating the equality, in general.
- *Dimension averaging* aggregation functions forming the class  $\overset{\leftrightarrow}{\mathcal{A}}$ , satisfying  $A(x_1, \dots, x_n, 0) \leq A(x_1, \dots, x_n) \leq A(x_1, \dots, x_n, 1)$  for any  $n \in \mathbb{N}$ ,  $x_1, \dots, x_n \in [0, 1]$ , and attaining strict inequalities for at least one  $x \in [0, 1]^n$ .

Evidently, the classes  $\mathcal{A}_{\searrow}$ ,  $\mathcal{A}_{\nearrow}$ , and  $\overset{\leftrightarrow}{\mathcal{A}}$  are disjoint and they, together with their reminder  $\mathcal{A} \setminus (\mathcal{A}_{\searrow} \cup \mathcal{A}_{\nearrow} \cup \overset{\leftrightarrow}{\mathcal{A}})$ , form a partition of  $\mathcal{A}$ . Let us note that each associative conjunctive aggregation function is dimension decreasing, and thus,  $\Pi, \text{Min} \in \mathcal{A}_{\searrow}$ . Similarly, each associative disjunctive aggregation function is dimension increasing, so,  $S_L, \text{Max} \in \mathcal{A}_{\nearrow}$ .

Recently, *Yager* has introduced extended aggregation functions with the self-identity property [4.24] characterized by the equality

$$A(x_1, \dots, x_n, A(x_1, \dots, x_n)) = A(x_1, \dots, x_n)$$

for any  $n \in \mathbb{N}$  and  $x_1, \dots, x_n \in [0, 1]$  (e.g., the arithmetic mean  $M$  or the geometric mean  $G$  satisfy this

property). Evidently, each such aggregation function satisfies

$$\begin{aligned} A(x_1, \dots, x_n, 0) &\leq A(x_1, \dots, x_n, x_{n+1}) \\ &\leq A(x_1, \dots, x_n, 1) \end{aligned}$$

for all  $n \in \mathbb{N}$ ,  $x_1, \dots, x_{n+1} \in [0, 1]$  and thus, if the strict inequalities are attained for some  $n \in \mathbb{N}$  and

$$x_1, \dots, x_{n+1} \in [0, 1],$$

$A$  belongs to  $\overset{\leftrightarrow}{\mathcal{A}}$ . So, for example,  $M, G \in \overset{\leftrightarrow}{\mathcal{A}}$ . The extended aggregation function  $V$  (4.2) also belongs to  $\overset{\leftrightarrow}{\mathcal{A}}$ . On the other hand, the first projection  $P_F$  does not belong to

$$\mathcal{A}_{\searrow} \cup \mathcal{A}_{\nearrow} \cup \overset{\leftrightarrow}{\mathcal{A}},$$

and the last projection  $P_L$  belongs to  $\overset{\leftrightarrow}{\mathcal{A}}$ . Recall that if  $A \in \mathcal{A}_{\searrow}$ , it is also said to have the *downward attitude property* [4.24]. Similarly, the upward attitude property introduced in [4.24] corresponds to the class  $\mathcal{A}_{\nearrow}$ . Dimension increasing aggregation functions were also considered in [4.25].

Let us return to the basic classification of aggregation functions and recall several distinguished types of aggregation functions belonging to the classes  $C$ ,  $D$ ,  $\mathcal{A}^{p^p}$ , and  $\mathcal{M}$ :

- *Conjunctive aggregation functions*: Triangular norms [4.26, 27], copulas [4.27, 28], quasi-copulas [4.29, 30], and semicopulas [4.31].
- *Disjunctive aggregation functions*: Triangular conorms [4.26, 27], dual copulas [4.28].
- *Averaging aggregation functions*: (Weighted) quasi-arithmetic means [4.10], idempotent uninorms [4.32], integrals based on capacities, including the Choquet and Sugeno integrals [4.18, 33–36], also covering OWA [4.21], ordered weighted maximum (OWMax) [4.37] and ordered modular average (OMA) [4.38] operators, as well as lattice polynomials [4.39].
- *Mixed aggregation functions*: nonidempotent uninorms [4.40], gamma-operators [4.41], special convex sums in fuzzy linear programming [4.42].

For more details concerning these aggregation functions see [4.17] or references given above.

## 4.3 Properties and Construction Methods

Properties of aggregation functions are mostly related to the field of their application, such as multicriteria decision aid, multivalued logics, or probability theory, for example. Besides the standard analytical properties of functions, such as continuity, the Lipschitz property, and (perhaps adapted) algebraic properties, such as symmetry, associativity, bisymmetry, neutral element, annihilator, cancellativity, or idempotency [4.17, Chapter 2], the above-mentioned applied fields have brought into aggregation theory properties as decomposability, conjunctivity, or  $n$ -increasiness. Each of the mentioned properties can be introduced for  $n$ -ary aggregation functions (excepting decomposability), and thus also for extended aggregation functions. However, in the case of extended aggregation functions, some properties can be introduced in a stronger form, involving different arities in a single formula.

For example, the (weak) idempotency of  $A \in \mathcal{A}$  means the idempotency of each  $A|_{[0,1]^n}$ , which means that for each  $n \in \mathbb{N}$  and

$$x \in [0, 1], \quad A(\underbrace{x, \dots, x}_{n\text{-times}}) = x.$$

Note that an extended aggregation function  $A$  is idempotent if and only if it is averaging, i.e.,  $A \in \mathcal{A}^v$ . The strong idempotency [4.15] of an extended aggregation function  $A \in \mathcal{A}$  means that

$$A(\underbrace{x, \dots, x}_{k\text{-times}}) = A(x)$$

for each  $k \in \mathbb{N}$  and  $x \in \bigcup_{n \in \mathbb{N}} [0, 1]^n$ . For example, the extended aggregation function  $W_p$  is idempotent but not strongly idempotent.

Similarly,  $e \in [0, 1]$  is a (weak) neutral element of an extended aggregation function  $A \in \mathcal{A}$  if and only if for each  $n \geq 2$  and  $x \in [0, 1]^n$  such that  $x_j = e$  for  $j \neq i$  it holds  $A(x) = x_i$ . On the other hand,  $e$  is a strong neutral element of an extended aggregation function  $A \in \mathcal{A}$  if and only if for any  $n \geq 2$ ,  $x \in [0, 1]^n$  with  $x_i = e$ , it holds

$$\begin{aligned} & A(x_1, \dots, x_{i-1}, e, x_{i+1}, \dots, x_n) \\ &= A(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n). \end{aligned}$$

Obviously, if  $e$  is a strong neutral element of  $A \in \mathcal{A}$  then it is also a (weak) neutral element of  $A$ . As an example, consider the extended copula  $D \in \mathcal{A}$  given by

$$D(x_1, \dots, x_n) = x_1 \cdot \min\{x_2, \dots, x_n\}.$$

Obviously,  $e = 1$  is a weak neutral element of  $D$ . However  $D(1, \frac{1}{2}, \frac{1}{2}) = \frac{1}{2} \neq \frac{1}{4} = D(\frac{1}{2}, \frac{1}{2})$ , i.e.,  $e = 1$  is not a strong neutral element of  $D$ . For a deeper discussion and exemplification of properties of aggregation functions we recommend [4.17].

Aggregation functions in many fields are constrained by the required properties – axioms in each considered field. As a typical example recall multivalued logics (fuzzy logics) with truth values domain  $[0, 1]$ , where conjunction is modeled by means of triangular norms [4.26, 43, 44]. Recall that a binary aggregation function  $T : [0, 1]^2 \rightarrow [0, 1]$  is called a triangular norm ( $t$ -norm for short) whenever it is symmetric, associative and  $e = 1$  is its neutral element. Due to associativity, there is a genuine extension of a  $t$ -norm  $T$  into an extended aggregation function (we will also use the same notation  $T$  in this case). Then  $e = 1$  is a strong neutral element for the extended  $T$ . However, without some additional properties we still cannot determine a  $t$ -norm convenient for our purposes. Requiring, for example, the idempotency of  $T$ , we obtain that the only solution is  $T = \text{Min}$ , the strongest triangular norm. Considering continuous triangular norms satisfying the diagonal inequalities  $0 < T(x, x) < x$  for all  $x \in ]0, 1[$ , we can show that  $T$  is isomorphic to the product  $\Pi$ , i.e., there is an automorphism  $\varphi : [0, 1] \rightarrow [0, 1]$  such that  $T(x, y) = \varphi^{-1}(\Pi(\varphi(x), \varphi(y)))$ , and in the extended form,  $T(x_1, \dots, x_n) = \varphi^{-1}(\Pi(\varphi(x_1), \dots, \varphi(x_n)))$ . For more details and several other results we recommend [4.26].

As another example consider probability theory, namely the relationship between the joint distribution function  $F_Z$  of a random vector  $Z = (X_1, \dots, X_n)$ , and the corresponding marginal one-dimensional distribution functions  $F_{X_1}, \dots, F_{X_n}$ . By the Sklar theorem [4.45], for all  $(x_1, \dots, x_n) \in \overline{\mathbb{R}}$  we have

$$F_Z(x_1, \dots, x_n) = C(F_{X_1}(x_1), \dots, F_{X_n}(x_n))$$

for some  $n$ -ary aggregation function  $C$ . Obviously, constrained by the basic properties of probabilities,  $C$  should possess a neutral element  $e = 1$  and annihilator (zero element)  $a = 0$ , and the function  $C$  should be  $n$ -increasing (i.e., probability  $P(Z \in [u_1, v_1] \times \dots \times [u_n, v_n]) \geq 0$  for any  $n$ -dimensional box  $[u_1, v_1] \times \dots \times [u_n, v_n]$ ), which yields an axiomatic definition of copulas. More details for interested readers can be found in [4.28]. Considering some additional constraints, we obtain special subclasses of

copulas. For example, if we fix  $n = 2$  and consider the stability of copulas with respect to positive powers, i.e., the property  $C(x^\lambda, y^\lambda) = (C(x, y))^\lambda$  for each  $\lambda \in ]0, \infty[$  and each  $(x, y) \in [0, 1]^2$ , then we obtain *extreme value copulas (EV copulas)* [4.46, 47]. Recall that a copula  $C : [0, 1]^2 \rightarrow [0, 1]$  is an *EV copula* if and only if there is a convex function  $d : [0, 1] \rightarrow [0, 1]$  such that for each  $t \in [0, 1]$ ,  $\max\{t, 1-t\} \leq d(t) \leq 1$  and for all  $(x, y) \in ]0, 1[^2$ ,

$$C(x, y) = (xy)^{d\left(\frac{\log x}{\log xy}\right)}$$

(observe that on  $[0, 1]^2 \setminus ]0, 1[^2$  for each copula it holds  $C(x, y) = \min\{x, y\}$ ).

Our third example comes from economics. In multicriteria decision problems, we often meet the requirement of the comonotone additivity of the considered  $n$ -ary (extended) aggregation function  $A$ , i.e., we expect that  $A(\mathbf{x} + \mathbf{y}) = A(\mathbf{x}) + A(\mathbf{y})$  for all  $\mathbf{x}, \mathbf{y} \in [0, 1]^n$  such that  $\mathbf{x} + \mathbf{y} \in [0, 1]^n$  and  $(x_i - x_j)(y_i - y_j) \geq 0$  for any  $i, j \in \{1, \dots, n\}$ . The comonotonicity of  $\mathbf{x}$  and  $\mathbf{y}$  means that the ordering on  $\{1, \dots, n\}$  induced by  $\mathbf{x}$  is not contradictory to that one induced by  $\mathbf{y}$ . Due to Schmeidler [4.48], we know that then  $A$  is necessarily the Choquet integral based on the fuzzy measure  $m : 2^{\{1, \dots, n\}} \rightarrow [0, 1]$ ,  $m(E) = A(1_E)$ , given by (4.6).

The axiomatic approach to aggregation characterizes some special classes of aggregation functions. Another important look at aggregation involves construction methods. We can roughly divide them into the next four groups:

- Optimization methods,
- Extension methods,
- Constructions based on the given aggregation functions,
- Introduction of weights.

An exhaustive overview of construction methods for aggregation functions can be found in [4.17, Chapter 6]. Here we briefly recall the most distinguished ones.

A typical *optimization* method is the penalty-based approach proposed in [4.49] and generalized in [4.3], where dissimilarity functions were introduced, see also [4.50].

#### **Definition 4.2**

A function  $D : [0, 1]^2 \rightarrow [0, \infty[$  given by

$$D(x, y) = K(f(x) - f(y)) ,$$

where  $f : [0, 1] \rightarrow \mathbb{R}$  is a continuous strictly monotone function and  $K : \mathbb{R} \rightarrow [0, \infty[$  is a convex function

attaining the unique minimum  $K(0) = 0$ , is called a *dissimilarity function*.

#### **Theorem 4.1**

Let  $D : [0, 1]^2 \rightarrow [0, \infty]$  be a dissimilarity function. Then for any  $n \in \mathbb{N}$ ,  $x_1, \dots, x_n \in [0, 1]$ , the function  $h : [0, 1] \rightarrow \mathbb{R}$  given by  $h(t) = \sum_{i=1}^n D(x_i, t)$  attains its minimal value exactly on a closed interval  $[a, b]$  and the formula

$$A(x_1, \dots, x_n) = \frac{a+b}{2}$$

defines a strongly idempotent symmetric extended aggregation function  $A$  on  $[0, 1]$ .

Construction given in Theorem 4.1 covers:

- the arithmetic mean ( $D(x, y) = (x - y)^2$ ),
- quasi-arithmetic means ( $D(x, y) = (f(x) - f(y))^2$ ),
- the median ( $D(x, y) = |x - y|$ ),

among others. This method is a generalization of the Appolonius of Perga method. Note that in general, a function  $D$  need not be symmetric, i.e.,  $K$  need not be an even function (compare with the symmetry of metrics). As a typical example, let us recall the dissimilarity function  $D_c : [0, 1]^2 \rightarrow [0, \infty]$ ,  $c \in ]0, \infty[$ , given by

$$D_c(x, y) = \begin{cases} x - y & \text{if } x \geq y , \\ c(y - x) & \text{if } x < y , \end{cases}$$

yielding by means of Theorem 4.1 the  $\alpha$ -quantile of a sample  $(x_1, \dots, x_n)$  with  $\alpha = \frac{1}{1+c}$ .

As a possible generalization of Theorem 4.1, one can consider different dissimilarity functions  $D_i$  (which violates the symmetry of the constructed aggregation function  $A$ ). Consider, for example,  $D_1(x, y) = |x - y|$  and  $D_2(x, y) = \dots = D_n(x, y) = \dots = (x - y)^2$ . Then the minimization of the sum  $\sum_{i=1}^n D_i(x_i, t)$  results in the extended aggregation function  $A : \bigcup_{n \in \mathbb{N}} [0, 1]^n \rightarrow [0, 1]$  given by

$$\begin{aligned} A(x_1, \dots, x_n) = & \\ \text{Med}(x_1, M(x_2, \dots, x_n) - 0.5, M(x_2, \dots, x_n) + 0.5) , & \end{aligned} \tag{4.5}$$

whenever  $n > 1$ .

Some other generalizations based on a generalized approach to dissimilarity (penalty) functions can be found in [4.16].

*Extension* methods are based on a partial information that is available about an aggregation function. As a typical example, we recall integral-based aggregation functions. Suppose that for a fixed arity  $n$  the values of an aggregation function  $A$  are known at Boolean inputs only, i.e., we know  $A \mid \{0, 1\}^n$  only. Identifying subsets of the space  $X = \{1, \dots, n\}$  with the corresponding characteristic functions, we get the set function  $m : 2^X \rightarrow [0, 1]$  given by  $m(E) = A(1_E)$ . Obviously,  $m$  is monotone, i.e.,  $m(E_1) \leq m(E_2)$  whenever  $E_1 \subseteq E_2 \subseteq X$ , and  $m(\emptyset) = A(0, \dots, 0) = 0$ ,  $m(X) = A(1, \dots, 1) = 1$ . Note that  $m$  is often called a *fuzzy measure* [4.51, 52] or a *capacity* [4.17].

Among several integral-based extension methods we recall:

- The *Choquet* integral [4.53],  $\text{Ch}_m : [0, 1]^n \rightarrow [0, 1]$ ,

$$\text{Ch}_m(\mathbf{x}) = \sum_{i=1}^n x_{\sigma(i)} \cdot (m(E_{\sigma,i}) - m(E_{\sigma,i+1})) , \quad (4.6)$$

where  $\sigma : X \rightarrow X$  is a permutation such that  $x_{\sigma(1)} \leq x_{\sigma(2)} \leq \dots \leq x_{\sigma(n)}$ ,  $E_{\sigma,i} = \{\sigma(i), \dots, \sigma(n)\}$  for  $i = 1, \dots, n$ , and  $E_{\sigma,n+1} = \emptyset$ . Note that the Choquet integral can be seen as a weighted arithmetic mean with the weights dependent on the ordinal structure of the input vector  $\mathbf{x}$ . If the capacity  $m$  is additive, i.e.,  $m(E) = \sum_{i \in E} m(\{i\})$ , then

$$\text{Ch}_m(\mathbf{x}) = \sum_{i=1}^n w_i x_i ,$$

where for the weights it holds  $w_i = m(\{i\})$ ,  $i \in X$  (hence  $\sum_{i=1}^n w_i = 1$ ).

- The *Sugeno* integral [4.51],  $\text{Su}_m : [0, 1]^n \rightarrow [0, 1]$ ,

$$\text{Su}_m(\mathbf{x}) = \max \{ \min \{x_{\sigma(i)}, m(E_{\sigma,i})\} \mid i \in X\} .$$

If  $m$  is maxitive, i.e.,  $m(E) = \max \{m(\{i\}) \mid i \in E\}$ , then we recognize the weighted maximum  $\text{Su}_m(\mathbf{x}) = \max \{ \min \{x_i, v_i\} \mid i \in X\}$ , with weights  $v_i = m(\{i\})$  (hence  $\max \{v_i \mid i \in X\} = 1$ ).

- The copula-based integral [4.34],  $I_{C,m} : [0, 1]^n \rightarrow [0, 1]$ , where  $C : [0, 1]^2 \rightarrow [0, 1]$  is a binary copula,

$$I_{C,m}(\mathbf{x}) = \sum_{i=1}^n (C(x_{\sigma(i)}, m(E_{\sigma,i})) - C(x_{\sigma(i)}, m(E_{\sigma,i+1}))) .$$

This integral covers the Choquet integral if  $C$  is equal to the product copula  $\Pi$ ,  $I_{\Pi,m} = \text{Ch}_m$ , as well as the Sugeno integral in the case of the greatest copula Min,  $I_{\text{Min},m} = \text{Su}_m$ . Observe that if the capacity  $m$  is symmetric, i.e.,  $m(E) = v_{\text{card } E}$ , where  $0 = v_0 \leq v_1 \leq \dots \leq v_n = 1$ , then  $I_{C,m}$  turns to **OMA** operator introduced in [4.38]. Its special instances are the **OWA** operators [4.21] based on the Choquet integral,

$$\text{OWA}(\mathbf{x}) = \sum_{i=1}^n x_{\sigma(i)} \cdot w_i ,$$

with  $w_i = v_i - v_{i-1}$ , and the **OWMax** operator [4.37],

$$\text{OWMax}(\mathbf{x}) = \max \{ \min \{x_{\sigma(i)}, v_i\} \mid i \in X\} .$$

For better understanding, fix  $n = 2$ , i.e., consider  $X = \{1, 2\}$ . Then  $m(\{1\}) = a$  and  $m(\{2\}) = b$  are any constants from  $[0, 1]$ , and  $m(\emptyset) = 0$ ,  $m(X) = 1$  due to the boundary conditions. The following equalities hold:

- $\text{Ch}_m(x, y) = \begin{cases} ax + (1-a)y & \text{if } x \geq y, \\ (1-b)x + by & \text{else,} \end{cases}$
- $\text{Su}_m(x, y) = \max \{ \min \{a, x\}, \min \{b, y\}, \min \{x, y\} \}$ ,
- $I_{C,m}(x, y) = \begin{cases} C(x, a) + y - C(y, a) & \text{if } x \geq y, \\ C(y, b) + x - C(x, b) & \text{else.} \end{cases}$

The considered capacity  $m$  is symmetric if and only if  $a = b$ , and then:

- $\text{Ch}_m(x, y) = \text{OWA}(x, y) = (1-a) \cdot \min \{x, y\} + a \cdot \max \{x, y\}$ ,
- $\text{Su}_m(x, y) = \text{OWMax}(x, y) = \text{Med}(x, a, y)$  is the so-called  $a$ -median [4.54, 55],
- $I_{C,m}(x, y) = \text{OMA}(x, y) = f_1(\min \{x, y\}) + f_2(\max \{x, y\})$ , where  $f_1, f_2 : [0, 1] \rightarrow [0, 1]$  are given by  $f_1(t) = t - C(t, a)$  and  $f_2(t) = C(t, a)$ .

For more details concerning integral-based constructions of aggregation functions we recommend [4.34, 36, 56] or [4.34] by Klement, Mesiar, and Pap.

Another kind of extension methods exploiting capacities is based on the Möbius transform. Recall that for a capacity  $m : 2^X \rightarrow [0, 1]$ , its Möbius transform  $\mu : 2^X \rightarrow \mathbb{R}$  is given by

$$\mu(E) = \sum_{L \subseteq E} (-1)^{\text{card}(E \setminus L)} m(L) .$$

**Theorem 4.2**

[4.57] Let  $C : [0, 1]^n \rightarrow [0, 1]$  be an  $n$ -ary copula, and  $m : 2^X \rightarrow [0, 1]$  a capacity. Then the function  $A_{C,m} : [0, 1]^n \rightarrow [0, 1]$  given by

$$A_{C,m}(x) = \sum_{E \subseteq X} \mu(E) \cdot C(x \vee 1_{E^c})$$

is an aggregation function.

Special instances of Theorem 4.2 are the Lovász extension [4.58] corresponding to the strongest copula  $\text{Min}$  ( $A_{\text{Min},m} = I_{\Pi,m} = \text{Ch}_m$  is just the Choquet integral), and the Owen extension [4.59] corresponding to the product copula  $\Pi$  ( $A_{\Pi,m}(x) = \sum_{E \subseteq X} (\mu(E) \prod_{i \in E} x_i)$ ).

Several extension methods were introduced for binary copulas, for example, in the case when only the information about their diagonal section  $\delta_C : [0, 1] \rightarrow [0, 1]$ ,  $\delta_C(x) = C(x, x)$  is available. If  $\delta : [0, 1] \rightarrow [0, 1]$  is any increasing 2-Lipschitz function such that  $\delta(0) = 0$ ,  $\delta(1) = 1$ , and  $\delta(x) \leq x$  for each  $x \in [0, 1]$ , then the formula

$$D(x, y) = \min \left\{ x, y, \frac{\delta(x) + \delta(y)}{2} \right\}, \quad (x, y) \in [0, 1]^2,$$

defines a binary copula with  $\delta_D = \delta$ . Note that  $D$  is the greatest symmetric copula with the given diagonal section. Among numerous papers dealing with such types of extensions we recommend the overview paper [4.60]. Similarly, one can extend horizontal or vertical sections to copulas [4.61]. An overview of extension methods for triangular norms can be found in [4.26].

The third group of construction methods involves methods creating new aggregation functions from the given ones. These methods are applied either to aggregation functions with a fixed arity  $n$ , or to extended aggregation functions. Some of them can be applied to any kind of aggregation functions. As a typical example, recall transformation of aggregation functions by means of an automorphism  $\varphi : [0, 1] \rightarrow [0, 1]$  (i.e., an isomorphic transformation) given by

$$A_\varphi(x_1, \dots, x_n) = \varphi^{-1}(A(\varphi(x_1), \dots, \varphi(x_n))). \quad (4.7)$$

Transformation (4.7) preserves all algebraic properties as well as the classification of aggregation functions. However, some analytical properties can be broken, for example, the Lipschitz property or  $n$ -increasiness. Some special classes of aggregation functions can be

characterized by a unique member and its isomorphic transforms. Consider, for example, triangular norms. Then strict triangular norms are isomorphic to the product  $t$ -norm  $\Pi$ , nilpotent  $t$ -norms are isomorphic to the Łukasiewicz  $t$ -norm  $T_L$ . Similarly, quasi-arithmetic means with no annihilator are isomorphic to the arithmetic mean  $M$ . The only  $n$ -ary aggregation functions invariant under isomorphic transformations are the lattice polynomials [4.62], i.e., the Choquet integrals with respect to  $\{0, 1\}$ -valued capacities. So, for  $n = 2$ , only  $\text{Min}$ ,  $\text{Max}$ ,  $P_F$  and  $P_L$  are invariant under isomorphic transformations. There are several generalizations of (4.7). One can consider, for example, decreasing bijections  $\eta : [0, 1] \rightarrow [0, 1]$  and define  $A_\eta$  via (4.7). This type of transformations reverses the conjunctivity of aggregation function into disjunctivity, and vice versa. It preserves the existence of a neutral element (annihilator), however, if  $e$  is a neutral element of  $A$  ( $a$  is an annihilator of  $A$ ) then  $\eta^{-1}(e)$  is a neutral element of  $A_\eta$  ( $\eta^{-1}(a)$  is an annihilator of  $A_\eta$ ). If  $\eta$  is involutive, i.e., if  $\eta \circ \eta = \text{id}_{[0,1]}$ , then  $(A_\eta)_\eta = A$ , so there is a duality between  $A$  and  $A_\eta$ . The most applied duality is based on the standard (or Zadeh's) negation  $\eta : [0, 1] \rightarrow [0, 1]$  given by  $\eta(x) = 1 - x$ . In that case, we use the notation  $A^d = A_\eta$  and  $A^d(x_1, \dots, x_n) = 1 - A(1 - x_1, \dots, 1 - x_n)$ . As a distinguished example recall the class of triangular conorms which are just the dual aggregation functions to triangular norms, i.e.,  $S$  is a triangular conorm [4.26] if and only if there is a triangular norm  $T$  such that  $S = T^d$ .

Further generalizations of (4.7) consider different automorphisms  $\varphi, \varphi_1, \dots, \varphi_n : [0, 1] \rightarrow [0, 1]$ ,

$$\begin{aligned} & A_{\varphi, \varphi_1, \dots, \varphi_n}(x_1, \dots, x_n) \\ &= \varphi(A(\varphi_1(x_1), \dots, \varphi_n(x_n))). \end{aligned} \quad (4.8)$$

Moreover, it is enough to suppose that  $\varphi_1, \dots, \varphi_n$  are monotone (not necessarily strictly) and satisfy  $\varphi_i(0) = 0$ ,  $\varphi_i(1) = 1$ ,  $i = 1, \dots, n$ , as in such case it also holds that for any aggregation function  $A$ ,  $A_{\varphi, \varphi_1, \dots, \varphi_n}$  given by (4.8) is an aggregation function.

Another construction well known from functional theory is linked to the composition of functions. We have two kinds of composition methods. In the first one, considering a  $k$ -ary aggregation function  $B : [0, 1]^k \rightarrow [0, 1]$ , we can choose arbitrary  $k$  aggregation functions  $C_1, \dots, C_k$  (either all of them are extended aggregation functions, or all of them are  $n$ -ary aggregation functions for some fixed  $n > 1$ ), and then we can introduce a new aggregation function  $A$  (either extended, with the con-

vention  $A(x) = x$ ,  $x \in [0, 1]$ ; or  $n$ -ary) such that

$$A(\mathbf{x}) = B(C_1(\mathbf{x}), \dots, C_k(\mathbf{x})). \quad (4.9)$$

As a typical example of construction (4.9), consider  $B$  to be a weighted arithmetic mean  $W$ ,  $W(x_1, \dots, x_n) = \sum_{i=1}^n w_i x_i$ . Then

$$A(\mathbf{x}) = \sum_{i=1}^k w_i \cdot C_i(\mathbf{x}),$$

i.e.,  $A$  is a convex combination of aggregation functions  $C_1, \dots, C_k$ .

The second method is based on a partition of the space of coordinates  $\{1, \dots, n\}$  into subspaces

$$\begin{aligned} & \{1, \dots, n_1\}, \{n_1 + 1, \dots, n_1 + n_2\}, \dots, \\ & \{n_1 + \dots + n_{k-1} + 1, n\}. \end{aligned}$$

Then, considering a  $k$ -ary aggregation function  $B : [0, 1]^k \rightarrow [0, 1]$  and aggregation functions  $C_i : [0, 1]^{n_i} \rightarrow [0, 1]$ ,  $i = 1, \dots, k$ , we can define a composite aggregation function  $A : [0, 1]^n \rightarrow [0, 1]$  by

$$\begin{aligned} & A(x_1, \dots, x_n) \\ & = B(C_1(x_1, \dots, x_{n_1}), C_2(x_{n_1+1}, \dots, x_{n_1+n_2}), \\ & \dots, C_k(x_{n_1+\dots+n_{k-1}}, \dots, x_n)). \end{aligned} \quad (4.10)$$

This method can be generalized by considering an arbitrary partition of  $\{1, \dots, n\}$  into  $\{I_1, \dots, I_k\}$ . As an example, consider the  $n$ -ary copula  $C : [0, 1]^n \rightarrow [0, 1]$  defined for a fixed partition  $\{I_1, \dots, I_k\}$  of  $\{1, \dots, n\}$  by

$$C(x_1, \dots, x_n) = \prod_{i=1}^k \min \{x_j \mid j \in I_i\}.$$

For more details, see [4.63].

The third group containing constructions based on some given aggregation functions can be seen as a group of patchwork methods. As typical examples, we can recall several types of ordinal sums. Besides the well-known Min-based ordinal sums for conjunctive aggregation functions (especially for triangular norms and copulas) [4.26, 64],  $W$ -ordinal sums for copulas (or quasi-copulas) [4.65], as well as  $g$ -ordinal sums for copulas [4.66], we recall one kind of ordinal sums introduced in [4.67] which is applicable to arbitrary aggregation functions.

### Theorem 4.3

Let  $f : [0, 1] \rightarrow [-\infty, \infty]$  be a continuous strictly monotone function, and let  $0 = a_0 < a_1 < \dots < a_k = 1$  be a given sequence of real constants. Then for any system  $(A_i)_{i=1}^k$  of  $n$ -ary (extended) aggregation functions the function  $A : [0, 1]^n \rightarrow [0, 1]$  ( $A : \cup_{n \in \mathbb{N}} [0, 1]^n \rightarrow [0, 1]$ ) given by

$$\begin{aligned} A(\mathbf{x}) = f^{-1} \left( \left( \sum_{j=1}^k f(a_{j-i} + (a_j - a_{j-1}) A_j(\mathbf{x}^{(j)})) \right. \right. \\ \left. \left. - \sum_{j=1}^{k-1} f(a_j) \right) \right), \end{aligned} \quad (4.11)$$

where

$$\mathbf{x}^{(j)} = (x_1^{(j)}, \dots, x_n^{(j)})$$

and

$$x_i^{(j)} = \max \left\{ 0, \min \left\{ 1, \frac{x_i - a_{j-1}}{a_j - a_{j-1}} \right\} \right\},$$

is an  $n$ -ary (extended) aggregation function.

Observe that if all  $A_i$ 's are triangular norms (copulas, quasi-copulas, triangular conorms, continuous aggregation functions, idempotent aggregation functions, symmetric aggregation functions) then so is the newly constructed aggregation function  $A$ .

The fourth group contains construction methods allowing one to introduce weights into the aggregation procedure. The *quantitative* look at weights can be seen as the corresponding *repetition* of inputs, and the weights roughly correspond to the occurrence of single input arguments. For example, when considering a strongly idempotent (symmetric) aggregation function constructed by means of a dissimilarity function  $D$  (see Theorem 4.1) and weights  $w_1, \dots, w_n$  (at least one of them should be positive, and all of them are nonnegative), we look for minimizers of the sum  $\sum_{i=1}^n w_i D(x_i, t)$ . For example, if  $D(x, y) = (x-y)^2$ , then we obtain the weighted arithmetic mean

$$W(x_1, \dots, x_n) = \frac{\sum_{i=1}^n w_i x_i}{\sum_{i=1}^n w_i}.$$

This approach can also be introduced in the case when different dissimilarity functions are applied. As an example, consider the aggregation function  $A : [0, 1]^n \rightarrow$

$[0, 1]$  given by (4.5). We look for minimizers of the expression  $w_1|x_1 - t| + \sum_{i=2}^n w_i(x_i - t)^2$  and the resulting weighted aggregation function  $A_w : [0, 1]^n \rightarrow [0, 1]$  is given by

$$\begin{aligned} A_w(x_1, \dots, x_n) &= \text{Med} \left( x_1, M(x_2, \dots, x_n) - \frac{w_1}{2 \sum_{i=2}^n w_i}, \right. \\ &\quad \left. M(x_2, \dots, x_n) + \frac{w_1}{2 \sum_{i=2}^n w_i} \right). \end{aligned}$$

Considering the integer weights  $w = (w_1, \dots, w_n)$ , for an extended aggregation function  $A$  which is symmetric and strongly idempotent, we obtain the weighted aggregation function  $A_w : [0, 1]^n \rightarrow [0, 1]$  given by

$$\begin{aligned} A_w(x_1, \dots, x_n) &= A \left( \underbrace{x_1, \dots, x_1}_{w_1\text{-times}}, \underbrace{x_2, \dots, x_2}_{w_2\text{-times}}, \dots, \underbrace{x_n, \dots, x_n}_{w_n\text{-times}} \right). \end{aligned}$$

The strong idempotency of  $A$  also allows one to introduce rational weights into aggregation. Observe that

## 4.4 Concluding Remarks

As already mentioned, all introduced results (sometimes for special types of aggregation functions only) can be straightforwardly extended to any interval  $I \subseteq [-\infty, \infty]$ . Moreover, one can aggregate more general objects than real numbers. For example, a quite expanding field concerns interval mathematics. The aggregation of interval inputs can be done coordinate-wise,

$$\begin{aligned} A([x_1, y_1], \dots, [x_n, y_n]) &= [A_1(x_1, \dots, x_n), A_2(y_1, \dots, y_n)], \end{aligned}$$

where  $A_1, A_2$  are an arbitrary couple of classical aggregation functions such that  $A_1 \leq A_2$  (mostly  $A_1 = A_2$  is considered). However, there are also more sophisticated approaches [4.69].

Already in 1942, *Menger* [4.43] introduced the aggregation of distribution functions whose supports are contained in  $[0, \infty]$  (distance functions), which led not only to the concept of triangular norms [4.44], but also to triangle functions directly aggregating

for each  $k \in \mathbb{N}$ , the weights  $k \cdot w$  result in the same weighted aggregation function as when considering the weights  $w$  only. For general weights the limit approach described in [4.17, Proposition 6.27] should be applied.

The *qualitative* approach to weights considers a transformation of inputs  $x_1, \dots, x_n$  accordingly to the considered weights (importances)  $w_1, \dots, w_n \in [0, 1]$ , with constraint that at least once it holds  $w_i = 1$ . This approach is applied when we consider an extended aggregation function  $A$  with a strong neutral element  $e \in [0, 1]$ . Then the weighted aggregation function  $A_w : [0, 1]^n \rightarrow [0, 1]$  is given by

$$A_w(x_1, \dots, x_n) = A(h(w_1, x_1), \dots, h(w_n, x_n)),$$

where  $h : [0, 1]^2 \rightarrow [0, 1]$  is a relevancy transformation (**RET**) operator [4.24, 68] satisfying  $h(0, x) = e$ ,  $h(1, x) = x$ , which is increasing in the second coordinate as well as in the first coordinate for all  $x \geq e$ , while  $h(\cdot, x)$  is decreasing for all  $x \leq e$ . As an example, consider the **RET** operator  $h$  given by

$$h(w, x) = wx + (1-w)e.$$

For more details, we recommend [4.17, Chapter 6].

such distribution functions [4.70]. Some triangle functions are derived from special aggregation functions (triangular norms), some of them have more complex background (as a distinguished example recall the standard convolution of distribution functions). For an overview and details we recommend [4.71, 72].

In 1965, *Zadeh* [4.73] introduced fuzzy sets. Their aggregation, in particular union and intersection, is again built by means of special aggregation functions on  $[0, 1]$ , namely by means of triangular conorms and triangular norms [4.26]. Triangular norms also play an important role in the *Zadeh* extension principle [4.74–76] allowing to extend standard aggregation functions acting on real inputs to the generalized aggregation functions acting on fuzzy inputs. As a typical example recall the arithmetic of fuzzy numbers [4.77]. In some special fuzzy logics also uninorms have found the application in modeling conjunctions. Among recent generalizations of fuzzy set theory recall the type 2-fuzzy sets, including interval-valued fuzzy sets, or

$n$ -fuzzy sets. In all these fields, a deep study of aggregation functions is one of the major theoretical tasks to build a sound background.

Observe that all mentioned particular domains are covered by the aggregation on posets, where up to now

only some particular general results are known [4.22, 78]. We expect an enormous growth of interest in this field, as it can be seen, for example, in its special sub-domain dealing with computing and aggregation with words [4.79–81].

# 5. Monotone Measures-Based Integrals

Erich P. Klement, Radko Mesiar

The theory of classical measures and integral reflects the genuine property of several quantities in standard physics and/or geometry, namely the  $\sigma$ -additivity. Though monotone measure not assuming  $\sigma$ -additivity appeared naturally in models extending the classical ones (for example, inner and outer measures, where the related integral was considered by Vitali already in 1925), their intensive research was initiated in the past 40 years by the computer science applications in areas reflecting human decisions, such as economy, psychology, multicriteria decision support, etc. In this chapter, we summarize basic types of monotone measures together with the basic monotone measures-based integrals, including the Choquet and Sugeno integrals, and we introduce the concept of universal integrals proposed by Klement et al. to give a common roof for all mentioned

integrals. Benvenuti's integrals linked to semicopulas are shown to be a special class of universal integrals. Up to several other integrals, we also introduce decomposition integrals due to Even and Lehrer, and show which decomposition integrals are inside the framework of universal integrals.

Before Cauchy, there was no definition of the integral in the actual sense of the word *definition*, though the integration was already well established and in many areas applied method. Recall that constructive approaches to integration can be traced as far back as the ancient Egypt around 1850 BC; the *Moscow Mathematical Papyrus* (Problem 14) contains a formula of a frustum of a square pyramid [5.1]. The first documented systematic technique, capable of determining integrals, is the method of exhaustion of the ancient Greek astronomer Eudoxus of Cnidos (ca. 370 BC) [5.2] who tried to find areas and volumes by approximating them by a (large) number of shapes for which the area or volume was known. This method was further developed by Archimedes in third-century BC who calculated the area of parabolas and gave an approximation to the area of a circle. Similar methods were independently developed in China around third-century AD by Liu Hui, who used it to find the area of the circle. This

was further developed in the fifth century by the Chinese mathematicians Zu Chongzhi and Zu Geng to find the volume of a sphere. In the same century, the Indian mathematician Aryabhata used a similar method in order to find the circumference of a circle. More than 1000 years later, Johannes Kepler invented the *Kepler'sche Fassregel* [5.3] (also known as *Simpson rule*) in order to compute the (approximative) volume of (wine) barrels.

Based on the fundamental work of Isaac Newton and Gottfried Wilhelm Leibniz in the 18th century (see [5.4, 5]), the first indubitable access to integration was given by Bernhard Riemann in his Habilitation Thesis at the University of Göttingen [5.6]. Note that Riemann has generalized the Cauchy definition of integral defined for continuous real functions (of one variable) defined on a closed interval  $[a, b]$ .

Among several other developments of the integration theory, recall the Lebesgue approach covering

measurable functions defined on a measurable space and general  $\sigma$ -additive measures. Here we recall the final words of H. Lebesgue from his lecture held at a conference in Copenhagen on May 8, 1926, entitled *The Development of the Notion of the Integral* (for the full text see [5.7]):

*... if you will, that a generalization made not for the vain pleasure of generalizing, but rather for the solution of problems previously posed, is always a fruitful generalization. The diverse applications which have already taken the concepts which we have just examine prove this super-abundantly.*

All till now mentioned approaches to integration are related to measurable spaces, measurable real functions and ( $\sigma$ -)additive real-valued measures. Though there are many generalizations and modifications concerning the range and domain of considered functions and measures (and thus integrals), in this chapter we will stay in the above-mentioned framework, with the only exception that the ( $\sigma$ -)additivity of measures is relaxed into their monotonicity, thus covering many natural generalizations of ( $\sigma$ -)additive measures, such as outer or inner measures, lower or upper envelopes of systems of measures, etc.

Maybe the first approach to integration not dealing with the additivity was due to Vitali [5.8]. Vitali was looking for integration with respect to lower/upper measures and his approach is completely covered by the later, more general, approach of Choquet [5.9], see Sect. 5.1. Note that the Choquet integral is a generalization of the Lebesgue integral in the sense

that they coincide whenever the considered measure is  $\sigma$ -additive (i.e., when the Lebesgue integral is meaningful).

A completely different approach, influenced by the starting development of fuzzy set theory [5.10], is due to Sugeno [5.11]. Sugeno even called his integral as fuzzy integral (and considered set functions as fuzzy measures), though there is no fuzziness in this concept (Sect. 5.1). Later, several approaches generalizing or modifying the above-mentioned integrals were introduced. In this chapter, we give a brief overview of these integrals, i.e., integrals based on monotone measures. In the next section, some preliminaries and basic notions are recalled, as well as the Choquet and Sugeno integrals. Section 5.2 brings a generalization of both Choquet and Sugeno integrals, now known as the Benvenuti integral. In Sect. 5.3, universal integrals as a rather general framework for monotone measures-based integral is given and discussed, including copula-based integrals, among others. In Sect. 5.4, we bring some integrals not giving back the underlying measure. Finally, some possible applications are indicated and some concluding remarks are added. Note that we will not discuss integrals defined only for some special subclasses of monotone measures, such as pseudoadditive integrals [5.12, 13] or  $t$ -conorms-based integrals of Weber [5.14]. Moreover, we restrict our considerations to normed measures satisfying  $m(X) = 1$ , and to functions with range contained in  $[0, 1]$ . This is done for the sake of higher transparency and the generalizations for  $m(X) \in ]0, \infty]$  and functions with different ranges will be covered by the relevant quotations only.

## 5.1 Preliminaries, Choquet, and Sugeno Integrals

For a fixed measurable space  $(X, \mathcal{A})$ , where  $\mathcal{A}$  is a  $\sigma$ -algebra of subsets of the universe  $X$ , we denote by  $\mathcal{F}_{(X, \mathcal{A})}$  the set of all  $\mathcal{A}$ -measurable functions  $f : X \rightarrow [0, 1]$ , and by  $\mathcal{M}_{(X, \mathcal{A})}$  the set of all monotone measures  $m : \mathcal{A} \rightarrow [0, 1]$  (i.e.,  $m(\emptyset) = 0$ ,  $m(X) = 1$  and  $m(A) \leq m(B)$  whenever  $A \subset B \subset X$ ). Note that functions  $f$  from  $\mathcal{F}_{(X, \mathcal{A})}$  can be seen as membership functions of fuzzy events on  $(X, \mathcal{A})$ , and that monotone measures are in different references also called fuzzy measures, capacities, pre-measures, etc. Moreover, if  $X$  is finite, we will always consider  $\mathcal{A} = 2^X$  only. In such case, any monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$  is determined by  $2^{|X|} - 2$  weights from  $[0, 1]$  (measures of proper subsets of  $X$ ) constraint by the monotonicity condition only, and to

each monotone measure  $m : \mathcal{A} \rightarrow [0, 1]$  we can assign its Möbius transform  $M_m : \mathcal{A} \rightarrow \mathbb{R}$  given by

$$M_m(A) = \sum_{B \subseteq A} (-1)^{|A \setminus B|} \cdot m(B). \quad (5.1)$$

Then

$$m(A) = \sum_{B \subseteq A} M_m(B). \quad (5.2)$$

Moreover, dual monotone measure  $m^d : \mathcal{A} \rightarrow [0, 1]$  is given by  $m^d(A) = 1 - m(A^c)$ .

Among several distinguished subclasses of monotone measures from  $\mathcal{M}_{(X,\mathcal{A})}$  we recall these classes, supposing the finiteness of  $X$ :

- *Additive* measures,  $m(A \cup B) = m(A) + m(B)$  whenever  $A \cap B = \emptyset$ ;
- *Maxitive* measures,  $m(A \cup B) = m(A) \vee m(B)$  (these measures are called also possibility measures [5.15, 16]);
- *k-additive* measures,  $M_m(A) = 0$  whenever  $|A| > k$  (hence additive measures are 1-additive);
- *Belief* measures,  $M_m(A) \geq 0$  for all  $A \subset X$ ;
- *Plausibility* measures,  $m^d$  is a belief measure;
- *Symmetric* measures,  $M_m(A)$  depends on  $|A|$  only.

For more details on monotone measures, we recommend [5.17–19] and [5.20].

Concerning the functions, for any  $c \in [0, 1], A \in \mathcal{A}$  we define a basic function  $b(c, A) : X \rightarrow [0, 1]$  by

$$b(c, A)(x) = \begin{cases} c & \text{if } x \in A, \\ 0 & \text{else.} \end{cases}$$

Obviously, basic functions can be related to the characteristic functions,  $1_A = b(1, A)$  and  $b(x, A) = c \cdot 1_A$ . However, as we are considering more general types of multiplication as the standard product, in general, we prefer not to depend in our consideration on the standard product.

The first integral introduced for monotone measures was proposed by Choquet [5.9] in 1953.

### Definition 5.1

For a fixed monotone measure  $m \in \mathcal{M}_{(X,\mathcal{A})}$ , a functional  $\text{Ch}_m : \mathcal{F}_{(X,\mathcal{A})} \rightarrow [0, 1]$  given by

$$\text{Ch}_m(f) = \int_0^1 m(f \geq t) dt \quad (5.3)$$

is called the *Choquet integral* (with respect to  $m$ ), where the right-hand side of (5.3) is the classical Riemann integral.

Note that the Choquet integral is well defined because of the monotonicity of  $m$ . Observe that if  $m$  is  $\sigma$ -additive, i. e., if it is a probability measure on  $(X, \mathcal{A})$ , then the function  $h : [0, 1] \rightarrow [0, 1]$  given by  $h(t) = m(f \geq t)$  is the standard survival function of the random variable  $f$ , and then  $\text{Ch}_m(f) = \int_0^1 h(t) dt = \int_X f dm$  is the standard expectation of  $f$  (i. e., Lebesgue integral of  $f$  with respect to  $m$ ).

Due to Schmeidler [5.21, 22], we have the following axiomatization of the Choquet integral.

### Theorem 5.1

A functional  $I : \mathcal{F}_{(X,\mathcal{A})} \rightarrow [0, 1], I(1_X) = 1$ , is the Choquet integral with respect to monotone measure  $m \in \mathcal{M}_{(X,\mathcal{A})}$  given by  $m(A) = I(1_A)$  if and only if  $I$  is comonotone additive, i. e., if  $I(f+g) = I(f) + I(g)$  for all  $f, g \in \mathcal{F}_{(X,\mathcal{A})}$  such that  $f+g \in \mathcal{F}_{(X,\mathcal{A})}$  and  $f$  and  $g$  are comonotone,  $(f(x) - f(y)) \cdot (g(x) - g(y)) \geq 0$  for any  $x, y \in X$ .

We recall some properties of the Choquet integral.

It is evident that the Choquet integral  $\text{Ch}_m$  is an increasing functional,  $\text{Ch}_m(f) \leq \text{Ch}_m(g)$  for any  $m \in \mathcal{M}_{(X,\mathcal{A})}, f, g \in \mathcal{F}_{(X,\mathcal{A})}$  such that  $f \leq g$ . Moreover, for each  $A \in \mathcal{A}$  it holds  $\text{Ch}_m(b(c, A)) = c \cdot m(A)$ , and especially  $\text{Ch}_m(1_A) = m(A)$ .

### Remark 5.1

- Due to results of Šipoš [5.23], see also [5.24], the comonotone additivity of the functional  $I$  in Theorem 5.1, which implies its positive homogeneity,  $I(cf) = c \cdot I(f)$  for all  $c > 0$  and  $f \in \mathcal{F}_{(X,\mathcal{A})}$  such that  $cf \in \mathcal{F}_{(X,\mathcal{A})}$  can be replaced by the positive homogeneity of  $I$  and its horizontal additivity, i. e.,

$$I(f) = I(f \wedge a) + I(f - f \wedge a)$$

for all  $f \in \mathcal{F}_{(X,\mathcal{A})}$  and  $a \in [0, 1]$ .

- Choquet integral  $\text{Ch}_m : \mathcal{F}_{(X,\mathcal{A})} \rightarrow [0, 1]$  is continuous from below,

$$\lim_{n \rightarrow \infty} \text{Ch}_m(f_n) = \text{Ch}_m(f)$$

whenever for  $(f_n)_{n \in \mathbb{N}} \in \mathcal{F}_{(X,\mathcal{A})}^{\mathbb{N}}$  we have  $f_n \leq f_{n+1}$  for all  $n \in \mathbb{N}$  and  $f = \lim_{n \rightarrow \infty} f_n$ , if and only if  $m$  is continuous from below,

$$\lim_{n \rightarrow \infty} m(A_n) = m(A)$$

whenever for  $(A_n)_{n \in \mathbb{N}} \in \mathcal{A}^{\mathbb{N}}$  we have  $A_n \subset A_{n+1}$  for all  $n \in \mathbb{N}$  and  $A = \bigcup_{n \in \mathbb{N}} A_n$ .

- Choquet integral  $\text{Ch}_m : \mathcal{F}_{(X,\mathcal{A})} \rightarrow [0, 1]$  is subadditive (superadditive),

$$I(f+g) \leq I(f) + I(g) \quad (I(f+g) \geq I(f) + I(g))$$

for all  $f, g, f + g \in \mathcal{F}_{(X, \mathcal{A})}$ , if and only if  $m$  is submodular (supermodular),

$$\begin{aligned} m(A \cup B) + m(A \cap B) &\leq m(A) + m(B), \\ (m(A \cup B) + m(A \cap B)) &\geq m(A) + m(B) \end{aligned}$$

for all  $A, B \in \mathcal{A}$ .

iv) For any  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and  $f \in \mathcal{F}_{(X, \mathcal{A})}$  it holds

$$\text{Ch}_{m^d}(f) = 1 - \text{Ch}_m(1-f),$$

i.e., in the framework of aggregation functions [5.25] the dual to a Choquet integral (with respect to a monotone measure  $m$ ) is again the Choquet integral (with respect to the dual monotone measure  $m^d$ ).

For the proofs and more details about the above results on Choquet integral, we recommend [5.18, 19, 24, 26].

Restricting our considerations to finite universes, we have also the next evaluation formula due to Chateauneuf and Jaffray [5.27]

$$\text{Ch}_m(f) = \sum_{A \subseteq X} M_m(A) \cdot \min(f(x) \mid x \in A). \quad (5.4)$$

In the Dempster–Shafer theory of evidence [5.28, 29], belief measures are considered, and then the Möbius transform  $M_m : 2^X \setminus \{\emptyset\} \rightarrow [0, 1]$  of a belief measure  $m$  is called a *basic probability assignment*. Evidently,  $M_m$  can be seen as a probability measure (of singletons) on the finite space  $2^X \setminus \{\emptyset\}$  (with cardinality  $2^{|X|} - 1$ ), and defining a function  $F : 2^X \setminus \{\emptyset\} \rightarrow [0, 1]$  by  $F(A) = \min(f(x) \mid x \in A)$ , the formula (5.4) can be seen as the Lebesgue integral of  $F$  with respect to  $M_m$  (i.e., it is the standard expectation of variable  $F$ )

$$\text{Ch}_m(f) = \sum_{A \in 2^X \setminus \{\emptyset\}} F(A) \cdot M_m(A).$$

Another genuine relationship of Choquet and Lebesgue integrals in the framework of the Dempster–Shafer theory is based on the fact that each belief measure  $m$  can be seen as a lower envelope of the class of dominating probability measures, i.e., for each  $A \subseteq X$  ( $X$  is finite)

$$m(A) = \inf \{P(A) \mid P \geq m\}.$$

Then

$$\text{Ch}_m(f) = \inf \left\{ \int_X f dP \mid P \geq m \right\}.$$

Similarly, for the related plausibility measure  $m^d$ , it holds

$$\begin{aligned} \text{Ch}_{m^d}(f) &= \sup \left\{ \int_X f dP \mid P \leq m^d \right\} \\ &= \sup \left\{ \int_X f dP \mid P \geq m \right\}. \end{aligned}$$

For interested readers, we recommend the collection [5.30].

In general, for any monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and any measurable (continuous from below) function  $f \in \mathcal{F}_{(X, \mathcal{A})}$  there is a probability measure  $P_{m,f}$  on  $(X, \mathcal{A})$  so that

$$\text{Ch}_m(f) = \int_X f dP_{m,f}, \quad (5.5)$$

see, e.g., [5.24, Theorem 2.6], where the right-hand side of (5.5) is the standard Lebesgue integral. Moreover, if  $f, g \in \mathcal{F}_{(X, \mathcal{A})}$  are comonotone, one can find unique probability measure  $P$  allowing to express the Choquet integral of  $f$  and  $g$  with respect to  $m$  as the Lebesgue integral of  $f$  and  $g$  with respect to  $P$ , respectively. As an immediate consequence of (5.5), Jensen's inequality for Choquet integral can be shown to be valid. Similarly, if  $f$  and  $g$  are comonotone, based on the above observations, one can prove the Minkowski and Chebyshev inequality. For more details, see [5.31].

For  $k \in \mathbb{N}$ , consider a probability measure  $P$  on the product space  $(X, \mathcal{A})^k$ , and define a set function  $m : \mathcal{A} \rightarrow [0, 1]$  by  $m(A) = P(A^k)$ . Then  $m \in \mathcal{M}_{(X, \mathcal{A})}$  is a  $k$ -additive monotone measure (and belief measure, as well), and for all  $f \in \mathcal{F}_{(X, \mathcal{A})}$  it holds

$$\text{Ch}_m(f) = \int_{X^k} F dP, \quad (5.6)$$

where  $F : X^k \rightarrow [0, 1]$  is given by  $F(x_1, \dots, x_k) = \min(f(x_1), \dots, f(x_k))$ . For more details see [5.32].

The Sugeno integral (in the original sources called fuzzy integral) was introduced by Sugeno in 1972 in Japanese in [5.33] and in English in 1974 in [5.11]. Inspired by the fuzzy set theory introduced by Zadeh [5.10], Sugeno has proposed a way how to formalize human subjectivity in spirit similar to the randomness but based only on ordinal scales. His concept is not fuzzy, though both fuzzy set theory and Sugeno's integral theory exploit the same aggregation functions (sup and inf), and considering functions  $f \in \mathcal{F}(X, \mathcal{A})$  as membership functions of fuzzy subsets of  $X$ , the corresponding Sugeno integral can be seen as a version of expectation of fuzzy sets.

### Definition 5.2

For a fixed monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$ , a functional  $\text{Su}_m : \mathcal{F}_{(X, \mathcal{A})} \rightarrow [0, 1]$  given by

$$\text{Su}_m(f) = \sup \{ \min(t, m(f \geq t)) \mid t \in [0, 1] \} \quad (5.7)$$

is called the *Sugeno integral* (with respect to  $m$ ).

There is an equivalent formula for the Sugeno integral, compare ([5.11, Definition 3.1]),

$$\text{Su}_m(f) = \sup \{ \min(m(A), \inf \{f(x) \mid x \in A\}) \mid A \in \mathcal{A} \}, \quad (5.8)$$

which in the case of finite  $X$  (and using also lattice notation  $\sup = \vee$ ,  $\min = \wedge$ ) can be rewritten as

$$\text{Su}_m(f) = \bigvee_{A \subset X} (M_m^\vee(A) \wedge \min(f(x) \mid x \in A)), \quad (5.9)$$

showing the striking similarity with the evaluation formula (5.4) for the Choquet integral. Here the set function  $M_m^\vee : 2^X \setminus \{\emptyset\} \rightarrow [0, 1]$  is the so-called possibilistic Möbius transform introduced by Mesiar in [5.34] and given by

$$M_m^\vee(A) = \begin{cases} 0 & \text{if } m(A) = m(B) \text{ for some } B \subsetneq A, \\ m(A) & \text{else.} \end{cases}$$

Sugeno integral has properties similar to the Choquet integral. Indeed, it is nondecreasing functional such that  $\text{Su}_m(b(c, A)) = c \wedge m(A)$ , and in particular  $\text{Su}_m(1_A) = m(A)$ . Moreover,  $\text{Su}_m$  is comonotone maxitive, i.e.,  $\text{Su}_m(f \vee g) = \text{Su}_m(f) \vee \text{Su}_m(g)$  for any comonotone  $f, g \in \mathcal{F}_{(X, \mathcal{A})}$ , and min-homogeneous,  $\text{Su}_m(c \wedge f) = c \wedge \text{Su}_m(f)$ . We have the next axiomatization of the Sugeno integral due to Marichal [5.35] (compare with Theorem 5.1 for the Choquet integral).

### Theorem 5.2

A functional  $I : \mathcal{F}_{(X, \mathcal{A})} \rightarrow [0, 1]$ ,  $I(1_X) = 1$ , is the Sugeno integral with respect to monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$  given by  $m(A) = I(1_A)$  if and only if  $I$  is comonotone maxitive and min-homogeneous.

For alternative axiomatizations see [5.24].

Choquet and Sugeno integrals with respect to a monotone measure  $m$  may differ not more than  $\frac{1}{4}$ , i.e., for all  $f \in \mathcal{F}_{(X, \mathcal{A})}$  it holds

$$|\text{Ch}_m(f) - \text{Su}_m(f)| \leq \frac{1}{4}.$$

Moreover,  $\text{Ch}_m(f) = \text{Su}_m(f)$  for all  $f \in \mathcal{F}_{(X, \mathcal{A})}$  if and only if  $m(A) \in \{0, 1\}$  for all  $A \in \mathcal{A}$ , and then

$$\text{Ch}_m(f) = \text{Su}_m(f) = \sup \{ \inf \{f(x) \mid x \in A\} \mid m(A) = 1 \},$$

which in case  $X$  is finite turns out to be a lattice polynomial.

Note that if  $X$  has cardinality  $n$  and  $m(A) \in \{0, 1\}$  for all  $A \subseteq X$ , then  $\text{Ch}_m = \text{Su}_m : [0, 1]^n \rightarrow [0, 1]$  are the only  $n$ -ary continuous aggregation functions invariant under each automorphism  $\phi : [0, 1] \rightarrow [0, 1]$ , i.e.,  $\phi \circ \text{Ch}_m(f) = \text{Ch}_m(f \circ \phi)$  for each  $f : [0, 1]^n$  (for  $f = (a_1, \dots, a_n), f \circ \phi = (\phi(a_1), \dots, \phi(a_n))$ ). For more details see [5.36].

### Example 5.1

i) Let  $X = \{1, 2, 3\}$  and define  $m : 2^X \rightarrow [0, 1]$  by

$$m(A) = \begin{cases} 0 & \text{if card } A \leq 1, \\ 1 & \text{otherwise.} \end{cases}$$

Then, for each  $f = (x, y, z) \in [0, 1]^3$ ,

$$\begin{aligned} \text{Ch}_m(f) &= \text{Su}_m(f) = (x \wedge y) \vee (x \wedge z) \vee (y \wedge z) \\ &= \text{med}(x, y, z) \end{aligned}$$

brings the classical median.

ii) Let  $X = \{1, 2\}$  and define  $m : 2^X \rightarrow [0, 1]$  by  $m(A) = \frac{\text{card } A}{2}$ . Then, for each  $f = (x, y) \in [0, 1]^2$ ,

$$\text{Ch}_m(f) = \frac{x + y}{2}$$

(i.e.,  $\text{Ch}_m$  is the standard arithmetic mean), while

$$\text{Su}_m(f) = (x \wedge y) \vee \left( (x \vee y) \wedge \frac{1}{2} \right).$$

For  $f_1 = \left(\frac{1}{2}, 1\right)$ ,  $\text{Ch}_m(f_1) = \frac{3}{4}$  and  $\text{Su}_m(f_1) = \frac{1}{2}$ .  
For  $f_2 = \left(0, \frac{1}{2}\right)$ ,  $\text{Ch}_m(f_2) = \frac{1}{4}$  and  $\text{Su}_m(f_2) = \frac{1}{2}$ .

In general,

$$|\text{Ch}_m(f) - \text{Su}_m(f)| = \frac{1}{2} (|x-y| \wedge |x+y-1|) \leq \frac{1}{4}.$$

- iii) Let  $X = [0, 1]$ ,  $\mathcal{A} = \mathcal{B}([0, 1])$  and let  $m: \mathcal{A} \rightarrow [0, 1]$  be given by  $m(A) = \lambda^p(A)$ , where  $p \in ]0, \infty[$  is a fixed constant and  $\lambda: \mathcal{A} \rightarrow [0, 1]$  is the standard Lebesgue measure. For any Lebesgue measure preserving function  $f: X \rightarrow [0, 1]$ , such as  $f(x) = x$ ,  $f(x) = 1-x$ , or  $f(x) = |2x-1|$ , we have

$$\text{Ch}_m(f) = \int_0^1 m(f \geq t) dt = \int_0^1 (1-t)^p dt = \frac{1}{p+1}$$

and

$$\text{Su}_m(f) = \sup \{ \min(t, (1-t)^p) \mid t \in [0, 1] \} = c_p,$$

where  $c_p$  is the unique solution of the equation  $t = (1-t)^p$ ,  $t \in ]0, 1[$ . Hence,

$$\text{if } p = 1, \text{Ch}_m(f) = \text{Su}_m(f) = \frac{1}{2};$$

$$\text{if } p = 2, \text{Ch}_m(f) = \frac{1}{3}$$

$$\text{and } \text{Su}_m(f) = \frac{3-\sqrt{5}}{2} \doteq 0.382;$$

$$\text{if } p = 3, \text{Ch}_m(f) = \frac{2}{3}$$

$$\text{and } \text{Su}_m(f) = \frac{\sqrt{5}-1}{2} \doteq 0.618.$$

## 5.2 Benvenuti Integral

Comparing Theorems 5.1 and 5.2, we see a striking similarity in the axiomatic characterization of the Choquet and Sugeno integrals. This similarity was generalized under a common roof by Benvenuti et al. [5.24], calling there introduced integral *general fuzzy integral*. This integral is now also known as Benvenuti integral (compare [5.25]).

Choquet integral is linked to the standard arithmetic operations  $+$  and  $\cdot$  on  $[0, \infty]$ , while the Sugeno integral deals with lattice operations  $\wedge$  and  $\vee$  on  $[0, 1]$ . To generalize these two couples of operations, pseudoaddition  $\oplus$  and pseudomultiplication  $\odot$  was introduced in [5.24].

### Definition 5.3

Let  $u \in [1, \infty]$  be a fixed constant. An operation  $\oplus: [0, u]^2 \rightarrow [0, u]$  is called a *pseudoaddition* on  $[0, u]$  whenever it is associative, nondecreasing in both components, 0 is its neutral element, and  $\oplus$  is continuous.

Observe that the structure  $([0, u], \oplus)$  with  $\oplus$  a pseudoaddition on  $[0, u]$  is just an *I-semigroup* of Mostert and Shields [5.37] and hence  $\oplus$  is also commutative. Moreover, considering the principles of Galois connections, we can introduce a *pseudodifference*  $\ominus$  related to  $\oplus$  satisfying, for all  $a, b, c \in [0, u]$ ,  $(a \ominus b) \leq c$  if and only if  $a \leq b \ominus c$ .

It is not difficult to see the link to the pseudodifference considered already by Weber [5.14].

### Lemma 5.1

Let  $\oplus: [0, u]^2 \rightarrow [0, u]$  be a given pseudoaddition on  $[0, u]$ . The related pseudo difference  $\ominus: [0, u]^2 \rightarrow [0, u]$  is given by

$$a \ominus b = \inf \{c \in [0, u] \mid b \oplus c \geq a\}.$$

Considering the standard addition  $+$  on  $[0, \infty]$ , and  $a \geq b$ , then the corresponding (pseudo-) difference is the standard difference  $a - b$ . On the other hand,  $\vee$  is a pseudoaddition on any interval  $[0, u]$ , and its corresponding pseudodifference  $\ominus_\vee$  is given by

$$a \ominus_\vee b = \begin{cases} 0 & \text{if } a \leq b, \\ a & \text{otherwise.} \end{cases}$$

Due to [5.37], each pseudoaddition  $\oplus$  on  $[0, u]$  can be represented as an ordinal sum,

$$a \oplus b = \begin{cases} g_k^{-1}(g_k(\beta_k) \wedge (g_k(a) + g_k(b))) & \text{if } (a, b) \in ]\alpha_k, \beta_k[^2, \\ a \vee b & \text{otherwise,} \end{cases}$$

where  $(]\alpha_k, \beta_k[_{k \in \mathcal{K}}$  is a disjoint system of open subintervals of  $[0, u]$ , and  $g_k: [\alpha_k, \beta_k] \rightarrow [0, \infty]$  is a continuous strictly increasing function such that  $g_k(\alpha_k) = 0, k \in \mathcal{K}$  ( $\mathcal{K}$  can be also empty). Two extremal cases correspond to  $\oplus = \vee$  (when  $\mathcal{K}$  is empty) and

Archimedean pseudoaddition  $\oplus$  on  $[0, u]$  generated by  $g : [0, u] \rightarrow [0, \infty]$  (when  $\mathcal{K}$  is singleton, say  $\mathcal{K} = \{1\}$ , and  $\alpha_1 = 0, \beta_1 = u$ ),

$$a \oplus b = g^{-1}(g(u) \wedge (g(a) + g(b))) .$$

Then  $g$  is called an *additive generator* of  $\oplus$  and it is unique up to a positive multiplicative constant.

Note that if  $g$  is a bijection, i.e.,  $g(u) = \infty$ , then  $a \oplus b = g^{-1}(g(a) + g(b))$  and  $\oplus$  is called a *strict pseudoaddition*.

For a fixed pseudoaddition  $\oplus$  on  $[0, u]$ , Benvenuti et al. [5.24] have introduced a  $\oplus$ -fitting pseudomultiplication  $\odot$ .

#### Definition 5.4

Fix  $u, v \in [1, \infty]$  and let  $\oplus$  be a given pseudoaddition on  $[0, u]$ . A mapping  $\odot : [0, u] \times [0, v] \rightarrow [0, u]$  is called a  $\oplus$ -fitting pseudomultiplication whenever it is nondecreasing in both components, 0 is its annihilator, i.e.,  $0 \odot b = a \odot 0 = 0$  for all  $a \in [0, u], b \in [0, v]$ , it is left distributive over  $\oplus$ , i.e.,  $(a \oplus b) \odot c = (a \odot c) \oplus (b \odot c)$  for all  $a, b \in [0, u], c \in [0, v]$ , and it is lower semicontinuous, i.e.,

$$(\vee_{n \in \mathbb{N}} a_n) \odot (\vee_{m \in \mathbb{N}} b_m) = \vee_{n, m \in \mathbb{N}} (a_n \odot b_m) .$$

The left distributivity of a pseudomultiplication  $\odot$  over  $\vee$  simply means the nondecreasingness of  $\odot$  in the first coordinate, and thus there are several kinds of  $\vee$ -fitting pseudomultiplication  $\odot$ . On the other hand, this is a rather restrictive constraint when  $\oplus$  is Archimedean, i.e., generated by an additive generator  $g : [0, u] \rightarrow [0, \infty]$ .

#### Proposition 5.1

Let  $\oplus : [0, u]^2 \rightarrow [0, u]$  be an Archimedean pseudoaddition generated by an additive generator  $g : [0, u] \rightarrow [0, \infty]$ . A mapping  $\odot : [0, u] \times [0, v] \rightarrow [0, u]$  is a  $\oplus$ -fitting pseudomultiplication if and only if there is a lower semicontinuous nondecreasing function  $h : [0, v] \rightarrow [0, \infty]$  such that  $h(w) = 0$  for some  $w \in [0, v]$ , and  $g(u) \cdot h(a) \geq g(u)$  for all  $a \in ]w, v]$ , so that

$$a \odot b = g^{-1}(g(u) \wedge g(a) \cdot h(b)) .$$

In particular, if  $\oplus$  is a strict pseudoaddition, then  $h : [0, v] \rightarrow [0, \infty]$  is a lower semicontinuous nondecreasing function, satisfying  $h(0) = 0$ , and  $a \odot b = g^{-1}(g(a) \cdot h(b))$ .

#### Definition 5.5

Let  $u, v \in [1, \infty]$  be fixed given constants and let  $\oplus : [0, u]^2 \rightarrow [0, u]$  be a given pseudoaddition, and  $\odot : [0, u] \times [0, v] \rightarrow [0, u]$  be a given  $\oplus$ -fitting pseudomultiplication such that  $1 \odot 1 \leq 1$ . For a fixed monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$ , a functional  $\mathcal{B}_m^{\oplus, \odot} : \mathcal{F}_{(X, \mathcal{A})} \rightarrow [0, 1]$  given by

$$\mathcal{B}_m^{\oplus, \odot}(f) = \sup \left\{ \bigoplus_{i=1}^n (a_i \odot m(A_i)) \mid n \in \mathbb{N}, \right. \\ \left. \bigoplus_{i=1}^n b(a_i, A_i) \leq f, (A_i)_{i=1}^n \text{ is a chain} \right\}$$

is called Benvenuti integral (with respect to  $m$ , based on  $\oplus$  and  $\odot$ ).

Observe that if  $s \in \mathcal{F}_{(X, \mathcal{A})}$  is a simple function, range  $s = \{b_1, \dots, b_n\}, b_1 < b_2 < \dots < b_n$ , then

$$\mathcal{B}_m^{\oplus, \odot}(s) = \bigoplus_{i=1}^n ((b_i \ominus b_{i-1}) \odot m(s \geq b_i)) ,$$

with the convention  $b_0 = 0$ . Then for any  $f \in \mathcal{F}_{(X, \mathcal{A})}$ ,

$$\mathcal{B}_m^{\oplus, \odot}(f) \\ = \sup \left\{ \mathcal{B}_m^{\oplus, \odot}(s) \mid s \in \mathcal{F}_{(X, \mathcal{A})} \text{ is simple, } s \leq f \right\} .$$

Evidently,

$$\mathcal{B}_m^{\oplus, \odot}(b(a, A)) = a \odot m(A)$$

and hence

$$\mathcal{B}_m^{\oplus, \odot}(1_A) = m(A)$$

for all  $m \in \mathcal{M}_{(X, \mathcal{A})}, A \in \mathcal{A}$  only if  $1 \odot b = b$  for all  $b \in [0, 1]$ .

If  $\oplus$  is a strict pseudoaddition on  $[0, u]$  generated by an additive generator  $g$ , this means that  $\odot$  restricted to  $[0, 1]^2$  is given by

$$a \odot b = g^{-1}\left(\frac{g(a) \cdot g(b)}{g(1)}\right) .$$

If  $\oplus$  is a nonstrict pseudoaddition, then there is no  $\oplus$ -fitting pseudomultiplication  $\odot$  such that  $1 \odot b = b$  for all  $b \in [0, 1]$ .

Note that for the standard arithmetic operations  $+$  and  $\cdot$  on  $[0, \infty]$ ,  $\mathcal{B}_m^{+, \cdot} = \text{Ch}_m$ , i.e., the Choquet integral is recovered. Similarly,  $\mathcal{B}_m^{\vee, \wedge} = \text{Su}_m$ .

**Example 5.2**

- i) Let  $u = v = 1$ ,  $\oplus = \vee$  and  $\odot : [0, 1]^2 \rightarrow [0, 1]$  be given by  $a \odot b = a^p \cdot b^q$ ,  $p, q \in ]0, \infty[$ . Then  $\mathcal{B}_m^{\oplus, \odot}(f) = \sup \{t^p \cdot (m(f \geq t))^q \mid t \in [0, 1]\}$  for any  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and  $f \in \mathcal{F}_{(X, \mathcal{A})}$ , and  $\mathcal{B}_m^{\oplus, \odot}(1_A) = (m(A))^q$ . Note that if  $p = q = 1$ , the Shilkret integral  $\text{Sh}_m = \mathcal{B}_m^{\oplus, \odot}$  is recovered, see [5.19, 38]. In general,  $\mathcal{B}_m^{\oplus, \odot}(f) = \text{Sh}_{m^q}(f^p)$  for any  $f \in \mathcal{F}_{(X, \mathcal{A})}$ .
- ii) For a strict pseudoaddition  $\oplus$  on  $[0, u]$  and a  $\oplus$ -fitting pseudomultiplication  $\odot$  on  $[0, u] \times [0, v]$ , see Proposition 5.1, the constraint  $1 \odot 1 \leq 1$  means  $h(b) \leq 1$ , and then  $\mathcal{B}_m^{\oplus, \odot}(f) = g^{-1}(\text{Ch}_{h(m)}(g(f)))$ , i.e.,  $\mathcal{B}_m^{\oplus, \odot}$  is obtained as a transformation of the Choquet integral.

For more details, we recommend the original source [5.24], but also [5.25, 39].

**Remark 5.2**

When considering  $u = 1$ , a pseudoaddition  $\oplus$  on  $[0, 1]$

## 5.3 Universal Integrals

The concept of universal integrals on  $[0, \infty]$  was proposed and discussed in [5.44]. As already mentioned, we will restrict our considerations to the interval  $[0, 1]$ .

**Definition 5.6**

Let  $S$  be the class of all measurable spaces. A mapping

$$I : \bigcup_{(X, \mathcal{A}) \in S} (\mathcal{M}_{(X, \mathcal{A})} \times \mathcal{F}_{(X, \mathcal{A})}) \rightarrow [0, 1]$$

is called a universal integral whenever it satisfies

- UI1  $I$  is nondecreasing in both components;
- UI2 there is a semicopula  $\otimes : [0, 1]^2 \rightarrow [0, 1]$  (i.e.,  $\otimes$  is nondecreasing in both components and  $1 \otimes a = a \otimes 1$  for all  $a \in [0, 1]$ ) such that  $I(m, b(a, E)) = a \otimes m(E)$  for all  $a \in [0, 1]$ , any  $(X, \mathcal{A}) \in S$ ,  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and  $E \in \mathcal{A}$ ;
- UI3  $I(m_1, f_1) = I(m_2, f_2)$  whenever  $(m_i, f_i) \in (X_i, \mathcal{A}_i)$ ,  $i = 1, 2$ , and  $m_1(f_1 \geq t) = m_2(f_2 \geq t)$  for all  $t \in [0, 1]$ .

Observe that the axiom (UI1) reflects the standard monotonicity of integrals. On the other hand,

becomes a (continuous)  $t$ -conorm. Integrals based on  $t$ -conorms closely related to Benvenuti integrals were discussed by Murofushi and Sugeno [5.40], resulting to the two classes of  $t$ -conorm based integrals. Those based on the smallest  $t$ -conorm  $\vee$  coincide with Benvenuti integral based on  $\vee$ , with stronger requirements on the corresponding  $\vee$ -fitting pseudomultiplication  $\odot$ . The second one, based on continuous Archimedean  $t$ -conorms, is a special transform of the Choquet integral, compare Example 5.2 ii),

$$\text{MS}_m(f) = k(\text{Ch}_{h(m)}(g(f))),$$

with appropriately chosen functions  $k, h, g : [0, 1] \rightarrow [0, \infty]$ . Note that the Murofushi–Sugeno integral covers also the integral of Weber [5.14] based on strict  $t$ -conorms. Another closely related approach to integration, fixing  $u = v = \infty$ , can be found in [5.41], where Choquet-like integrals were introduced and discussed. For more details on these types of integrals we refer to [5.42, 43].

(UI2) expresses the fact that an integral of a basic function  $b(a, E)$  with respect to a monotone measure  $m$  depends on the values  $a$  and  $m(E)$  only, independently of the considered measurable space  $(X, \mathcal{A})$  and a monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$  (compare the truth values principle in the propositional logics). Finally, (UI3) generalizes the well-known fact from the probability theory that two random variables (defined possibly on two different probability spaces) have the same expectation whenever their distribution functions coincide (in fact, for a probability measure  $P$ ,  $P(f \geq t)$  defines a survival function which is complementary to the related distribution function).

There are several construction methods for universal integrals. First of all, for any given semicopula  $\otimes : [0, 1]^2 \rightarrow [0, 1]$ , one can introduce the smallest universal integral  $I_\otimes$  and the greatest universal integral  $I^\otimes$  related to  $\otimes$  through (UI2):

$$I_\otimes(m, f) = \sup \{t \otimes m(f \geq t) \mid t \in [0, 1]\}$$

and

$$I^\otimes(m, f) = \text{essup}_m(f) \otimes m(\text{supp } f),$$

where

$$\text{essup}_m(f) = \sup \{t \in [0, 1] | m(f \geq t) > 0\}$$

and

$$\text{supp } f = \{x \in X | f(x) > 0\}.$$

Observe that  $I_{\wedge}(m, \cdot) = \text{Su}_m$  is the Sugeno integral,  $I_{\Pi}(m, \cdot) = \text{Sh}_m$  is the Shilkret integral ( $\Pi$  denotes the product semicopula), while  $I_T$  with  $T$  a strict  $t$ -norm is an integral introduced by Weber in [5.45].

Considering the Benvenuti integral based on a pseudodaddition  $\oplus$  on  $[0, u]$  and a  $\oplus$ -fitting pseudomultiplication  $\odot : [0, u] \times [0, v] \rightarrow [0, u]$ ,  $u, v \in [1, \infty]$ , such that  $\otimes = \odot|_{[0, 1]^2}$  is a semicopula, one get a universal integral given by

$$I^{\oplus, \otimes}(m, f) = \mathcal{B}_m^{\oplus, \odot}(f).$$

Note that  $I^{+, \cdot}(m, f) = \text{Ch}_m(f)$  and  $I^{\vee, \wedge}(m, f) = \text{Su}_m(f)$ .

As an important class of universal integrals we introduce copula-based integrals. Recall that a semicopula  $C : [0, 1]^2 \rightarrow [0, 1]$  is called a copula [5.46] whenever it is supermodular, i.e., for any  $x, y \in [0, 1]^2$  it holds

$$C(x \vee y) + C(x \wedge y) \geq C(x) + C(y).$$

Note that there is a one-to-one correspondence between copulas and probability measures on Borel subsets of  $[0, 1]^2$  with uniformly distributed margins, this relation is stated by the equality

$$P_C([0, a] \times [0, b]) = C(a, b), \quad (a, b) \in [0, 1]^2.$$

The next result is extracted from [5.44], also compare [5.47, 48].

### Proposition 5.2

Let  $C : [0, 1]^2 \rightarrow [0, 1]$  be a fixed copula. Then the mapping

$$K_C : \bigcup_{(X, \mathcal{A}) \in S} (\mathcal{M}_{(X, \mathcal{A})} \times \mathcal{F}_{(X, \mathcal{A})}) \rightarrow [0, 1]$$

given by

$$K_C(m, f) = P_C(\{(u, v) \in [0, 1]^2 | v \leq m(f \geq u)\})$$

is a universal integral (with  $C$  being the corresponding semicopula).

Note that for the product copula  $\Pi$ ,  $K_{\Pi}(m, \cdot) = \text{Ch}_m$  is the Choquet integral, while for the greatest copula  $\wedge = \text{Min}$ ,  $K_{\wedge}(m, \cdot) = \text{Su}_m$  is the Sugeno integral. For the smallest copula  $W : [0, 1]^2 \rightarrow [0, 1]$  given by

$$W(a, b) = \max(0, a + b - 1),$$

$K_W$  was called *opposite Sugeno integral* in [5.49] and it is given by

$$K_W(m, f) = \lambda(\{t \in [0, 1] | m(f \geq t) \geq 1 - t\}),$$

where  $\lambda$  is the standard Lebesgue measure on Borel subsets of  $[0, 1]$ .

### Remark 5.3

The class of universal integrals is convex, i.e., for  $I_1, I_2$  universal integrals and a constant  $c \in [0, 1]$ , also

$$I = cI_1 + (1 - c)I_2$$

is a universal integral (related to the semicopula  $\odot = c \cdot \odot_1 + (1 - c) \cdot \odot_2$ ).

Though the class of semicopulas is also convex, for the weakest universal integrals we can ensure only the inequality

$$I_{c \cdot \odot_1 + (1 - c) \cdot \odot_2} \leq cI_{\odot_1} + (1 - c)I_{\odot_2}.$$

On the other hand, for the convex class of copulas it holds

$$K_{cC_1 + (1 - c)C_2} = cK_{C_1} + (1 - c)K_{C_2},$$

i.e., the class of copula-based integrals is convex.

## 5.4 General Integrals Which Are Not Universal

There are several integrals defined on any measurable space  $(X, \mathcal{A})$ , for any monotone measure  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and any function  $f \in \mathcal{F}_{(X, \mathcal{A})}$  which are not universal. We recall two of them based on the standard arithmetic operations  $+$  and  $\cdot$ .

### Definition 5.7

A mapping

$$G : \bigcup_{(X, \mathcal{A}) \in S} (\mathcal{M}_{(X, \mathcal{A})} \times \mathcal{F}_{(X, \mathcal{A})}) \rightarrow [0, \infty]$$

given by

$$G(m, f) = \sup \left\{ \sum_{i=1}^n a_i \cdot m(A_i) \mid n \in \mathbb{N}, a_1, \dots, a_n \geq 0, \right.$$

$$\left. \sum_{i=1}^n b(a_i, A_i) \leq f \text{ and } (A_i)_{i=1}^n \text{ is a disjoint subsystem of } \mathcal{A} \right\}$$

is called a PAN-integral.

Note that this integral was introduced by Yang [5.50], see also [5.51] in more general setting on  $[0, \infty]$  involving operations  $\oplus$  and  $\odot$ . Due to the results of [5.52], each PAN-integral on  $[0, 1]$  is either a transformation of integral given in Definition 5.7,  $I(m, f) = g^{-1}(G(g(m), g(f)))$  for some automorphism  $g : [0, 1] \rightarrow [0, 1]$ , or if  $\oplus = \vee$ , it is a special instant of integrals  $I_\odot$  discussed in Sect. 5.3. Also observe that a deep discussion on PAN-integral  $G$  can be found in [5.53].

PAN-integral allows one to recognize the underlying monotone measure  $m$  only if  $m$  is superadditive. Moreover, as a major defect of this integral we recall that it does not exclude the equality of integrals based on two different monotone measures, i.e., there are monotone measures  $m_1, m_2 \in \mathcal{M}_{(X, \mathcal{A})}$ ,  $m_1 \neq m_2$ , such that  $G(m_1, f) = G(m_2, f)$  for all  $f \in \mathcal{F}_{(X, \mathcal{A})}$ . Note that PAN-integral coincide with the Lebesgue integral whenever  $m$  is  $\sigma$ -additive. A similar situation is linked to the concave integral introduced by Lehrer [5.54], see also [5.55].

### Definition 5.8

A mapping

$$L : \bigcup_{(X, \mathcal{A}) \in S} (\mathcal{M}_{(X, \mathcal{A})} \times \mathcal{F}_{(X, \mathcal{A})}) \rightarrow [0, \infty]$$

given by

$$L(m, f) = \sup \left\{ \sum_{i=1}^n a_i \cdot m(A_i) \mid n \in \mathbb{N}, \right.$$

$$\left. a_1, \dots, a_n \geq 0, \sum_{i=1}^n b(a_i, A_i) \leq f \right\}$$

is called a concave integral.

Observe that this integral is concave in the sense that for each  $m \in \mathcal{M}_{(X, \mathcal{A})}$ ,  $f, g \in \mathcal{F}_{(X, \mathcal{A})}$  and  $c \in [0, 1]$ ,

$$L(m, cf + (1 - c)g) \geq cL(m, f) + (1 - c)L(m, g).$$

Concave integral coincides with the Choquet integral whenever  $m$  is supermodular. However, also here  $L(m_1, f) = L(m_2, f)$  may hold for all  $f \in \mathcal{F}_{(X, \mathcal{A})}$  for some monotone measures  $m_1, m_2 \in \mathcal{M}_{(X, \mathcal{A})}$ ,  $m_1 \neq m_2$ . Finally, recall that it trivially holds

$$L(m, f) \geq G(m, f) \text{ and } L(m, f) \geq \text{Ch}_m(f)$$

for all  $m \in \mathcal{M}_{(X, \mathcal{A})}$  and  $f \in \mathcal{F}_{(X, \mathcal{A})}$ .

### Example 5.3

- i) Consider  $X = [0, 1]$ ,  $\mathcal{A} = \mathcal{B}([0, 1])$  and  $\lambda$  the standard Lebesgue measure on  $\mathcal{A}$ . Let  $m = \lambda^p$ ,  $p \in ]0, 1[$ . Then for any  $f \in \mathcal{F}_{(X, \mathcal{A})}$  with nonvanishing support (i.e.,  $m(f > 0) > 0$ ) it holds

$$G(m, f) = L(m, f) = +\infty.$$

On the other hand, for  $m = \lambda^2$  (observe that  $m$  is supermodular, and thus also superadditive) we get, considering  $f = \text{id}_X$ ,

$$G(m, f) = \frac{2}{13} \text{ while } L(m, f) = \text{Ch}_m(f) = \frac{1}{3}.$$

- ii) For  $X = \{1, 2, 3\}$  and  $\mathcal{A} = 2^X$ , let  $m_a : \mathcal{A} \rightarrow \mathbb{R}$  be given by  $m_a(\emptyset) = 0$ ,  $m_a(A) = 0.1$  if  $\text{card } A = 1$ ,

$m_a(A) = a$  if  $\text{card } A = 2$  and  $m_a(X) = 1$ . Evidently,  $m_a \in \mathcal{M}_{(X, \mathcal{A})}$  if and only if  $a \in [0.1, 1]$ . Let  $f \in \mathcal{F}_{(X, \mathcal{A})}$  be given by  $f(1) = \frac{1}{3}, f(2) = \frac{2}{3}, f(3) = 1$ . Then

$$\begin{aligned} G(m_a, f) &= \sup \left\{ \frac{1}{3} \cdot 1, \frac{1}{3} \cdot 0.1 + \frac{2}{3} \cdot a \right\} \\ &= \begin{cases} \frac{1}{3} & \text{if } a \in [0.1, 0.45], \\ \frac{0.1+2a}{3} & \text{if } a \in ]0.45, 1], \end{cases} \end{aligned}$$

and

$$\begin{aligned} L(m_a, f) &= \sup \left\{ \frac{1}{3} \cdot 1 + \frac{1}{3} \cdot a + \frac{1}{3} \cdot 0.1, \frac{1}{3} \cdot 1 \right. \\ &\quad \left. + \frac{1}{3} \cdot 0.1 + \frac{2}{3} \cdot 0.1, \frac{1}{3} \cdot a + \frac{2}{3} \cdot a \right\} \\ &= \begin{cases} \frac{1.3}{3} & \text{if } a \in [0.1, 0.2[, \\ \frac{1.1+a}{3} & \text{if } a \in [0.2, 0.55[, \\ a & \text{if } a \in ]0.55, 1]. \end{cases} \end{aligned}$$

Moreover,

$$\text{Ch}_{m_a}(f) = \frac{1.1+a}{3}.$$

Observe that  $m_a$  is supermodular if and only if  $a \in [0.2, 0.55]$  and then

$$L(m_a, f) = \text{Ch}_{m_a}(f) = \frac{1.1+a}{3}.$$

- iii) For  $X$  finite and  $m \in \mathcal{M}_{(X, \mathcal{A})}$  such that  $m(A) \in \{0, 1\}$  for all  $A \subseteq X$ , all universal integrals coincide, independently of the underlying semicopula  $\otimes$ ,  $I_m(f) = \sup \{\min(f(x)|x \in A) | m(A) = 1\}$ . However, this does not hold for PAN-integral  $G(m, \cdot)$  neither for the concave integral  $L(m, \cdot)$ . Consider as an example the greatest monotone measure  $m^* \in \mathcal{M}_{(X, 2^X)}$  given by

$$m^*(A) = \begin{cases} 0 & \text{if } A = \emptyset, \\ 1 & \text{else.} \end{cases}$$

Then for any universal integral  $I$  it holds  $I(m^*, f) = \max(f(x)|x \in X)$ , but  $G(m^*, f) = L(m^*, f) = \sum_{x \in X} f(x)$ .

- iv) The only monotone measures  $m \in \mathcal{M}_{(X, 2^X)}$ ,  $X$  finite, such that all universal integrals as well as the

PAN and concave integrals coincide, are so-called unanimity measures

$$m_B, B \subseteq X, B \neq \emptyset, m_B(A) = \begin{cases} 1 & \text{if } B \subseteq A, \\ 0 & \text{else.} \end{cases}$$

Then

$$\begin{aligned} I(m_B, f) &= G(m_B, f) = L(m_B, f) \\ &= \min(f(x)|x \in B). \end{aligned}$$

Recently, a new concept of decomposition integrals was proposed in [5.56], unifying the PAN integral  $G$ , the concave integral  $L$ , the Choquet integral  $\text{Ch}$ , and the Shilkret integral  $\text{Sh}$ .

#### Definition 5.9

Let  $(X, \mathcal{A})$  be a measurable space and let  $\mathcal{H}$  be a system of some finite subsystems (i. e., of collections) from  $\mathcal{A}$ . Then the mapping

$$D_{\mathcal{H}} : \mathcal{M}_{(X, \mathcal{A})} \times \mathcal{F}_{(X, \mathcal{A})} \rightarrow [0, \infty]$$

given by

$$\begin{aligned} D_{\mathcal{H}}(m, f) &= \sup \left\{ \sum_{i \in I} a_i \cdot m(A_i) | a_i \geq 0, i \in I, \right. \\ &\quad \left. \sum_{i \in I} b(a_i, A_i) \leq f, (A_i)_{i \in I} \in \mathcal{H} \right\} \end{aligned}$$

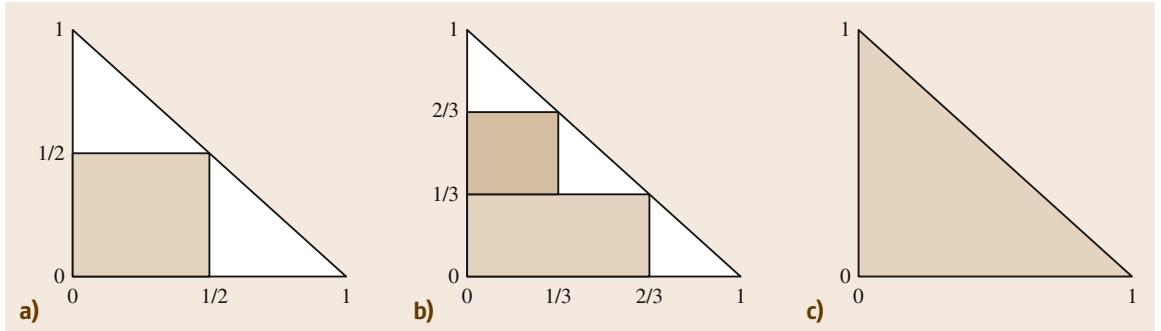

is called a  $\mathcal{H}$ -decomposition integral.

Consider the next decomposition systems

$$\begin{aligned} \mathcal{H}^{(n)} &= \{(A_i)_{i=1}^n \text{ is a chain in } \mathcal{A}\}, n \in \mathbb{N}; \\ \mathcal{H}_G &= \{(A_i)_{i \in I} \text{ is a finite measurable partition of } X\}; \\ \mathcal{H}_L &= \mathcal{A}; \\ \mathcal{H}_{\text{Ch}} &= \{\mathcal{B} | \mathcal{B} \text{ is a finite chain in } \mathcal{A}\}. \end{aligned}$$

Then

$$\begin{aligned} D_{\mathcal{H}^{(1)}}(m, \cdot) &= \text{Sh}_m; \\ D_{\mathcal{H}_G}(m, \cdot) &= G; \\ D_{\mathcal{H}_L}(m, \cdot) &= L; \\ D_{\mathcal{H}_{\text{Ch}}}(m, \cdot) &= \text{Ch}_m. \end{aligned}$$

**Fig. 5.1a–c** The function  $\lambda(\text{id}_X \geq t)$  with shaded areas expressing the corresponding integrals  $D_{\mathcal{H}^{(1)}}(\lambda, \text{id}_X)$  (a),  $D_{\mathcal{H}^{(2)}}(\lambda, \text{id}_X)$  (b),  $\text{Ch}_\lambda(\text{id}_X)$  (c)

Further, the only decomposable integrals which are also universal integrals are the Choquet integral and  $\mathcal{H}^{(n)}$ -decomposition integrals  $D_{\mathcal{H}^{(n)}}$  and they satisfy

$$\text{Sh} = D_{\mathcal{H}^{(1)}} \leq D_{\mathcal{H}^{(2)}} \leq \dots \leq D_{\mathcal{H}^{(n)}} \leq \dots \leq \text{Ch}.$$

Observe that if  $X$  is finite,  $\text{card } X = n$ , then  $D_{\mathcal{H}^{(n)}} = \text{Ch}$  and that

$$\text{Ch} = \lim_{n \rightarrow \infty} D_{\mathcal{H}^{(n)}} = \sup \{D_{\mathcal{H}^{(n)}} \mid n \in \mathbb{N}\}.$$

For more details and further discussion about decomposition integrals, we recommend [5.56–58].

#### Example 5.4

Using the notation from Example 5.3 i), it holds

$$D_{\mathcal{H}^{(n)}}(\lambda, \text{id}_X) = \frac{n}{2(n+1)}$$

and

$$\lim_{n \rightarrow \infty} \frac{n}{2(n+1)} = \frac{1}{2} = \text{Ch}_\lambda(\text{id}_X).$$

For better understanding, see Fig. 5.1 with the graph of the function  $\lambda(\text{id}_X \geq t)$  and with shaded areas expressing the corresponding integrals.

## 5.5 Concluding Remarks, Application Fields

We have recalled and discussed several kinds of integrals defined on any measurable space for any monotone measure and any nonnegative measurable functions, restricting our considerations to the unit interval  $[0, 1]$ . There are several possible extensions of these integrals to the bipolar scale  $[-1, 1]$ , i.e., for integrating functions with range in  $[-1, 1]$ . Recall only the case of the Choquet integral with bipolar extensions of different kinds, such as:

- Asymmetric Choquet integral,

$$\text{Ch}_m^{\text{as}}(f) = \text{Ch}_m(f^+) - \text{Ch}_{m^d}(f^-),$$

where  $f^+ : X \rightarrow [0, 1]$  is given by  $f^+(x) = \max(0, f(x))$ ,  $f^- : X \rightarrow [0, 1]$  is given by  $f^-(x) = \max(0, -f(x))$ , and  $m^d : \mathcal{A} \rightarrow [0, 1]$  is a monotone measure dual to  $m$ . For more details see [5.18, 19, 26];

- Symmetric (Šipoš) Choquet integral,  

$$\text{Ch}_m^{\text{sym}}(f) = \text{Ch}_m(f^+) - \text{Ch}_m(f^-),$$
see [5.18, 19, 23, 26];
- In the case when  $X$  is finite, two other extensions called a balanced Choquet integral [5.59] and a merging Choquet integral [5.60] reflecting (partial) compensation of positive and negative inputs were also introduced and discussed. Further generalizations yield the background of cumulative prospect theory **CPT** (Cumulative Prospect Theory) of Tversky and Kahneman [5.61, 62], however, then two monotone measures are considered,

$$\text{Ch}_{m_1, m_2}(f) = \text{Ch}_{m_1}(f^+) - \text{Ch}_{m_2}(f^-).$$

Observe that economical applications of **CPT** have resulted into Nobel Prize for Tversky and Kahneman in 2002.

Some of introduced integrals were introduced because of solving some practical problems. For example, concave integral of Lehrer [5.54] is a solution of an optimization problem looking for a maximal global performance.

Among many fields where integrals discussed in this chapter are an important tool, we recall decision making under multiple criteria, multiobjective optimization, multiperson decision making, pattern recognition and classification, image analysis, etc. For more details, we recommend [5.25, Appendix B] or [5.19].

# The Origin of Fuzzy Extensions

Humberto Bustince, Edurne Barrenechea, Javier Fernández, Miguel Pagola, Javier Montero

Many different kinds of sets have been defined within the framework of fuzzy sets. This paper focusses on those fuzzy set extensions that address the difficulties that experts find in order to build the membership values. In particular, we analyze type-2 fuzzy sets, interval-valued fuzzy sets, Atanassov's intuitionistic fuzzy sets, or bipolar sets of type-2 and Atanassov's interval-valued fuzzy sets. After stating a general approach to these extensions, we remark some structural problems in the extension problem and stress some applications for which the results obtained with extensions are better than those obtained with Zadeh's fuzzy sets.

Many different types of fuzzy sets have appeared in the literature since Zadeh introduced the concept of fuzzy set (or type-1 fuzzy set) [6.1]. Roughly speaking, the basic characteristics of all those definitions are the following:

- i) They are particular instances of the  $L$ -fuzzy sets defined by Goguen [6.2].
- ii) They arise from theoretical problems and are very efficient to solve such theoretical problems.
- iii) The specific characteristics of the new definitions do not use to play a formal role, quite often becoming an easy adaptation of Zadeh's fuzzy sets.
- iv) It is not always shown to what extent the new proposal implies a practical advantage when compared to Zadeh's fuzzy sets.

The last point gives rise to a key criticism when additional information is needed for the management of a new kind of fuzzy sets, but the improvement we obtain in practice cannot be justified by the effort required to obtain such an information. But more important than that is the previous criticism (iii), about the difficulty of building the best family of sets for the application we are considering. Surprisingly, this key issue has not captured the attention of too many researchers.

In this paper, we shall focus on those sets conceived to address the problem stated by Zadeh in 1971 in order to address the difficulty of finding the membership degree of each element (we shall refer to these sets as *extensions of the fuzzy sets*), and then we shall point out applications that can be found in the literature in which the use of some extensions provides better

results than the use of type-1 fuzzy sets, according to the comparison carried out in the papers where this improvement is shown. Once the definition of extension of fuzzy sets has been introduced, we shall describe some of its properties and remark the structural problems of the different types of these extensions. Among those extensions we shall consider type-2 fuzzy sets, interval-valued fuzzy sets, Atanassov's intuitionistic fuzzy sets or type-2 bipolar fuzzy sets and Atanassov's interval-valued fuzzy sets.

We have organized this chapter as follows. In Sect. 6.2 we start recalling the reasons that led Zadeh to introduce fuzzy sets. We also remind the basic notions in Brouwer's intuitionistic theory to later justify the terminological problems linked to the sets defined by Atanassov. In Sect. 6.3 we present the origin of the extensions of fuzzy sets as well as the definitions. Section 6.4 is devoted to type-2 fuzzy sets. We stress the problems related to the definition of the basic operations and the terminology. In Sect. 6.5 we analyze a particular case of the previous sets, namely, interval-valued fuzzy sets. We present their properties and different construction methods, depending on the application that we are dealing with. We also refer to the papers in which it is shown that the results that we obtain with these sets are better than those obtained with other techniques. In Sects. 6.6 and 6.7 we describe the sets defined by Atanassov. Section 6.8 explains the links between the considered extensions. In Sect. 6.9 we exhibit some other definitions of fuzzy sets in the literature that do not fall into the scope of our notion of extension. We finish with some conclusions and references.

## 6.1 Considerations Prior to the Concept of Extension of Fuzzy Sets

In classical logic, propositions can only be either true or false. Aristotle formulated the basic principles of this logic: the noncontradiction principle (a statement cannot be true and false at the same time) and the middle-excluded principle (every statement is either true or false).

It is easy to note that there are many situations for which more than two truth values are needed. This fact led C.S. Peirce to say that Aristotle's formulation is the *simplest hypothesis* we can work with. In fact, meanwhile human knowledge representation is based upon concepts [6.3], and these concepts are not crisp in nature, we should not expect that human beings use binary logic so often in their daily life.

Everyday situations such as taste, meaning of adjectives, etc., can only be studied precisely if gradings more complex than true or false are considered. Even very widely used mathematical models can lead to paradoxes. For instance, quite often we are forced to establish arbitrary cuts in order to make reality fit our binary model.

These considerations led to propose different logical formulations which allowed for more than two truth values, like Brouwer's intuitionistic logic (partially caught by the so-called intuitionistic propositional calculus modeled by Heyting algebras), multivalued logics presented by Lukasiewicz, or Zadeh's fuzzy logic (which replaces the set  $\{0, 1\}$  by the set  $[0, 1]$ ), for example.

### 6.1.1 Brouwer's Intuitionistic Logic

In 1907, the Dutch mathematician L.E.J. Brouwer (1881–1966) introduced the intuitionistic logic. Between the precursors of intuitionistic logic, we can include Kronecker, Poincare, Borel, or Weyl.

For intuitionistic researchers, the objects of study in Mathematics are just some intuitions of the mind and the constructions that can be made with them. Hence, the intuitionistic mathematics only handles built objects and only recognizes the properties assigned to these objects in their construction. In particular, the negation of the impossibility of a fact is not a construction of such a fact, and so both the double negation principle and the reduction ad absurdum method are not acceptable for the intuitionist. In the same way, it may happen that it is impossible to build both a fact and its negation, so also the middle-excluded principle is excluded by intuitionism.

In 1930 Heyting, a Brouwer's disciple, went one step ahead and defined a propositional calculus in terms of axioms and rules in Hilbert's style. This calculus is known as intuitionistic propositional calculus (intuitionistic logic). For several decades, the research in intuitionism was almost stopped. But it has reappeared with strength in the logic of categories and topos [6.4, 5]. In this sense, the studies by Takeuti and Titani in 1984 [6.6] on intuitionistic fuzzy logic and intuitionistic fuzzy set theory are of special interest for us. In [6.7], it is settled that

*Takeuti and Titani's intuitionistic fuzzy logic is simply an extension of intuitionistic logic, i.e., all formulas provable in the intuitionistic logic are provable in their logic. They give a sequent calculus which extends Heyting intuitionistic logic, an extension that does not collapse to classical logic and keeps the flavor of intuitionism.*

### 6.1.2 Lukasiewicz's Multivalued Logics

In 1920s, Jan Lukasiewicz (1878–1956) along with Lesniewski founded a school of logic in Warsaw that became one of the most important mathematical teams in the world, and among whose members was Alfred Tarski.

Lukasiewicz's idea consists in distributing the truth values uniformly on the  $[0, 1]$  interval: if  $n$  values are considered, they should be  $0, \frac{1}{n-1}, \frac{2}{n-1}, \dots, \frac{n-2}{n-1}, 1$ ; if they are infinite, we should take  $\mathbb{Q} \cap [0, 1]$ . Negation is

defined as  $n(x) = 1 - x$ , and the following operation is also defined:  $x \oplus y = \min(1, x + y)$ .

### 6.1.3 Zadeh's Fuzzy Logic. First Generalization by Goguen

Consistently to Lukasiewicz's studies, Zadeh [6.1] introduced fuzzy logic in his 1965 paper, *Fuzzy Sets*. Born in Azerbaijan in 1921, he moved to the University of California at Berkeley in 1959. His ideas on fuzzy sets were soon applied to different areas such as artificial intelligence, natural language, decision making, expert systems, neural networks, control theory, etc.

In mathematics, every subset of a given referential universe  $U$  can be identified with its *characteristic function*  $f$ ; that is, the function  $f: U \rightarrow \{0, 1\}$  which takes the value 1 if the element belongs to the considered subset and 0 in other case. In contrast, a fuzzy set is a mapping from the universe  $U$  to  $[0, 1]$ ; that is,

#### Definition 6.1

A fuzzy set (or type-1 fuzzy set)  $A$  over a referential set  $U$  is an object

$$A = \{(u_i, \mu_A(u_i)) | u_i \in U\},$$

where  $\mu_A: U \rightarrow [0, 1]$ .

$\mu_A(u_i)$  represents the degree of membership of the element  $u_i \in U$  to the set  $A$ . The elements for which  $\mu_A(u_i) = 1$  belong to the set  $A$ ; those for which  $\mu_A(u_i) = 0$  do not belong to  $A$  and there are elements with a greater or smaller degree of membership to  $A$  depending on  $\mu_A(u_i)$ .

We are going to denote by  $FS(U)$  the class of fuzzy sets defined over  $U$ ; that is,  $FS(U) \equiv [0, 1]^U$ . The membership degree of an element  $u_i \in U$  to the fuzzy set  $A$  is usually denoted by  $A(u_i)$  instead of  $\mu_A(u_i)$ .

From the classical definition of union and intersection for crisp sets, Zadeh proposes the following definitions:

$$\begin{aligned} A \cup B(u_i) &= \max(A(u_i), B(u_i)), \\ A \cap B(u_i) &= \min(A(u_i), B(u_i)). \end{aligned} \quad (6.1)$$

A key concept in the following developments is that of lattice. We review now its definition, that can be found for instance in [6.8].

Recall that an order relationship over a set  $L$  is a relation  $\leq_L$  such that

- i)  $x \leq_L x$  for all  $x \in L$  (reflexivity);
- ii) if  $x \leq_L y$  and  $y \leq_L z$  then  $x \leq_L z$  for any  $x, y, z \in L$  (transitivity);
- iii) if  $x \leq_L y$  and  $y \leq_L x$ , then  $x = y$ , for any  $x, y \in L$  (antisymmetry).

If  $\leq_L$  is an order relationship over  $L$  then  $(L, \leq_L)$  is called a partially ordered set. Now, in order to define a lattice we need first to introduce the following definition.

### **Definition 6.2**

Let  $(L, \leq_L)$  be a partially ordered set and  $A \subset L$  (in the sense of the usual set theory). The greatest lower bound of  $A$  (if it exists) is the element  $x_{\inf} \in L$  such that:

- i)  $x_{\inf} \leq_L z$  for all  $z \in A$  and
- ii) for any  $y \in L$  such that  $y \leq_L z$  for all  $z \in A$  it follows that  $y \leq_L x_{\inf}$ .

Analogously, the least upper bound of  $A$  (if it exists) is the element  $x_{\sup} \in L$  such that

- i)  $z \leq_L x_{\sup}$  for all  $z \in A$  and
- ii) for any  $y \in L$  such that  $z \leq_L y$  for all  $z \in A$  it follows that  $x_{\sup} \leq_L y$ .

Now we can introduce the notion of lattice.

### **Definition 6.3**

A lattice is a partially ordered set  $(L, \leq_L)$  such that any two elements  $x, y \in L$  have the greatest lower bound or meet, denoted by  $x \wedge y$  and the lowest upper bound or join, denoted by  $x \vee y$ . A lattice  $L$  is called complete if any subset of  $L$  has the lowest upper bound and the greatest lower bound.

Given a lattice  $(L, \leq_L)$ , we will call supremum of  $L$  and denote by  $1_L$  the lowest upper bound of  $L$  (if it exists). Analogously, we will call the infimum of  $L$  and denote by  $0_L$  the greatest lower bound of  $L$ . In case both  $1_L$  and  $0_L$  exist,  $L$  is called a bounded lattice.

Observe that if we know how the join and meet operations are defined for any two elements of a set  $L$ , we can recover the ordering  $\leq_L$  just by defining for any  $x, y \in L$

$$\begin{aligned} x \leq_L y &\text{ if and only if } x \wedge y = x \\ &\text{if and only if } x \vee y = y \end{aligned}$$

Taking into account (6.1) and Definition 6.3, it is easy to prove the following theorem.

### **Theorem 6.1**

$(FS(U), \cup, \cap)$  is a complete lattice.

From Theorem 6.1 and the concept of lattice, we can define the following partial order relation: For  $A, B \in FS(U)$

$$A \leq_{FS} B \text{ if and only if } A(u_i) \leq B(u_i) \text{ for every } u_i \in U.$$

The first criticism to fuzzy sets theory arises from this order relation  $\leq_{FS}$ . Since Zadeh presented fuzzy sets to represent uncertainty, it comes out that  $\leq_{FS}$  is a crisp relation. Note that the following may happen: Let  $U$  be a referential set with 1000 elements and let  $A$  and  $B$  be two fuzzy sets over  $U$  such that for every element except for one  $A(u_i) \leq B(u_i)$ . Then, from the previous relation,  $A$  is not less than  $B$ . This fact led Willmott [6.9], Bandler and Kohout [6.10] and others to consider the concept of inclusion measure. These measures have been widely used in fuzzy morphologic mathematics [6.11], in image processing [6.12], etc.

It is easy to see that with the operations defined in (6.1) and the standard negation,  $n(x) = 1 - x$  for all  $x \in [0, 1]$ , neither the noncontradiction principle nor the middle excluded principle hold. Nowadays, operations in (6.1) are given in terms of  $t$ -norms and  $t$ -conorms [6.13–16].

Definition 6.1 can be clearly extended to consider mappings valued over any kind of set. In particular, for our future developments and following Goguen's work [6.2], it is interesting to consider the case of mappings that take values over a lattice  $L$ . In this case, we speak of  $L$ -fuzzy sets.

Taking into account Definition 6.3 Goguen presents the concept of  $L$ -fuzzy set as follows:

### **Definition 6.4**

Let  $(L, \vee, \wedge)$  be a lattice. An  $L$ -fuzzy set over the referential set  $U$  is a mapping

$$A: U \rightarrow L.$$

For a given lattice  $L$ , we will denote by  $L\text{-}FS(U)$ , the space of  $L$ -fuzzy sets over the referential  $U$ . That is,  $L\text{-}FS(U) \equiv L^U$ .

Union and intersection of  $L$ -fuzzy sets can be easily defined as follows.

#### **Definition 6.5**

Let  $L$  be a lattice, and let  $\vee$  and  $\wedge$  be its join and meet operators respectively. Then intersection and union are defined, respectively, by:

- i)  $\cap_L : L\text{-FS}(U) \times L\text{-FS}(U) \rightarrow L\text{-FS}(U)$  given by  
 $\cap_L(A, B)(u_i) = A(u_i) \wedge B(u_i)$ .

In order to recover the usual notation for fuzzy sets, we will write  $\cap_L(A, B)$  as  $A \cap_L B$ ;

- ii)  $\cup_L : L\text{-FS}(U) \times L\text{-FS}(U) \rightarrow L\text{-FS}(U)$  given by  
 $\cup_L(A, B)(u_i) = A(u_i) \vee B(u_i)$ .

In order to recover the usual notation for fuzzy sets, we will write  $\cup_L(A, B)$  as  $A \cup_L B$ .

We can state the following result for  $L$ -fuzzy sets.

#### **Proposition 6.1**

Let  $L$  be a bounded lattice with a supremum given by  $1_L$  and an infimum given by  $0_L$ . Let  $\vee$  and  $\wedge$  be the join and meet operators of  $L$ , respectively. Then, the set

$(L\text{-FS}(U), \leq_{L\text{-FS}(U)})$  is a bounded lattice, where the order is defined as

$$A \leq_{L\text{-FS}(U)} B \text{ if and only if } A \cup_L B = B$$

or equivalently

$$A \leq_{L\text{-FS}(U)} B \text{ if and only if } A \cap_L B = A.$$

That is

$$\begin{aligned} A \leq_{L\text{-FS}(U)} B \text{ if and only if } A(u_i) \vee B(u_i) &= B(u_i) \\ \text{for all } u_i \in U \end{aligned}$$

or equivalently

$$\begin{aligned} A \leq_{L\text{-FS}(U)} B \text{ if and only if } A(u_i) \wedge B(u_i) &= A(u_i) \\ \text{for all } u_i \in U. \end{aligned}$$

The supremum of this lattice is given by

$$\begin{aligned} 1_{L\text{-FS}(U)} : U &\rightarrow L, \\ u_i &\rightarrow 1_L \end{aligned}$$

and the infimum is given by

$$\begin{aligned} 0_{L\text{-FS}(U)} : U &\rightarrow L, \\ u_i &\rightarrow 0_L. \end{aligned}$$

## 6.2 Origin of the Extensions

In 1971, Zadeh in his paper [6.17] settled that the construction of the fuzzy sets, that is, the determination of the membership degree of each element to the set, is the biggest problem for using fuzzy sets theory in applications. This fact led him to introduce the concept of type-2 fuzzy set.

Later, in December 11, 2008, in the *bisc-group* mail list Zadeh proposes the following definitions.

#### **Definition 6.6**

Fuzzy logic is a precise system of reasoning, deduction, and computation in which the objects of discourse and analysis are associated with information which is, or is allowed to be, imperfect.

#### **Definition 6.7**

Imperfect information is defined as information which in one or more respects is imprecise, uncertain, vague, incomplete, partially true, or partially possible.

On the same date and place, Zadeh made the following remarks:

1. In fuzzy logic everything is or is allowed to be a matter of degree. Degrees are allowed to be fuzzy.
2. Fuzzy logic is not a replacement for bivalent logic or bivalent-logic-based probability theory. Fuzzy logic adds to bivalent logic and bivalent-logic-based probability theory a wide range of concepts and techniques for dealing with imperfect information.
3. Fuzzy logic is designed to address problems in reasoning, deduction, and computation with imperfect information which are beyond the reach of traditional methods based on bivalent logic and bivalent-logic-based probability theory.
4. In fuzzy logic the writing instrument is a spray pen (Fig. 6.1) with a precisely known adjustable spray pattern. In bivalent logic the writing instrument is a ballpoint pen.

5. The importance of fuzzy logic derives from the fact that in much of the real-world imperfect information is the norm rather than exception.

All these considerations justify the use of fuzzy sets theory whenever objects are linked to soft concepts, those that do not show clear boundaries. Of course, applications might require tools other than fuzzy [6.18]. In any case, if we decide to use fuzzy sets and it is hard for us to build the characteristic functions of the involved sets, then we must use set representations that take into account these difficulties, and focus on those fuzzy sets that we call *extensions*.

## 6.3 Type-2 Fuzzy Sets

The idea of taking into account the experts' uncertainty when they build the membership degrees of the elements to a given fuzzy sets led *Zadeh* to present in 1971 the notion of type-2 fuzzy set [6.17] as follows: A type-2 fuzzy set is a fuzzy set over a referential set  $U$  for which the membership degrees of the elements are given by fuzzy sets defined over the referential set  $[0, 1]$ .

The mathematical formalization of this concept was made in 1976 by *Mizumoto* and *Tanaka* in [6.19] and in 1979 by *Dubois* and *Prade* in [6.20] as follows:

### Definition 6.8

A type-2 fuzzy set is a mapping  $A: U \rightarrow FS([0, 1])$ .

In Fig. 6.2 we show an example of type-2 fuzzy set.

We denote by  $T2FS(U)$  the set of all type-2 fuzzy sets over  $U$ . That is

$$T2FS(U) \equiv (FS([0, 1]))^U.$$

### 6.3.1 Type-2 Fuzzy Sets as a Lattice

From Definition 6.8, the following result is obvious.

#### Corollary 6.1

Type-2 fuzzy sets are a particular type of Goguen's  $L$ -fuzzy sets.

Taking into account Corollary 6.1, it is clear that we can define the following operations over type-2 fuzzy sets [6.21].

#### Definition 6.9

The operations of union  $\cup_{T2}$  and intersection  $\cap_{T2}$  of

So the origin of the concept of extension of fuzzy sets is directly associated with the idea of building fuzzy sets that allow us to represent objects that are described through imperfect information, and that also allow us to represent the lack of knowledge or uncertainty associated with the membership degrees that are given by the experts.

It is clear that working with extensions implies that we need to use more information than in the basic model of Zadeh. As already pointed out, in order to justify the use of these extensions in practice, the results obtained with them must be better than those obtained with usual fuzzy sets.

$A, B \in T2FS(U)$  (in the sense of lattices) are defined, respectively, as

$$\begin{aligned} \cup_{T2}(A, B): U &\rightarrow FS([0, 1]) \text{ given by} \\ A \cup_{T2} B(u_i) &= A(u_i) \cup B(u_i) \end{aligned}$$

and

$$\begin{aligned} \cap_{T2}(A, B): U &\rightarrow FS([0, 1]), \\ A \cap_{T2} B(u_i) &= A(u_i) \cap B(u_i). \end{aligned}$$

#### Proposition 6.2

The set  $(T2FS(U), \cup_{T2}, \cap_{T2})$  is a bounded lattice with respect to the order

$$A \leq_{T2FS(U)} B \text{ if and only if } A \cup_{T2} B = B$$

or equivalently

$$A \leq_{T2FS(U)} B \text{ if and only if } A \cap_{T2} B = A.$$

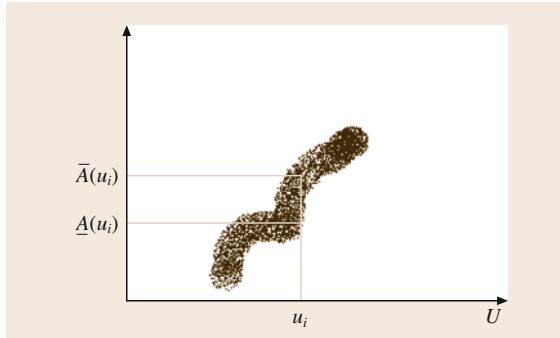

That is

$$\begin{aligned} A \leq_{T2FS(U)} B \text{ if and only if } A(u_i) \cup B(u_i) &= B(u_i) \\ \text{for all } u_i \in U \end{aligned}$$

or equivalently

$$\begin{aligned} A \leq_{T2FS(U)} B \text{ if and only if } A(u_i) \cap B(u_i) &= A(u_i) \\ \text{for all } u_i \in U. \end{aligned}$$

The supremum of this lattice is given by  $1_{T2FS(U)}$ :  $U \rightarrow FS(U)$  where, for every  $u_i \in U$ ,  $1_{T2FS(U)}(u_i)$  is

**Fig. 6.1** The writing instrument is a spray pen

the fuzzy sets that assigns to every  $t \in [0, 1]$  membership equal to 1. The infimum is given by  $0_{T2FS(U)}: U \rightarrow FS(U)$  where, for every  $u_i \in U$ ,  $0_{T2FS(U)}(u_i)$  is the fuzzy sets that assigns to every  $t \in [0, 1]$  membership equal to 0.

### 6.3.2 Remarks on the Notation

*Mizumoto and Tanaka* in 1976 [6.19] and *Mendel and John* in 2000 [6.22] used the following notation:

$$\int_{u \in U} \int_{t \in J_u} \frac{A(u, t)}{(u, t)}, \quad J_u \subset [0, 1],$$

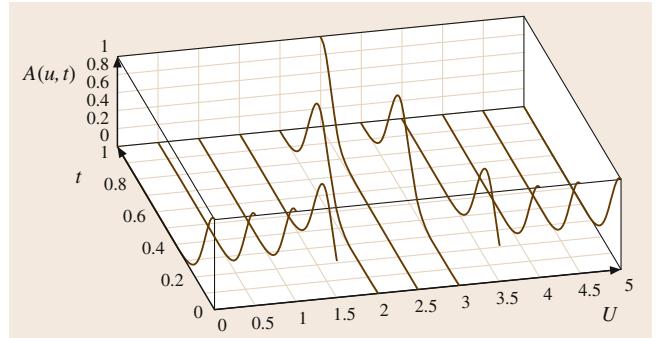

where  $J_u$  is the primary membership of  $u \in U$  and, for each fixed  $u = u_0$ , the fuzzy set  $\int_{t \in J_{u_0}} A(u_0, t)/t$  is the secondary membership of  $u_0$ .

From our point of view, this notation is not the most appropriate one, so now we try to introduce a more clarifying notation. Observe that a type-2 fuzzy set assigns to an element in the referential  $U$  a mapping  $A(u): [0, 1] \rightarrow [0, 1]$ . To represent fuzzy sets (or type-1 fuzzy sets) defined by a mapping  $A$  it is quite usual the notation

$$\{(u_i, A(u_i)) \mid u_i \in U\}. \quad (6.2)$$

In this type-1 case,  $A(u)$  is a real number in  $[0, 1]$  for every  $u_i \in U$ . In the case of type-2 fuzzy sets, if we imitate this notation, we formally lead to  $\{(u_i, A(u_i)) \mid u_i \in U\}$ . But now for each  $u_i \in U$ , we have that  $A(u_i)$  is not a real number but a mapping (a type-1 fuzzy set)

$$\begin{aligned} A(u): [0, 1] &\rightarrow [0, 1], \\ t &\rightarrow A(u)(t). \end{aligned}$$

**Fig. 6.2** Example of a type-2 fuzzy set

Taking into account these considerations *Harding et al.* [6.21] and *Aisbett et al.* [6.23] suggested the following notation for a type-2 fuzzy set  $A$ :

$$A = \{(u_i, (t, A(u_i)(t))) \mid u_i \in U, t \in [0, 1]\}.$$

But an easier one to use one could be the following.

#### Definition 6.10

Let  $A: U \rightarrow FS([0, 1])$  be a type-2 fuzzy set. Then  $A$  is denoted as

$$\{(u_i, A(u_i, t)) \mid u_i \in U, t \in [0, 1]\}.$$

where  $A(u_i, \cdot): [0, 1] \rightarrow [0, 1]$  is defined as  $A(u_i, t) = A(u_i)(t)$ .

### 6.3.3 A First Definition of Operations Between Type-2 Fuzzy Sets: Lattice-Based Approach

With Definition 6.10, if we have two type-2 fuzzy sets

$$A = \{(u_i, (A(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

and

$$B = \{(u_i, (B(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

we have (Fig. 6.3)

$$A \cup_{T2FS} B = \{(u_i, A \cup B(u_i, t)) \mid u_i \in U, t \in [0, 1]\},$$

where, for each  $u_i \in U$  and each  $t \in [0, 1]$ , we have

$$\begin{aligned} A \cup B(u_i, t) &= \max(A(u_i, t), B(u_i, t)) \\ &= \max(A(u_i)(t), B(u_i)(t)) \end{aligned} \quad (6.3)$$

Analogously,

$$A \cap_{T2FS} B = \{(u_i, A \cap B(u_i, t)) \mid u_i \in U, t \in [0, 1]\},$$

where, for each  $u_i \in U$  and each  $t \in [0, 1]$ , we have

$$\begin{aligned} A \cap B(u_i, t) &= \min(A(u_i, t), B(u_i, t)) \\ &= \min(A(u_i)(t), B(u_i)(t)) \end{aligned} \quad (6.4)$$

Observe that this notation is very similar to that proposed by *Deschrijver and Kerre* [6.24, 25].

### 6.3.4 Problems with the Lattice-Based Definitions. Operations Based on Zadeh's Extension Principle

Although meaningful from a mathematical point of view, as pointed out by *Dubois and Prade* in [6.26], from these definitions we do not recover the usual ones for fuzzy sets. To see it, just consider a finite referential set  $U = \{u_1, u_2, u_3\}$  with three elements, and consider the following two fuzzy sets over  $U$ . We use the notation of (6.2) for the sake of brevity.

$$A = \left\{ \left( u_1, \frac{1}{2} \right), \left( u_2, \frac{1}{3} \right), (u_3, 1) \right\}$$

and

$$B = \left\{ \left( u_1, \frac{1}{4} \right), \left( u_2, \frac{1}{2} \right), \left( u_3, \frac{1}{7} \right) \right\}.$$

Then we have, for instance,

$$A \cup B = \left\{ \left( u_1, \frac{1}{2} \right), \left( u_2, \frac{1}{2} \right), (u_3, 1) \right\}$$

On the other hand, we can also see  $A$  and  $B$  as type-2 fuzzy sets, that we denote by  $A_{T2}$  and  $B_{T2}$ , respectively, just taking

$$A_{T2}(u_1)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{2} \\ 0 & \text{in other case} \end{cases},$$

$$A_{T2}(u_2)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{3} \\ 0 & \text{in other case} \end{cases},$$

$$A_{T2}(u_3)(t) = \begin{cases} 1 & \text{if } t = 1 \\ 0 & \text{in other case} \end{cases},$$

and

$$B_{T2}(u_1)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{4} \\ 0 & \text{in other case} \end{cases},$$

$$B_{T2}(u_2)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{2} \\ 0 & \text{in other case} \end{cases},$$

$$B_{T2}(u_3)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{7} \\ 0 & \text{in other case} \end{cases}.$$

Then we have

$$A_{T2} \cup_{T2FS} B_{T2}(u_1)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{4} \text{ or } t = \frac{1}{2} \\ 0 & \text{in other case} \end{cases},$$

$$A_{T2} \cup_{T2FS} B_{T2}(u_2)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{2} \text{ or } t = \frac{1}{3} \\ 0 & \text{in other case} \end{cases},$$

and

$$A_{T2} \cup_{T2FS} B_{T2}(u_3)(t) = \begin{cases} 1 & \text{if } t = \frac{1}{7} \text{ or } t = 1 \\ 0 & \text{in other case} \end{cases},$$

which does not coincide with our previous result. Moreover, observe that we do not even recover a fuzzy set but a *true* type-2 fuzzy set.

In order to solve this problem, several authors [6.19, 22, 26] proposed the following definitions of the operations of union and intersection.

### 6.3.5 Second Definition of the Operations: Zadeh's Extension Principle Approach

#### Definition 6.11

Given two type-2 fuzzy sets

$$A = \{(u_i, A(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

and

$$B = \{(u_i, B(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

we can define (Fig. 6.4)

$$A \sqcap B = \{(u_i, A \sqcap B(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

with

$$A \sqcap B(u_i, t) = \sup_{\min(z,w)=t} \min(A(u_i, z), B(u_i, w))$$

and

$$A \sqcup B = \{(u_i, A \sqcup B(u_i, t)) \mid u_i \in U, t \in [0, 1]\}$$

with

$$A \sqcup B(u_i, t) = \sup_{\max(z,w)=t} \min(A(u_i, z), B(u_i, w)).$$

For instance, let us recover our previous example. Consider the type-2 fuzzy sets  $A_{T2}$  and  $B_{T2}$ . Then we have that

$$A_{T2} \sqcup B_{T2}(u_1, t) =$$

$$\begin{cases} 0 & \text{if } t \notin \left\{\frac{1}{4}, \frac{1}{2}\right\} \\ \sup_{\max(z,w)=t} (\min(A_{T2}(u_1, z), B_{T2}(u_1, w))) & \text{in other case} \end{cases}$$

But if  $t = \frac{1}{4}$ , then, as  $\frac{1}{2} > \frac{1}{4}$  and since  $A_{T2}(u_1, z) = 0$  for all  $z \leq \frac{1}{4}$ , it follows that  $\min(A_{T2}(u_1, z), B_{T2}(u_1, w)) = 0$  whenever  $\max(z, w) = \frac{1}{4}$ . Finally, if  $t = \frac{1}{2}$ , then  $\min(A_{T2}(u_1, \frac{1}{2}), B_{T2}(u_1, \frac{1}{4})) = 1$ , so we finally arrive at

$$A_{T2} \sqcup B_{T2}(u_1, t) = \begin{cases} 0 & \text{if } t \neq \frac{1}{2} \\ 1 & \text{if } t = \frac{1}{2} \end{cases}.$$

Since for  $u_2$  and  $u_3$  the same arguments work, we see that we indeed recover the fuzzy case. In particular, with respect to these new operations, we have the following result [6.21].

#### **Proposition 6.3**

Let  $U$  be a referential set.  $(T2FS(U), \sqcup, \sqcap)$  is not a lattice.

In fact, the problem is that the absorption laws

$$A \sqcap (A \sqcup B) = A$$

and

$$A \sqcup (A \sqcap B) = A$$

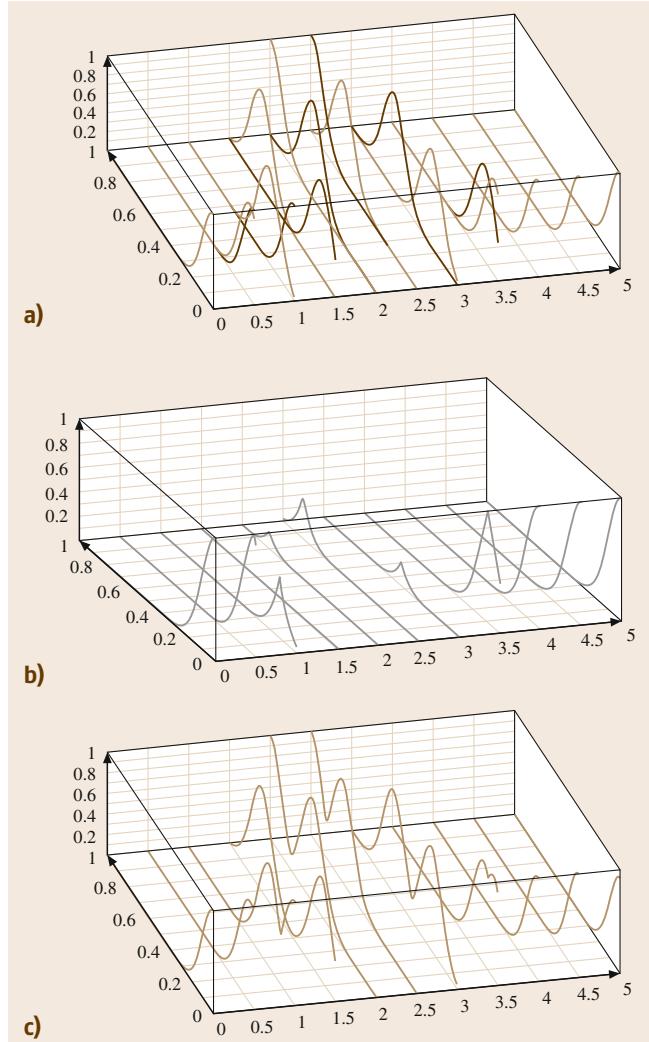

do not hold. Nevertheless, it is also possible to provide a positive result [6.21].

#### **Proposition 6.4**

Let  $U$  be a referential set. Then for any  $A, B, C \in T2FS(U)$  the following properties hold:

- i)  $A \sqcup A = A$  and  $A \sqcap A = A$ ;
- ii)  $A \sqcup B = B \sqcup A$  and  $A \sqcap B = B \sqcap A$ ;
- iii)  $A \sqcup (B \sqcup C) = (A \sqcup B) \sqcup C$ .

That is,  $(T2FS(U), \sqcup, \sqcap)$  is a bisemilattice.

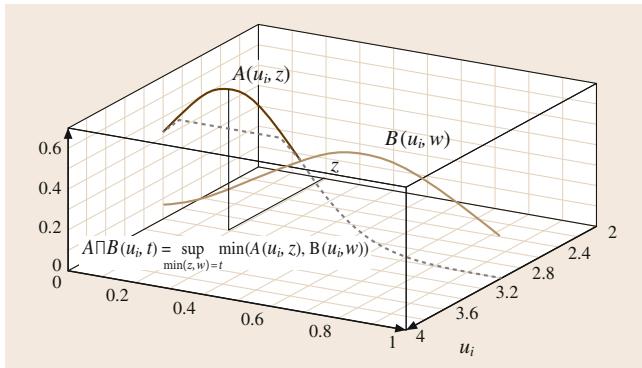

**Fig. 6.3a–c** Two different type 2 fuzzy sets (a)  $A \cup_{T2FS} B$  (b)  $A \cap_{T2FS} B$  (c)

#### **Remark 6.1**

We should remark the following:

1. If we work with the operations defined in Eqs. (6.3) and (6.4), and consider fuzzy sets as particular instances of type-2 fuzzy sets, then we do not recover the classical operations defined by Zadeh.
2. If we use the operations in Definition 6.11, then we recover Zadeh's classical operations for fuzzy sets, but we do not have a lattice structure. This fact makes that the use of type-2 fuzzy sets in many

**Fig. 6.4** Example of intersection of two membership sets  $A(u_i, t)$  and  $B(u_i, t)$ . Green line is the set obtained

applications, such as decision making, is very complex.

Obviously, an interesting problem is to analyze which further conclusions and results can be obtained from this new formulation of the operations between type-2 fuzzy sets.

### 6.3.6 About Computational Efficiency

Note also that although the computational complexity and the efficiency in time of type-2 fuzzy sets are not as high as used to be a few years ago, it is clear that the use

of these kinds of sets introduces additional complexity in any given problem. For this reason, many times the possible improvement of results is not as big as replacing type-1 fuzzy sets by type-2 fuzzy sets in many applications.

On the other hand, we can also define type-3 fuzzy sets as those fuzzy sets whose membership of each element is given by a type-2 fuzzy set [6.27]. Even more, it is possible to define recursively type-n fuzzy sets as those fuzzy sets whose membership values are type- $(n-1)$  fuzzy sets. The computational efficiency of these sets decreases as the complexity level of the building increases. From a theoretical point of view, we consider that it is necessary to carry out a complete analysis of type-n fuzzy sets structures and operations. But up to now no applications has been developed on the basis of a type-n fuzzy sets.

### 6.3.7 Applications

It is worth to mention the works by *Mendel* in computing with words and perceptual computing [6.28–31], of *Hagras* [6.32, 33], of *Sepulveda* et al. [6.34] in control, of *Xia* et al. in mobiles [6.35] and of *Wang* in neural networks [6.36]. We will see in the next section that the advantage of using these kinds of sets versus usual fuzzy sets has been shown only for a particular type of them, namely, the so-called interval-valued fuzzy sets.

## 6.4 Interval-Valued Fuzzy Sets

These sets were introduced in the 1970s. In May 1975, *Sambuc* [6.37] presented, in his doctoral thesis, the concept of an interval-valued fuzzy set named a  $\Phi$ -fuzzy set. That same year, *Jahn* [6.38] wrote about these sets. One year later, *Grattan-Guinness* [6.39] established a definition of an interval-valued membership function. In that decade interval-valued fuzzy sets appeared in the literature in various guises and it was not until the 1980s, with the work of *Gorzalczany* and *Türk-sen* [6.40–45], that the importance of these sets, as well as their name, was definitely established.

Let us denote by  $L([0, 1])$  the set of all closed subintervals in  $[0, 1]$ , that is,

$$L([0, 1]) = \left\{ \underline{x} = \left[ \underline{x}, \bar{x} \right] \mid (\underline{x}, \bar{x}) \in [0, 1]^2 \text{ and } \underline{x} \leq \bar{x} \right\}. \quad (6.5)$$

### Definition 6.12

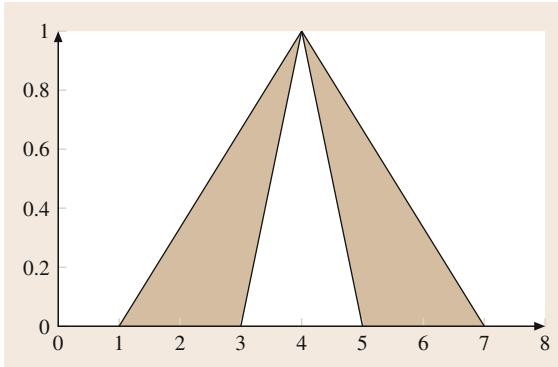

An interval-valued fuzzy set (or interval type-2 fuzzy set)  $A$  on the universe  $U \neq \emptyset$  is a mapping

$$A: U \rightarrow L([0, 1]),$$

such that the membership degree of  $u \in U$  is given by  $A(u) = [\underline{A}(u), \bar{A}(u)] \in L([0, 1])$ , where  $\underline{A}: U \rightarrow [0, 1]$

and  $\bar{A}: U \rightarrow [0, 1]$  are mappings defining the lower and the upper bounds of the membership interval  $A(u)$ , respectively (Fig. 6.5).

From Definition 6.12, it is clear that for these sets the membership degree of each element  $u_i \in U$  to  $A$  is given by a closed subinterval in  $[0, 1]$ ; that is,  $A(u_i) = [\underline{A}(u_i), \bar{A}(u_i)]$ . Obviously, if for every  $u_i \in U$ , we have  $\underline{A}(u_i) = \bar{A}(u_i)$ , then the considered set is a fuzzy set. So

**Fig. 6.5** Example of interval valued fuzzy set

fuzzy sets are particular cases of interval-valued fuzzy sets.

In 1989, Deng [6.46] presented the concept of Grey sets. Later Dubois proved that these are also interval-valued fuzzy sets.

We denote by  $IVFS(U)$  the class of all interval-valued fuzzy sets over  $U$ ; that is,  $IVFS(U) \equiv L([0, 1])^U$ . From Zadeh's definitions of union and intersections, Sambuc proposed the following definition:

#### Definition 6.13

Given  $A, B \in IVFS(U)$ .

$$A \cup_{L([0,1])} B(u_i) = [\max(\underline{A}(u_i), \underline{B}(u_i)), \max(\bar{A}(u_i), \bar{B}(u_i))]$$

$$A \cap_{L([0,1])} B(u_i) = [\min(\underline{A}(u_i), \underline{B}(u_i)), \min(\bar{A}(u_i), \bar{B}(u_i))]$$

These operations can be generalized by the use of the widely analyzed concepts of IV  $t$ -conorm and IV  $t$ -norm [6.47–49].

#### Corollary 6.2

Interval valued fuzzy sets are a particular case of  $L$ -fuzzy sets.

*Proof:* Just note that  $L([0, 1])$  with the operations in Definition 6.13 is a lattice. ■

#### Proposition 6.5

The set  $(IVFS(U), \cup_{L([0,1])}, \cap_{L([0,1])})$  is a bounded lattice, where the order is defined as

$$A \leq_{IVFS(U)} B \text{ if and only if } A \cup_{L([0,1])} B = B$$

or equivalently

$$A \leq_{IVFS(U)} B \text{ if and only if } A \cap_{L([0,1])} B = A .$$

That is

$$\begin{aligned} A \leq_{IVFS(U)} B &\text{ if and only if} \\ \max(\underline{A}(u_i), \underline{B}(u_i)) &= \underline{B}(u_i) \text{ and} \\ \max(\bar{A}(u_i), \bar{B}(u_i)) &= \bar{B}(u_i) \end{aligned}$$

for all  $u_i \in U$ , or equivalently

$$\begin{aligned} A \leq_{IVFS(U)} B &\text{ if and only if} \\ \min(\underline{A}(u_i), \underline{B}(u_i)) &= \underline{A}(u_i) \text{ and} \\ \min(\bar{A}(u_i), \bar{B}(u_i)) &= \bar{A}(u_i) \end{aligned}$$

for all  $u_i \in U$ .

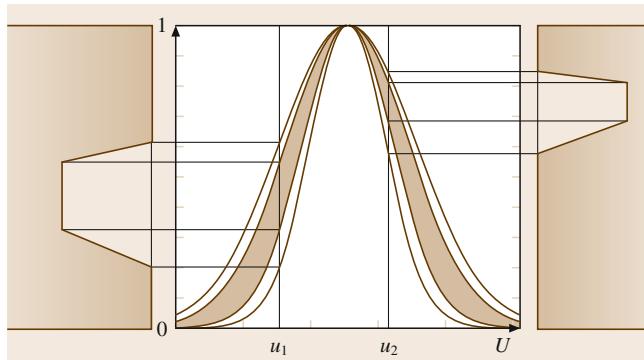

From Proposition 6.5, we deduce that the order  $A \leq_{IVFS(U)} B$  if and only if  $\underline{A}(u_i) \leq \underline{B}(u_i)$  and  $\bar{A}(u_i) \leq \bar{B}(u_i)$  for all  $u_i \in U$  is not linear. The use of these sets in decision making has led several authors to consider the problem of defining total orders between intervals [6.50]. In this sense, in [6.51] a construction method for such orders by means of aggregation functions can be found.

#### 6.4.1 Two Interpretations of Interval-Valued Fuzzy Sets

From our point of view, interval-valued fuzzy sets can be understood in two different ways [6.52]:

1. The membership degree of an element to the set is a value that belongs to the considered interval. The interval representation is used since we cannot say precisely which that number is. For this reason, we provide bounds for that number. We think this is the correct interpretation for these sets.
2. The membership degree of each element is the whole closed subinterval provided as membership. From a mathematical point of view, this interpretation is very interesting, but, in our opinion, it is very difficult to understand it in the applied field. Moreover, in this case, we find the following paradox [6.53]:

For fuzzy sets and with the standard negation it holds that  $\min(A(u_i), 1 - A(u_i)) \leq 0.5$  for all  $u_i \in U$ . But for interval-valued fuzzy sets, if we use the stan-

**Fig. 6.6** Construction of type-2 fuzzy sets from interval-valued fuzzy sets

dard negation  $N(A(u_i)) = [1 - \bar{A}(u_i), 1 - \underline{A}(u_i)]$ , we have that there is no equivalent bound for

$$\min [\underline{A}(u_i), \bar{A}(u_i)], [1 - \bar{A}(u_i), 1 - \underline{A}(u_i)].$$

#### 6.4.2 Shadowed Sets Are a Particular Case of Interval-Valued Fuzzy Sets

The so-called shadow sets were suggested by Pedrycz [6.54] and developed later together with Vukovic [6.55, 56]. A shadowed set  $B$  induced by a given fuzzy set  $A$  defined in  $U$  is an interval-valued fuzzy set in  $U$  that maps elements of  $U$  into  $[0, 1]$  and the unit interval  $[0, 1]$ , i.e.,  $B$  is a mapping  $B: U \rightarrow \{0, 1, [0, 1]\}$ , where  $0, 1, [0, 1]$  denote complete exclusion from  $B$ , complete inclusion in  $B$  and complete ignorance, respectively. Shadow sets are isomorphic with a three-valued logic.

#### 6.4.3 Interval-Valued Fuzzy Sets Are a Particular Case of Type-2 Fuzzy Sets

In 1995, Klir and Yuan proved in [6.27] that from an interval-valued fuzzy set, we can build a type-2 fuzzy set as pointed out in Fig. 6.6.

Later in 2007 Deschrijver and Kerre [6.24, 25] and Mendel [6.57], proved that interval-valued fuzzy sets are particular cases of type-2 fuzzy sets.

#### 6.4.4 Some Problems with Interval-Valued Fuzzy Sets

1. Taking into account the definition of interval-valued fuzzy sets, we follow Gorzalczany [6.41] and de-

fine the compatibility degree between two interval-valued fuzzy sets as an element in  $L([0, 1])$ . The other information measures [6.58–62] (interval-valued entropy, interval-valued similarity, etc.) should also be given by an interval. However, in most of the works about these measures, the results are given by a number, and not by an interval. This consideration leads us to settle that, from a theoretical point of view, we should distinguish between two different types of information measures: those which give rise to a number and those which give rise to an interval. Obviously, the problem of interpreting both types of measures arises. Moreover, if the result of the measure is an interval, we should consider its amplitude as a measure of the lack of knowledge [6.63] linked to the considered measure.

2. In [6.57], Mendel writes:

*It turns out that an interval type-2 fuzzy set is the same as an interval-valued fuzzy set for which there is a very extensive literature. These two seemingly different kinds of fuzzy sets were historically approached from very different starting points, which as we shall explain next has turned out to be a very good thing.*

Nonetheless, we consider that interval-valued fuzzy sets are a particular case of interval type-2 fuzzy sets and therefore they are not the same thing.

3. Due to the current characteristics of computers, we can say that the computational cost of working with these sets is not much higher than the cost of working with type-1 fuzzy sets [6.64].
4. We have already said that the commonly used order is not linear. This is a problem for some applications, such as decision making. In [6.65], it is shown that the choice of the order should depend on the considered application. Often experts do not have enough information to choose a total order. This is a big problem since the choice of the order influences strongly the final outcome.

#### 6.4.5 Applications

*We can say that there already exist applications of interval-valued fuzzy sets that provide results which are better than those obtained with fuzzy sets. For instance:*

1. *In classification problems.* Specifically, in [6.66–69] a methodology to enhance the performance of fuzzy rule-based classification systems (FRBCSs)

is presented. The methodology used in these papers has the following structure:

- 1) An initial **FRBCS** is generated by using a fuzzy rule learning algorithm.
- 2) The linguistic labels of the learned fuzzy rules are modeled with interval-valued fuzzy sets in order to take into account the ignorance degree associated with the assignment of a number as the membership degree of the elements to the sets. These sets are constructed starting from the fuzzy sets used in the learning process and their shape is determined by the value of one or two parameters.
- 3) The fuzzy reasoning method is extended so as to take into account the ignorance represented by the interval-valued fuzzy sets throughout the inference process.
- 4) The values of the system's parameters, for instance the ones determining the shape of the interval-valued fuzzy sets, are tuned applying evolutionary algorithms. See [6.66–69] for details about the specific features of each proposal.

The methodology allows us to statistically outperforming the performance of the following approaches:

- a) In [6.66], the performance of the initial **FRBCS** generated by the *Chi et al.* algorithm [6.70] and the fuzzy hybrid genetics-based machine learning method [6.71] are outperformed. In addition, the results of the **GAGRAD** (genetic algorithm gradient) approach [6.72] are notably improved.
- b) A new tuning approach is defined in [6.67], where the results obtained by the tuning of the lateral position of the linguistic labels ([6.73]) and the performance provided by the tuning approach based on the linguistic 3-tuples representation [6.74] are outperformed.
- c) Fuzzy decision trees (**FDTs**) are used as the learning method in [6.68]. In this contribution, numerous decision trees are enhanced, including crisp decision trees, **FDTs**, and **FDTs** constructed using genetic algorithms. For instance, the well-known C4.5 decision tree ([6.75]) or the fuzzy decision tree proposed by *Janikow* [6.76] is outperformed.
- d) The proposal presented in [6.69] is the most remarkable one, since it allows outperforming two state-of-the-art fuzzy classifiers, namely, the FARC-HD method [6.77] and the unordered fuzzy rule induction algorithm (**FURIA**) [6.78].

Furthermore, the performance of the fuzzy counterpart of the presented approach is outperformed as well.

2. *Image processing.* In [6.63, 79–85], it has been shown that if we use interval-valued fuzzy sets to represent those areas of an image for which the experts have problems to build the fuzzy membership degrees, then edges, segmentation, etc., are much better.
3. In some decision-making problems, it has also been shown that the results obtained with interval-valued fuzzy sets are better than the ones obtained with fuzzy sets [6.86]. They have also been used in Web problems [6.87], pattern recognition [6.88], medicine [6.89], etc., see also [6.90, 91].

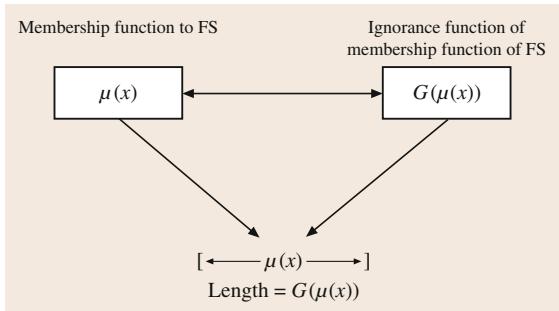

### Construction of Interval-Valued Fuzzy Sets

In many cases, it is easier for experts to give the membership degrees by means of numbers instead of by means of intervals. In this case it may happen that the obtained results are not the best ones. If this is so, we should build intervals from the numerical values provided by the experts. For this reason, we study methods to build intervals from real numbers. For any such methods, we require the following:

- i) The numerical value provided by the expert should be interior to the considered interval. We require this property since we assume that the membership degree for the expert is a number but he or she is not able to fix it exactly so he or she provides two bounds for it.
- ii) The amplitude of the built interval is going to represent the degree of ignorance of the expert to fix the numerical value he or she has provided us.

The previous considerations have led us to define in [6.63] the concept of ignorance degree  $G_i$  associated with the value given by an expert. In such definition, it is settled that if the degree of membership given by the expert is equal to 0 or 1, then the ignorance is equal to 0, since the expert is sure of the fact that the element belongs or does not belong to the considered set. However, if the provided membership degree is equal to 0.5, then ignorance is maximal, since the expert does not know at all whether the element belongs or not to the set. Different considerations and construction methods for such ignorance functions using overlap functions can be found in [6.92].

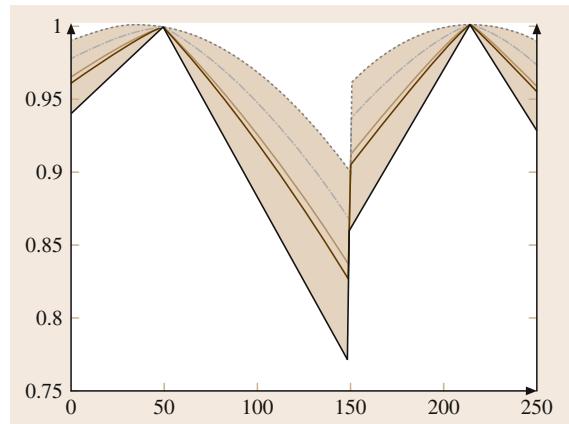

Taking into account the previous argumentation, in Fig. 6.7 we show the schema of construction of an interval from a membership degree  $\mu$  given by the expert

**Fig. 6.7** Construction with ignorance functions

and from an ignorance function  $G_i$  chosen for the considered problem [6.63]:

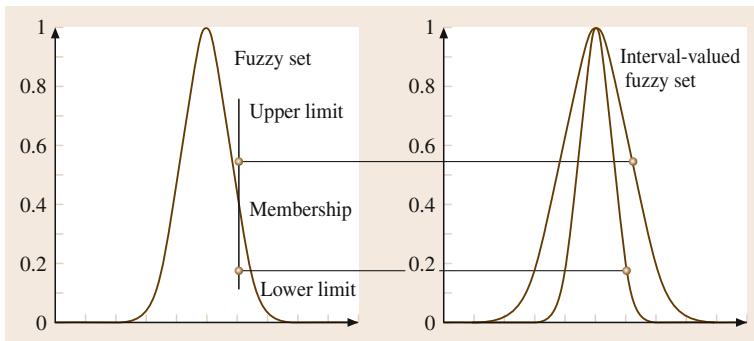

There exist other methods for constructing interval-valued fuzzy sets. The choice of the method depends on the application we are working in. One of the most used methods in magnetic resonance image processing (for fuzzy theory) is the following: several doctors are asked for building, for a specific region of an image, a fuzzy set representing that region. At the end, we will have several fuzzy sets, and with them we build an interval-valued fuzzy set as follows. For each element's membership, we take as lower bound the minimum of the values provided by the doctors, and as the upper bound, the maximum. This method has shown itself very useful in particular images [6.83]. In Fig. 6.8, we represent the proposed construction.

**Fig. 6.8** Construction with different experts

In [6.63], it is shown that for some specific ultrasound images, if we use fuzzy theory to obtain the objects in the image, results are worse than if we use interval-valued fuzzy sets using the method proposed by Tizhoosh in [6.84]. Such method consists of the following (see Fig. 6.9): from the numerical membership degree  $\mu_A$  given by the expert and from a numerical coefficient  $\alpha > 1$ , associated with the doubt of the expert when he or she constructs  $\mu_A$  we generate the membership interval

$$\left[ \mu_{A_t}^{\alpha}(q), \mu_{A_t}^{\frac{1}{\alpha}}(q) \right].$$

**Fig. 6.9** Tizhoosh's construction

## 6.5 Atanassov's Intuitionistic Fuzzy Sets or Bipolar Fuzzy Sets of Type 2 or IF Fuzzy Sets

In 1983, Atanassov presented his definition of intuitionistic fuzzy set [6.93]. This paper was written in Bulgarian, and in 1986 he presented his ideas in English in [6.94].

### Definition 6.14

An intuitionistic fuzzy set over  $U$  is an expression  $A$  given by

$$A = \{(u_i, \mu_A(u_i), v_A(u_i)) | u_i \in U\},$$

where  $\mu_A: U \rightarrow [0, 1]$

$$v_A: U \rightarrow [0, 1]$$

such that  $0 \leq \mu_A(u_i) + v_A(u_i) \leq 1$  for every  $u_i \in U$ .

Atanassov also introduced the following two essential characteristics of these sets:

1. The complementary of

$$A_c = \{(u_i, \mu_A(u_i), v_A(u_i)) | u_i \in U\}.$$

is

$$A_c = \{(u_i, v_A(u_i), \mu_A(u_i)) | u_i \in U\}.$$

2. For each  $u_i \in U$ , the intuitionistic or hesitance index of such element in the considered set  $A$  is given by

$$\pi_A(u_i) = 1 - \mu_A(u_i) - v_A(u_i).$$

$\pi_A(u_i)$  is a measure of the hesitance of the expert to assign a numerical value to  $\mu_A(u_i)$  and  $v_A(u_i)$ . For this reason, we consider that these sets are an extension of fuzzy sets. It is clear that if for each  $u_i \in U$  we take  $v_A(u_i) = 1 - \mu_A(u_i)$ , then the considered set  $A$  is a fuzzy set in Zadeh's sense. So fuzzy sets are a particular case of those defined by Atanassov.

In 1993, Gau and Buehre [6.95] introduced the concept of vague set and later in 1994 it was shown that these are the same as those introduced by Atanassov in 1983 [6.96].

We denote by  $A - IFS(U)$  the class of all intuitionistic sets (in the sense of Atanassov) defined over the referential  $U$ . Atanassov also gave the following definition:

### Definition 6.15

Given  $A, B \in A - IFS(U)$ .

$$A \cup_{A - IFS} B = \{(u_i, \max(\mu_A(u_i), \mu_B(u_i)), \min(v_A(u_i), v_B(u_i))) | u_i \in U\}$$

$$A \cap_{A - IFS} B = \{(u_i, \min(\mu_A(u_i), \mu_B(u_i)), \max(v_A(u_i), v_B(u_i))) | u_i \in U\}.$$

Definitions of connectives for Atanassov's sets in terms of  $t$ -norms, etc. can be found in [6.49, 97].

### Corollary 6.3

Atanassov's intuitionistic fuzzy sets are a particular case of  $L$ -fuzzy sets.

*Proof:* Just note that  $L = \{(x_1, x_2) | x_1 + x_2 \leq 1 \text{ with } x_1, x_2 \in [0, 1]\}$  with the operations in Definition 6.15 is a lattice. ■

### Proposition 6.6

The set  $(A - IFS(U), \cup_{A - IFS}, \cap_{A - IFS})$  is a bounded lattice, where the order is defined as

$$A \leq_{A - IFS} B \text{ if and only if } A \cup_{A - IFS} B = B$$

or equivalently

$$A \leq_{A - IFS} B \text{ if and only if } A \cap_{A - IFS} B = A.$$

From Proposition 6.6, we see that the order

$$A \leq_{A - IFS} B \text{ if and only if } \mu_A(u_i) \leq \mu_B(u_i) \text{ and} \\ v_A(u_i) \geq v_B(u_i) \text{ for all } u_i \in U$$

is not linear. Different methods to get linear orders for these sets can be found in [6.50, 51].

### 6.5.1 Relation Between Interval-Valued Fuzzy Sets and Atanassov's Intuitionistic Fuzzy Sets: Two Different Concepts

In 1989, Atanassov and Gargov [6.98] and later De Schrijver and Kerre [6.24] proved that from an interval-valued fuzzy set we can build an intuitionistic fuzzy set and vice-versa.

**Theorem 6.2**

The mapping

$$\Phi: IVFS(U) \rightarrow A - IFS(U), \\ A \rightarrow A',$$

where  $A' = \{(u_i, \underline{A}(u_i), 1 - \bar{A}(u_i)) | u_i \in U\}$ , is a bijection.

Theorem 6.2 shows that interval-valued fuzzy sets and Atanassov's intuitionistic fuzzy sets, are equivalent from a mathematical point of view. But, as pointed out in [6.52], the absence of a structural component in their description might explain this result, since from a conceptual point of view they very different models:

- The representation of the membership of an element to a set using an interval means that the expert doubts about the exact value of such membership, so such an expert provides two bounds, and we never consider the representation of the nonmembership to a set.
- By means of the intuitionistic index we, represent the hesitance of the expert in simultaneously building the membership and the nonmembership degrees.

From an applied point of view, the conceptual difference between both concepts has also been clearly displayed in [6.99]. On page 204 of this paper, Ye adapts an example by Herrera and Herrera-Viedma appeared in 2000 [6.100]. Ye's example runs as follows:  $n$  experts are asked about a money investment in four different companies. Ye considers that the membership to the set that represents each company is given by the number of experts who would invest their money in that company (normalized by  $n$ ), and the non-membership is given by the number of experts who would not invest their money in that company. Clearly, the intuitionistic index corresponds to the experts that do not provide either a positive or a negative answer about investing in that company. In this way, Ye proves that:

- The results obtained with this representation are more realistic than those obtained in [6.100] using Zadeh's fuzzy sets.
- In the considered problem, the interval interpretation does not make much sense besides its use as a mathematical tool.

### 6.5.2 Some Problems with the Intuitionistic Sets Defined by Atanassov

Besides the missed structural component pointed out in [6.52]:

- In these sets, each element has two associated values. For this reason, we consider that the information measures as entropy [6.59, 61], similarity [6.101, 102], etc. should also be given by two numerical values. That is, in our opinion, we should distinguish between those measures that provide a single number and those others that provide two numbers. This fact is discussed in [6.103] where the two concepts of entropy given in [6.59] and [6.61] are jointly used to represent the uncertainty linked to Atanassov's intuitionistic fuzzy set. So we think that it is necessary to carry out a conceptual revision of the definitions of similarity, dissimilarity, entropy, comparability, etc., given for these sets. Even more since nowadays working with two numbers instead of a single one does not imply a much larger computational cost.
- As in the case of interval-valued fuzzy sets, in many applications, there is a problem to choose the most appropriate linear order associated with that application [6.50, 51]. We should remark that the chosen order directly influences the final outcome, so it is necessary to study the conditions that determine the choice of one order or another [6.65].

### 6.5.3 Applications

Extensions have shown themselves very useful in problems of decision making [6.99, 104–108]. In general, they work very well in problems for which we have to represent the difference between the positive and the negative representation of something [6.109], in particular in cognitive psychology and medicine [6.110]. Also in image processing they have been used often, as in [6.111, 112]. We should remark that the mathematical equivalence between these sets and interval-valued fuzzy sets makes that in many applications in which interval-valued fuzzy sets are useful, so are Atanassov's intuitionistic fuzzy sets [6.113].

### 6.5.4 The Problem of the Name

From Sect. 6.1.1, it is clear that the term *intuitionistic* was used in 1907 by Brouwer, in 1930 by Heyting, etc. So, 75 years before Atanassov used it, it already had

a specific meaning in logic. Moreover, one year after Atanassov first used it in Bulgarian, Takeuti and Titani (1984) presented a set representation for Heyting ideas, using the expression *intuitionistic fuzzy sets*. From our point of view, this means that in fact the correct terminology is that of Takeuti and Titani. Nevertheless, all these facts have originated a serious notation problem in the literature about the subject.

In 2005, in order to solve these problems, Dubois et al. published a paper [6.7] on the subject and, they proposed to replace the name intuitionistic fuzzy sets by *bipolar fuzzy sets*, justifying this change. Later, Atanassov has answered in [6.114], where he defends the reasons he had to choose the name intuitionistic and states a clear fact: the sets he defined are much more cited and used than those defined by Takeuti and Titani, so in his opinion the name must not change.

In Dubois and Prade's works about bipolarity types [6.115, 116], these authors stated that Atanassov's sets are included in the type-2 bipolar sets, so they call these sets fuzzy bipolar sets of type-2.

But we must say that nine years before Dubois et al.'s paper about the notation, Zhang in [6.117, 118] used the word bipolar in connection with the fuzzy sets theory and presented the concept of bipolar-valued set.

All these considerations have led some authors to propose the name Atanassov's *intuitionistic fuzzy sets*. However, Atanassov himself disagrees with this notation and asserts that his notation must be hold; that is, intuitionistic fuzzy sets. Other authors use the name **IF-** sets (intuitionistic fuzzy) [6.119].

In any case, only time will fix the appropriate names.

## 6.6 Atanassov's Interval-Valued Intuitionistic Fuzzy Sets

In 1989, Atanassov and Gargov presented the following definition [6.98]:

### Definition 6.16

An Atanassov's interval-valued intuitionistic fuzzy set over  $U$  is an expression  $A$  given by

$$A = \{(u_i, M_A(u_i), N_A(u_i)) \mid u_i \in U\},$$

where  $M_A: U \rightarrow L([0, 1])$ ,

$$N_A: U \rightarrow L([0, 1])$$

such that  $0 \leq \overline{M}_A(u_i) + \overline{N}_A(u_i) \leq 1$  for every  $u_i \in U$ .

In this definition, authors adapt Atanassov's intuitionistic sets to Zadeh's ideas on the problem of building the membership degrees of the elements to the fuzzy set. Moreover, if for every  $u_i \in U$ , we have that  $\underline{M}_A(u_i) = \overline{M}_A(u_i)$  and  $\underline{N}_A(u_i) = \overline{N}_A(u_i)$ , then we recover an Atanassov's intuitionistic fuzzy set, so the latter are a particular case of Atanassov's interval-valued intuitionistic fuzzy sets. As in the case of Atanassov's intuitionistic fuzzy sets, the complementary of a set is obtained by interchanging the membership and non-membership intervals.

We represent by  $A - IVIFS(U)$  the class of all Atanassov's interval-valued intuitionistic fuzzy sets over a referential set  $U$ .

### Definition 6.17

Given  $A, B \in A - IVIFS(U)$ :

$$\begin{aligned} A \cup_{A - IVIFS} B &= \{(u_i, A \cup_{A - IVIFS} B(u_i)) \mid u_i \in U\} \\ \text{where } A \cup_{A - IVIFS} B(u_i) &= [\max(\underline{M}_A(u_i), \underline{M}_B(u_i)), \max(\overline{M}_A(u_i), \overline{M}_B(u_i))] \\ &\quad [\min(\underline{N}_A(u_i), \underline{N}_B(u_i)), \min(\overline{N}_A(u_i), \overline{N}_B(u_i))] , \\ A \cap_{A - IVIFS} B &= \{(u_i, A \cap_{A - IVIFS} B(u_i)) \mid u_i \in U\} \\ \text{where } A \cap_{A - IVIFS} B(u_i) &= (\min(\underline{M}_A(u_i), \underline{M}_B(u_i)), \min(\overline{M}_A(u_i), \overline{M}_B(u_i))) \\ &\quad [\max(\underline{N}_A(u_i), \underline{N}_B(u_i)), \max(\overline{N}_A(u_i), \overline{N}_B(u_i))] , \end{aligned}$$

### Corollary 6.4

Atanassov's interval-valued intuitionistic fuzzy sets are a particular case of  $L$ -fuzzy sets.

*Proof:* Just note that  $LL([0, 1]) = \{(\mathbf{x}, \mathbf{y}) \in L([0, 1])^2 \mid \bar{x} + \bar{y}\}$  with the operations in Definition 6.17 is a lattice. ■

### Proposition 6.7

The set  $(A - IVIFS(U), \cup_{A - IVIFS}, \cap_{A - IVIFS})$  is a bounded lattice, where the order is defined as

$$A \leq_{A - IVIFS} B \text{ if and only if } A \cup_{A - IVIFS} B = B$$

or equivalently

$$A \leq_{A-IVIFS} B \text{ if and only if } A \cap_{A-IVIFS} B = A.$$

Note that  $A \leq_{A-IVIFS} B$  if and only if  $M_A(u_i) \leq_{IVFS} M_B(u_i)$  and  $N_A(u_i) \geq_{IVFS} N_B(u_i)$  for all  $u_i \in U$ ; that is,  $A \leq_{A-IVIFS} B$  if and only if  $\underline{M}_A(u_i) \leq \underline{M}_B(u_i)$ ,  $\overline{M}_A(u_i) \leq \overline{M}_B(u_i)$ ,  $\underline{N}_A(u_i) \geq \underline{N}_B(u_i)$ , and  $\overline{N}_A(u_i) \geq \overline{N}_B(u_i)$  for all  $u_i \in U$  is not linear.

We make the following remarks regarding these extensions:

1. It is necessary to study two different types of information measures: those whose outcome is a single number [6.120] and those whose outcomes are two

intervals in  $[0, 1]$  [6.120]. It is necessary a study of both types.

2. Nowadays, there are many works using these sets [6.121–123]. However none of them displays an example where the results obtained with these sets are better than those obtained with fuzzy sets or other techniques. As it happened until recent years with interval-valued fuzzy sets, it is necessary to find an application that provides better results using these extensions rather than using other sets. To do so, we should compare the results with those obtained with other techniques, which is something that it is not done for the moment in the papers that make use of these sets. From the moment, most of the studies are just theoretical [6.124–126].

## 6.7 Links Between the Extensions of Fuzzy Sets

Taking into account the study carried out in previous sections, we can describe the following links between the different extensions.

1.  $FS \subset IVFS \equiv \text{Grey Sets} \equiv A-IFS \equiv \text{Vague sets} \subset A-IVIFS \subset L-FS.$

2. If we consider the operations in Definition 6.11, we have the sequence of inclusions:

$$\begin{aligned} FS \subset IVFS &\equiv \text{Grey Sets} \equiv A-IFS \\ &\equiv \text{Vague sets} \subset T2FS \subset L-FS. \end{aligned}$$

## 6.8 Other Types of Sets

In this section, we present the definition of other types of sets that have arisen from the idea of Zadeh's fuzzy set. However, for us none of them should be considered an extension of a fuzzy set, since we do not represent with them the degree of ignorance or uncertainty of the expert.

### 6.8.1 Probabilistic Sets

These sets were introduced in 1981 by Hirota [6.127].

#### Definition 6.18

Let  $(\Omega, B, P)$  be a probability space and let  $B(0, 1)$  denote the family of Borel sets in  $[0, 1]$ . A probabilistic set  $A$  over the universe  $U$  is a function

$$A: U \times \Omega \rightarrow ([0, 1], B(0, 1)),$$

where  $A(u_i, \cdot)$  is measurable for each  $u_i \in U$ .

### 6.8.2 Fuzzy Multisets and $n$ -Dimensional Fuzzy Sets

The idea of multiset was given by Yager in 1986 [6.128] and later developed by Miyamoto [6.129]. In these multilevel sets, several degrees of membership are assigned to each element.

#### Definition 6.19

Let  $U$  be a nonempty set and  $n \in N^+$ . A fuzzy multiset  $A$  over  $U$  is given by

$$A = \{(u_i, \mu_{A_1}(u_i), \mu_{A_2}(u_i), \dots, \mu_{A_n}(u_i)) | u_i \in U\},$$

where  $\mu_{A_i}: U \rightarrow [0, 1]$  is called the  $i$ th membership degree of  $A$ .

If in Definition 6.19 we require that:  $\mu_{A_1} \leq \mu_{A_2} \leq \dots \leq \mu_{A_n}$  we have an  $n$ -Dimensional fuzzy set [6.130, 131]. Nevertheless, it is worth to point out the relation of these families of fuzzy set with the classification

model proposed in [6.132], and the particular model proposed in [6.133], where fuzzy preference intensity was arranged according to the basic preference attitudes.

### 6.8.3 Bipolar Valued Set or Bipolar Set

In 1996, *Zhang* presented the concept of bipolar set as follows [6.117]:

#### Definition 6.20

A bipolar-valued set or a bipolar set on  $U$  is an object

$$A = \{(u_i, \varphi^+(u_i), \varphi^-(u_i))|u_i \in U\}$$

with  $\varphi^+: U \rightarrow [0, 1]$ ,  $\varphi^-: U \rightarrow [-1, 0]$ .

In these sets, the value  $\varphi^-(u_i)$  must be understood as how much the environment of the problem opposes to the fulfillment of  $\varphi^+(u_i)$ . Nowadays interesting studies exist about these sets [6.134–138].

### 6.8.4 Neutrosophic Sets or Symmetric Bipolar Sets

These sets were first studied by Smarandache in 2002 [6.139]. They arise from Atanassov's intuitionistic fuzzy sets ignoring the restriction on the sum of the membership and the nonmembership degrees.

#### Definition 6.21

A neutrosophic set or symmetric bipolar set on  $U$  is an object

$$A = \{(u_i, \mu_A(u_i), v_A(u_i))|u_i \in U\},$$

with  $\mu_A: U \rightarrow [0, 1]$ ,  $v_A: U \rightarrow [0, 1]$ .

### 6.8.5 Hesitant Sets

These sets were introduced by *Torra* and *Narukawa* in 2009 to deal with decision-making problems [6.140, 141].

#### Definition 6.22

Let  $\wp([0, 1])$  be the set of all subsets of the unit interval and  $U$  be a nonempty set. Let  $\mu_A: U \rightarrow \wp([0, 1])$ , then a *hesitant fuzzy set* (HFS in short)  $A$  defined over  $U$  is given by

$$A = \{(u_i, \mu_A(u_i))|u_i \in U\}. \quad (6.6)$$

### 6.8.6 Fuzzy Soft Sets

Based on the definition of soft set [6.142], *Maji* et al. present the following definition [6.143].

#### Definition 6.23

A pair  $(F, A)$  is called a fuzzy soft set over  $U$ , where  $F$  is a mapping given by  $F: A \rightarrow FP(U)$ .

Where  $FP(U)$  denotes the set of all fuzzy subsets of  $U$ .

### 6.8.7 Fuzzy Rough Sets

From the concept of rough set given by *Pawlak* in [6.144], *Dubois* and *Prade* in 1990 proposed the following definition [6.145]. *From different point of views these sets could be considered as an extension of fuzzy sets in our sense*, besides these sets are being exhaustively studied, for this reason we consider that these sets need another chapter.

#### Definition 6.24

Let  $U$  be a referential set and  $R$  be a fuzzy similarity relation on  $U$ . Take  $A \in FS(U)$ . A fuzzy rough set over  $U$  is a pair  $(R \downarrow A, R \uparrow A) \in FS(U) \times FS(U)$ , where

- $R \downarrow A: U \rightarrow [0, 1]$  is given by  

$$R \downarrow A(u) = \inf_{v \in U} \max(1 - R(v, u), A(v))$$
- $R \uparrow A: U \rightarrow [0, 1]$  is given by  

$$R \uparrow A(u) = \sup_{v \in U} \min(R(v, u), A(v)).$$

## 6.9 Conclusions

In this chapter, we have reviewed the main types of fuzzy sets defined since 1965. We have classified these sets in two groups: those that take into account the problem of building the membership functions, which we have included in the so-called extensions of fuzzy sets, and those that appear as an answer to such a key issue.

We have introduced the definitions and first properties of the extensions, that is, type-2 fuzzy sets, interval-valued fuzzy sets; Atanassov's intuitionistic fuzzy sets or type-2 bipolar fuzzy sets, and Atanassov's interval-valued fuzzy sets. We have described the properties and problems linked to type-2 fuzzy sets, and we have pre-

sented several construction methods for interval-valued fuzzy sets, depending on the application. We have also referred to some papers where it is shown that the use of interval-valued fuzzy sets improves the results obtained with fuzzy sets.

In general, we have stated the main problem in fuzzy sets extensions, namely, to find applications for which the results obtained with these sets are better than those obtained with other techniques. This has only been proved, up to now, for interval-valued fuzzy sets. We think that the great defy for some sets that are initially justified as a theoretical need is to prove their practical usefulness.

# F-Transform

Irina Perfilieva

The theory of the  $F$ -transform is presented and discussed from the perspective of the latest developments and applications. Various fuzzy partitions are considered. The definition of the  $F$ -transform is given with respect to a generalized fuzzy partition, and the main properties of the  $F$ -transform are listed. The applications to image processing, namely image compression, fusion and edge detection, are discussed with sufficient technical details.

## 7.1 Fuzzy Modeling

Fuzzy modeling is still regarded as a modern technique with a nonclassical background. The goal of this chapter is to bridge standard mathematical methods and methods for the construction of fuzzy approximation models. We will present the theory of the *fuzzy transform* (the  $F$ -transform), which was introduced in [7.1] for the purpose of encompassing both classical (usually, integral) transforms and approximation models based on fuzzy IF–THEN rules (*fuzzy approximation models*). We start with an informal characterization of integral transforms, and from this discussion, we examine the similarities and differences among integral transforms, the  $F$ -transform, and fuzzy approximation models. An integral transform is performed using some kernel. The kernel is represented by a function of two variables and can be understood as a *collection of local factors* or closeness areas around elements of an original space. Each factor is then assigned an aver-

age value of a transforming object (usually, a function). Consequently, the transformed object is a new function defined on a space of *local factors*. The  $F$ -transform can be implicitly characterized by a *discrete kernel* that is associated with a finite collection of fuzzy subsets (local factors or closeness areas around chosen *nodes*) of an original space. We say that this collection establishes a *fuzzy partition* of the space. Then, similar to integral transforms, the  $F$ -transform assigns an average value of a transforming object to each fuzzy subset from the fuzzy partition of the space. Consequently, the  $F$ -transformed object is a finite vector of average values.

Similar to the  $F$ -transform, a fuzzy approximation model can also be implicitly characterized by a discrete kernel that establishes a fuzzy partition of an original space. Each element of the established fuzzy partition is a fuzzy set in the IF part (antecedent) of the re-

spective fuzzy IF–THEN rule. The rule characterizes a correspondence between an antecedent and an average value of a transforming object (singleton model) or a fuzzy subset of a space of object values (fuzzy set model).

To emphasize the differences among integral transforms, the  $F$ -transform, and fuzzy approximation models, we note that the last two are actually finite collections of local descriptions of a considered object. Each collection produces a global description of the considered object in the form of the direct  $F$ -transform or the system of fuzzy IF–THEN rules.

The idea of producing collections of local descriptions by fuzzy IF–THEN rules originates from the early works of Zadeh [7.2–5] and from the Takagi–Sugeno [7.6] approximation models.

Similar to the conventional integral transforms (the Fourier and Laplace transforms, for example), the  $F$ -transform performs a transformation of an original universe of functions into a universe of their *skeleton*

(vectors of  $F$ -transform components) for which further computations are easier (see, e.g., an application to the initial value problem with fuzzy initial conditions [7.7]). In this respect, the  $F$ -transform can be as useful in applications as traditional transforms (see applications to image compression [7.8, 9] and time series processing [7.10–14], for example). Moreover, sometimes the  $F$ -transform can be more efficient than its counterparts; see the details below.

The structure of this chapter is as follows. In Sect. 7.2, we consider various fuzzy partitions: uniform and with and without the Ruspini condition, among others; in Sect. 7.3, definitions of the  $F$ -transforms (direct and inverse) and their main properties are considered; in Sect. 7.4, the discrete  $F$ -transform is defined; in Sect. 7.5, the direct and inverse  $F$ -transform of a function of two variables is introduced; in Sect. 7.6, a higher degree  $F$ -transform is considered; in Sect. 7.7, applications of the  $F$ -transform and  $F^1$ -transform to image processing are discussed.

## 7.2 Fuzzy Partitions

In this section, we present a short overview of various fuzzy partitions of a universe in which transforming objects (functions) are defined. As we learned from Sect. 7.1, a fuzzy partition is a finite collection of fuzzy subsets of the universe that determines a discrete kernel and thus a respective transform. Therefore, we have as many  $F$ -transforms as fuzzy partitions.

### 7.2.1 Fuzzy Partition with the Ruspini Condition

The *fuzzy partition with the Ruspini condition* (7.1) (simply, *Ruspini partition*) was introduced in [7.1]. This condition implies normality of the respective fuzzy partition, i.e., the *partition-of-unity*. It then leads to a simplified version of the inverse  $F$ -transform. In later publications [7.15, 16], the Ruspini condition was weakened to obtain an additional degree of freedom and a better approximation by the inverse  $F$ -transform.

#### Definition 7.1

Let  $x_1 < \dots < x_n$  be fixed nodes within  $[a, b]$  such that  $x_1 = a$ ,  $x_n = b$  and  $n \geq 2$ . We say that the fuzzy sets  $A_1, \dots, A_n$ , identified with their membership functions defined on  $[a, b]$ , establish a Ruspini partition of

$[a, b]$  if they fulfill the following conditions for  $k = 1, \dots, n$ :

1.  $A_k : [a, b] \rightarrow [0, 1]$ ,  $A_k(x_k) = 1$
2.  $A_k(x) = 0$  if  $x \notin (x_{k-1}, x_{k+1})$ , where for uniformity of notation, we set  $x_0 = a$  and  $x_{n+1} = b$
3.  $A_k(x)$  is continuous
4.  $A_k(x)$ , for  $k = 2, \dots, n$ , strictly increases on  $[x_{k-1}, x_k]$  and  $A_k(x)$  for  $k = 1, \dots, n-1$ , strictly decreases on  $[x_k, x_{k+1}]$
5. for all  $x \in [a, b]$ ,

$$\sum_{k=1}^n A_k(x) = 1. \quad (7.1)$$

The condition (7.1) is known as the Ruspini condition. The membership functions  $A_1, \dots, A_n$  are called the *basic functions*. A point  $x \in [a, b]$  is *covered* by the basic function  $A_k$  if  $A_k(x) > 0$ .

The shape of the basic functions is not predetermined and therefore, it can be chosen according to additional requirements (e.g., smoothness). Let us give examples of various fuzzy partitions with the Ruspini condition. In Fig. 7.1, two such partitions with triangular and cosine basic functions are shown. The following formulas represent generic fuzzy partitions with the

Ruspini condition and triangular functions

$$A_1(x) = \begin{cases} 1 - \frac{(x-x_1)}{h_1}, & x \in [x_1, x_2], \\ 0, & \text{otherwise,} \end{cases}$$

$$A_k(x) = \begin{cases} \frac{(x-x_{k-1})}{h_{k-1}}, & x \in [x_{k-1}, x_k], \\ 1 - \frac{(x-x_k)}{h_k}, & x \in [x_k, x_{k+1}], \\ 0, & \text{otherwise,} \end{cases}$$

$$A_n(x) = \begin{cases} \frac{(x-x_{n-1})}{h_{n-1}}, & x \in [x_{n-1}, x_n], \\ 0, & \text{otherwise,} \end{cases}$$

where  $k = 2, \dots, n-1$  and  $h_k = x_{k+1} - x_k$ .

We say that a Ruspini partition of  $[a, b]$  is *h-uniform* if its nodes  $x_1, \dots, x_n$ , where  $n \geq 3$ , are equidistant, i.e.,  $x_k = a + h(k-1)$ , for  $k = 1, \dots, n$ , where  $h = (b-a)/(n-1)$ , and the two additional properties are met:

6.  $A_k(x_k - x) = A_k(x_k + x)$ , for all  $x \in [0, h]$ ,  $k = 2, \dots, n-1$ ,
7.  $A_k(x) = A_{k-1}(x-h)$ , for all  $k = 2, \dots, n-1$  and  $x \in [x_k, x_{k+1}]$ , and  $A_{k+1}(x) = A_k(x-h)$ , for all  $k = 2, \dots, n-1$  and  $x \in [x_k, x_{k+1}]$ .

## 7.2.2 Fuzzy Partitions with the Generalized Ruspini Condition

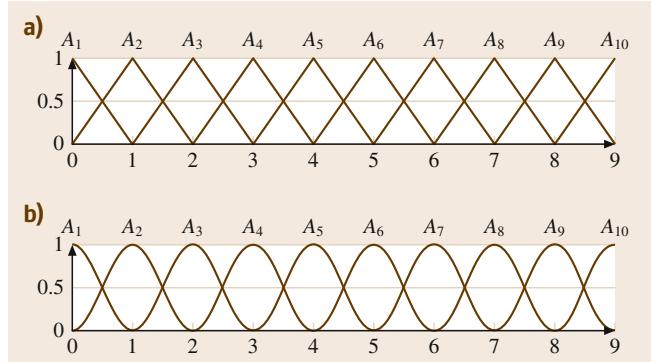

Fuzzy partitions with the generalized Ruspini condition were introduced in [7.15]. The generalization consists in replacing *partition-of-unity* (7.1) by *fuzzy r-partition* (7.2). This type of partition was investigated in [7.15, 17], where the focus was on smoothing or filtering data using the inverse *F*-transform. The following definition is taken from [7.15].

### Definition 7.2

Let  $r \geq 1$  and  $n \geq 2$  be fixed integers such that  $r \leq n$ . Let  $a = x_1 < \dots < x_n = b$  be nodes within  $[a, b]$ , and let  $x_{1-r} < \dots < x_0 < a$  and  $b < x_{n+1} < \dots < x_{n+r}$  be nodes outside of  $[a, b]$ . A fuzzy *r*-partition of  $[a, b]$  is a family of  $n+2r-2$  continuous, normal, convex fuzzy sets

$$A_{2-r}^{(r)}, \dots, A_1^{(r)}, \dots, A_n^{(r)}, \dots, A_{n+r-1}^{(r)}$$

such that the following conditions are fulfilled:

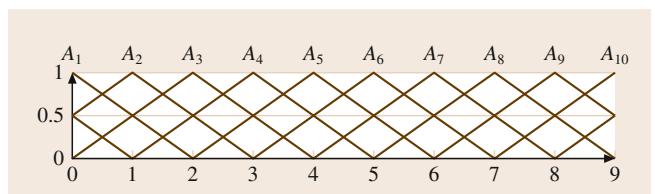

**Fig. 7.1a, b** Two Ruspini partitions with triangular (a) and cosine basic functions

1. For  $k = 1, \dots, n$ ,  $A_k^{(r)}$  is a continuous function on  $[a, b]$  such that  $A_k^{(r)}(x_k) = 1$  and  $A_k^{(r)}(x) = 0$  for  $x \notin [\max(x_{k-r}, a), \min(x_{k+r}, b)]$
2. For  $k = 1, \dots, n$ ,  $A_k^{(r)}$  is increasing on  $[\max(x_{k-r}, a), x_k]$  and decreasing on  $[x_k, \min(x_{k+r}, b)]$
3. For  $k = -r+2, \dots, 0$ ,  $A_k^{(r)}$  is decreasing on  $[\max(x_k, a), x_{k+r}]$
4. For  $k = n+1, \dots, n+r-1$ ,  $A_k^{(r)}$  is increasing on  $[x_{k-r}, \min(x_k, b)]$
5. For all  $x \in [a, b]$ , the following *partition-of-r* condition holds

$$\sum_{k=-r+2}^{n+r-1} A_k^{(r)}(x) = r. \quad (7.2)$$

If  $r = 1$ , then a fuzzy *r*-partition in the sense of Definition 7.2 becomes the standard fuzzy partition in the sense of Definition 7.1, i.e., the *partition-of-unity*. In Fig. 7.2, the fuzzy 2-partition with triangular basic functions is shown.

**Fig. 7.2** An example of a fuzzy 2-partition with triangular basic functions

### 7.2.3 Generalized Fuzzy Partitions

A *generalized fuzzy partition* appeared in [7.16] in connection with the notion of the higher degree  $F$ -transform. Its even weaker version was implicitly introduced in [7.18] with the purpose of meeting the requirements of image compression. We summarize both these notions and propose the following definition.

#### Definition 7.3

Let  $[a, b]$  be an interval on  $\mathbb{R}$ ,  $n \geq 2$ , and let  $x_0, x_1, \dots, x_n, x_{n+1}$  be nodes such that

$$a = x_0 \leq x_1 < \dots < x_n \leq x_{n+1} = b.$$

We say that the fuzzy sets

$$A_1, \dots, A_n : [a, b] \rightarrow [0, 1]$$

constitute a *generalized fuzzy partition* of  $[a, b]$  if for every  $k = 1, \dots, n$  there exist  $h'_k, h''_k \geq 0$  such that

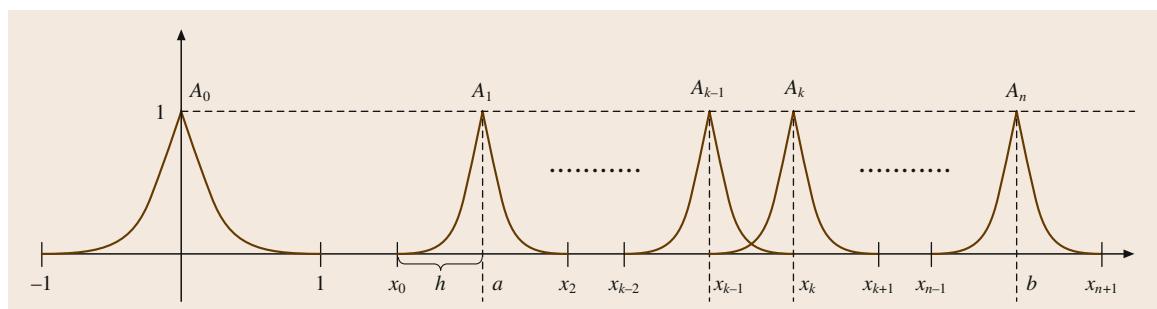

$$h'_k + h''_k > 0, [x_k - h'_k, x_k + h''_k] \subseteq [a, b]$$

and the following three conditions are fulfilled:

1. (locality) –  $A_k(x) > 0$  if  $x \in (x_k - h'_k, x_k + h''_k)$ , and  $A_k(x) = 0$  if  $x \in [a, b] \setminus [x_k - h'_k, x_k + h''_k]$
2. (continuity) –  $A_k$  is continuous on  $[x_k - h'_k, x_k + h''_k]$
3. (covering) – for  $x \in [a, b]$ ,  $\sum_{k=1}^n A_k(x) > 0$ .

It is important to remark that by conditions of *locality* and *continuity*,

$$\int_a^b A_k(x) dx > 0.$$

**Fig. 7.3** Generating function  $A_0$  of an  $h$ -uniform generalized fuzzy partition (after [7.19])

An  $(h, h')$ -uniform generalized fuzzy partition of  $[a, b]$  is defined for equidistant nodes

$$x_k = a + h(k-1), k = 1, \dots, n,$$

where  $h = (b-a)/(n-1)$ ,  $h' > h/2$  and two additional properties are satisfied:

4.  $A_k(x) = A_{k-1}(x-h)$  for all  $k = 2, \dots, n-1$  and  $x \in [x_k, x_{k+1}]$ , and  $A_{k+1}(x) = A_k(x-h)$  for all  $k = 2, \dots, n-1$  and  $x \in [x_k, x_{k+1}]$ .
5.  $h'_1 = h''_n = 0$ ,  $h''_1 = h'_2 = \dots = h''_{n-1} = h'_n = h'$  and for all  $k = 2, \dots, n-1$  and all  $x \in [0, h']$ ,  $A_k(x_k - x) = A_k(x_k + x)$ .

An  $(h, h')$ -uniform generalized fuzzy partition of  $[a, b]$  can also be defined using the *generating function*  $A_0 : [-1, 1] \rightarrow [0, 1]$ , which is assumed to be *even*, continuous, and positive everywhere except for on boundaries, where it vanishes. (The function  $A_0 : [-1, 1] \rightarrow \mathbb{R}$  is even if for all  $x \in [0, 1]$ ,  $A_0(-x) = A_0(x)$ .) Then, basic functions  $A_k$  of an  $(h, h')$ -uniform generalized fuzzy partition are shifted copies of  $A_0$  in the sense that

$$A_1(x) = \begin{cases} A_0\left(\frac{x-x_1}{h'}\right), & x \in [x_1, x_1 + h'], \\ 0, & \text{otherwise,} \end{cases}$$

and for  $k = 2, \dots, n-1$ ,

$$A_k(x) = \begin{cases} A_0\left(\frac{x-x_k}{h'}\right), & x \in [x_k - h', x_k + h'], \\ 0, & \text{otherwise,} \end{cases}$$

$$A_n(x) = \begin{cases} A_0\left(\frac{x-x_n}{h'}\right), & x \in [x_n - h', x_n], \\ 0, & \text{otherwise.} \end{cases}$$

(7.3)

As an example, we note that the function  $A_0(x) = 1 - |x|$  is a generating function for all uniform triangular partitions. The difference between them is in parameters  $h$

and  $h'$ . An  $(h, h)$ -uniform generalized fuzzy partition is simply called an  $h$ -uniform one (Fig. 7.3).

### Remark 7.1

A generalized fuzzy partition can also be considered in connection with radial membership functions;

## 7.3 Fuzzy Transform

The  $F$ -transform establishes a correspondence between a set of continuous functions on an interval of real numbers and the set of  $n$ -dimensional (real) vectors. Each component of the resulting vector is a weighted local mean of a corresponding function over an area covered by a corresponding basic function. The vector of the  $F$ -transform components is a simplified representation of an original function that can be used instead of the original function in many applications. Among them, let us mention applications to image compression [7.8, 9], image fusion, image reduction, time series processing [7.10–14], and the initial value problem with fuzzy initial conditions [7.7].

### 7.3.1 Direct $F$ -Transform

In this section, we give the definition of the  $F$ -transform according to [7.1] and recall the main properties of it. We assume that the universe is an interval  $[a, b]$  and  $x_1 < \dots < x_n$  are fixed nodes from  $[a, b]$  such that  $x_1 = a$ ,  $x_n = b$  and  $n \geq 2$ . Let us formally extend the set of nodes by  $x_0 = a$  and  $x_{n+1} = b$ . Let  $A_1, \dots, A_n$  be the basic functions that form a fuzzy partition of  $[a, b]$  according to Definition 7.3. Let  $C([a, b])$  be the set of continuous functions on the interval  $[a, b]$ . The following definition introduces the fuzzy transform of a function  $f \in C([a, b])$ .

### Definition 7.4

Let  $A_1, \dots, A_n$  be the basic functions that form a generalized fuzzy partition of  $[a, b]$  and  $f$  be any function from  $C([a, b])$ . We say that the  $n$ -tuple of real numbers  $\mathbf{F}[f] = (F_1, \dots, F_n)$  given by

$$F_k = \frac{\int_a^b f(x)A_k(x)dx}{\int_a^b A_k(x)dx}, \quad k = 1, \dots, n, \quad (7.4)$$

is the (integral)  $F$ -transform of  $f$  with respect to  $A_1, \dots, A_n$ .

see [7.20]. In this case, every basic function has a generic representation in terms of a kernel  $\varphi : \mathbb{R}^+ \rightarrow \mathbb{R}$  such that

$$A_k(x) = \varphi(\|x - x_k\|_2), \quad k = 1, \dots, n.$$

The elements  $F_1, \dots, F_n$  are called the *components of the  $F$ -transform*. If  $A_1, \dots, A_n$  is an  $h$ -uniform Ruspini partition, then (7.4) may be simplified as follows,

$$\begin{aligned} F_1 &= \frac{2}{h} \int_{x_1}^{x_2} f(x)A_1(x)dx, \\ F_n &= \frac{2}{h} \int_{x_{n-1}}^{x_n} f(x)A_n(x)dx, \\ F_k &= \frac{1}{h} \int_{x_{k-1}}^{x_{k+1}} f(x)A_k(x)dx, \quad k = 2, \dots, n-1. \end{aligned} \quad (7.5)$$

The following is a list of some properties of the  $F$ -transform of  $f$  with respect to a generalized fuzzy partition of  $[a, b]$ :

- (a) If for all  $x \in [a, b]$ ,  $f(x) = C$ , then  $F_k = C$ ,  $k = 1, \dots, n$ .
- (b) If  $f = \alpha g + \beta h$ , then  $\mathbf{F}[f] = \alpha \mathbf{F}[g] + \beta \mathbf{F}[h]$ .
- (c) If  $[c, d] = \{f(x) \mid x \in [a, b]\}$ , then  $F_k = \min_{[c, d]} \int_a^b (f(x) - y)^2 A_k(x)dx$ ,  $k = 1, \dots, n$ .
- (d) If  $f$  is twice continuously differentiable on  $[a, b]$ , then  $F_k = f(x_k) + O(h^2)$ ,  $k = 1, \dots, n$ . (This is true for an  $h$ -uniform Ruspini partition of  $[a, b]$  only. A similar estimation of the  $F$ -transform component  $F_k$  as a linear combination of  $f(x_k - r + 1), \dots, f(x_k), \dots, f(x_k + r - 1)$  can be established for a fuzzy  $r$ -partition [7.15].)
- (e) If a generalized fuzzy partition is  $(h, h')$ -uniform, then for each  $k = 1, \dots, n-1$ ,

$$|f(t) - F_k| \leq 2\omega(\tilde{h}, f),$$

$$|f(t) - F_{k+1}| \leq 2\omega(\tilde{h}, f),$$

where  $\tilde{h} = \max(h, h')$ ,  $t \in [x_k, x_k + \tilde{h}]$ , and

$$\omega(\tilde{h}, f) = \max_{|\delta| \leq \tilde{h}} \max_{x \in [a, b - \delta]} |f(x + \delta) - f(x)|. \quad (7.6)$$

(f)

$$\int_a^b f(x)dx = h\left(\frac{F_1}{2} + \frac{F_n}{2} + \sum_{k=2}^{n-1} F_k\right).$$

(This is true for an  $h$ -uniform Ruspini partition of  $[a, b]$  only.)

### 7.3.2 Inverse $F$ -Transform

It is clear that an original nonconstant function  $f$  cannot be precisely reconstructed from its  $F$ -transform  $\mathbf{F}[f]$  because we lose information when passing from  $f$  to  $\mathbf{F}[f]$ . However, the inverse  $F$ -transform  $\hat{f}$  that can be reconstructed (using the inversion formula (7.7)) approximates  $f$  in such a way that universal convergence can be established.

#### Definition 7.5

Let  $A_1, \dots, A_n$  be the basic functions that form a generalized fuzzy partition of  $[a, b]$  and  $f$  be a function from  $C([a, b])$ . Let  $\mathbf{F}[f] = (F_1, \dots, F_n)$  be the  $F$ -transform of  $f$  with respect to  $A_1, \dots, A_n$ . Then, the function  $\hat{f} : [a, b] \rightarrow \mathbb{R}$  represented by

$$\hat{f}(x) = \frac{\sum_{k=1}^n F_k A_k(x)}{\sum_{k=1}^n A_k(x)}, \quad (7.7)$$

is called the *inverse  $F$ -transform*.

#### Remark 7.2

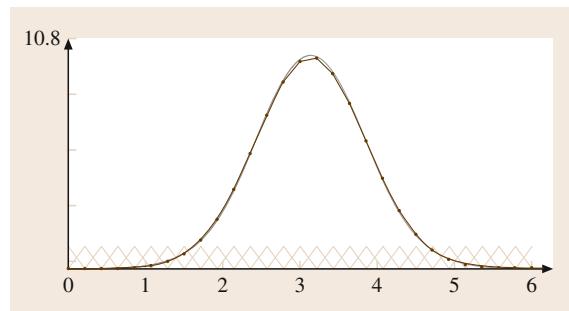

If a fuzzy partition of  $[a, b]$  fulfills the generalized Ruspini condition (7.2) with  $r \geq 1$ , then the inversion formula (7.7) can be simplified to

$$\hat{f}(x) = \frac{1}{r} \sum_{k=1}^n F_k A_k(x)$$

or to (in the case of the Ruspini partition for which  $r = 1$ )

$$\hat{f}(x) = \sum_{k=1}^n F_k A_k(x).$$

The following theorem demonstrates that the inverse  $F$ -transform  $\hat{f}$  can approximate a continuous function  $f$  with arbitrary precision. Thus, it explains why the  $F$ -transform has convincing applications in various fields, including image and time series processing, and data mining [7.21]. In Fig. 7.4, we illustrate

**Fig. 7.4** The function  $f(x) = 10e^{-(x-\pi)^2}$  (gray) and its inverse  $F$ -transform (brown) with respect to the uniform Ruspini partition of  $[0, 6]$  by 29 triangular-shaped basic functions. The  $F$ -transform components are marked by small circles

how the inverse  $F$ -transform approximates the function  $10e^{-(x-\pi)^2}$ .

#### Theorem 7.1

Let  $f$  be a continuous function on  $[a, b]$ . Then, for any  $\varepsilon > 0$ , there exist  $n_\varepsilon$  and a generalized fuzzy partition  $A_1, \dots, A_{n_\varepsilon}$  of  $[a, b]$  such that for all  $x \in [a, b]$ ,

$$eq8|f(x) - \hat{f}_\varepsilon(x)| \leq \varepsilon, \quad (7.8)$$

where  $\hat{f}_\varepsilon$  is the inverse  $F$ -transform of  $f$  with respect to the fuzzy partition  $A_1, \dots, A_{n_\varepsilon}$ .

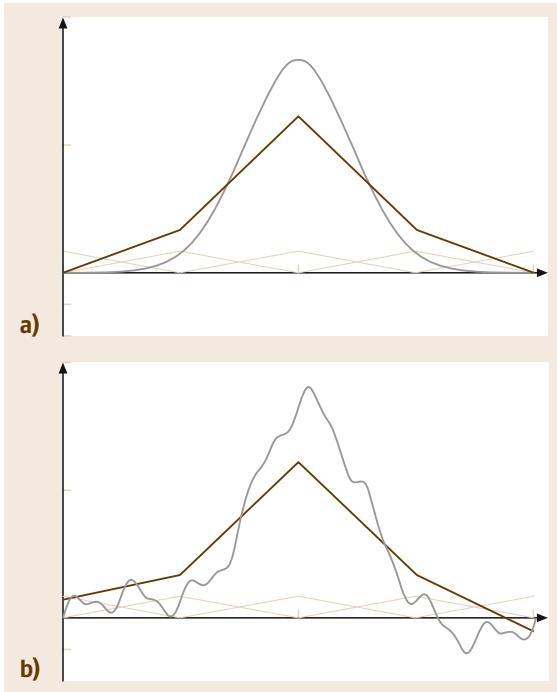

From Theorem 7.2, which is given below, we learn that for a pointwise approximation (as in Theorem 7.1), it is sufficient to compute the  $F$ -transform with respect to the simplest triangular fuzzy partition. Therefore, almost all applications of the  $F$ -transform are based on this type of partition.

#### Theorem 7.2

Let  $f$  be any continuous function on  $[a, b]$ , and let  $A'_1, \dots, A'_n$  and  $A''_1, \dots, A''_n$ , for  $n \geq 3$ , be the basic functions that form different  $(h, h')$ -uniform generalized fuzzy partitions of  $[a, b]$ . Let  $\hat{f}'$  and  $\hat{f}''$  be the two inverse  $F$ -transforms of  $f$  with respect to different sets of basic functions  $A'_1, \dots, A'_n$  or  $A''_1, \dots, A''_n$ . Then, for arbitrary  $x \in [a, b]$ ,

$$|\hat{f}'(x) - \hat{f}''(x)| \leq 4\omega(\tilde{h}, f),$$

where  $h = \frac{b-a}{n-1}$ ,  $\tilde{h} = \max(h, h')$  and  $\omega(\tilde{h}, f)$  is the modulus of continuity (7.6) of  $f$  on the interval  $[a, b]$ .

**Fig. 7.5** (a) Function  $f(x) = 10e^{-(x-\pi)^2}$  (gray) and its inverse  $F$ -transform (brown) with respect to the Ruspini partition given by the triangular-shaped basic functions  $A_1, \dots, A_5$  (gray). (b) Noisy function  $f + s$  (gray), where  $s(x) = \sin(2x) + 0.6 \sin(8x) + 0.3 \sin(16x)$ , and its inverse  $F$ -transform (brown) with respect to the same fuzzy partition. Both inverse  $F$ -transforms  $\hat{f}$  and  $\widehat{f+s}$  are equal on  $[x_2, x_4]$

The proofs of Theorems 7.1 and 7.2 can be obtained from the respective proofs in [7.22, Theorems 2 and 3] after some necessary changes caused by the usage of the generalized fuzzy partition.

Below, we list some properties of the inverse  $F$ -transform  $\hat{f}$  of  $f$  that were considered and proved in [7.1, 15, 23]. If not specially mentioned, it is assumed that the  $F$ -transform is computed with respect to a generalized fuzzy partition of  $[a, b]$ :

- (a) If for all  $x \in [a, b]$ ,  $f(x) = C$ , then  $\hat{f}(x) = C$
- (b) If  $f = \alpha g + \beta h$ , then  $\hat{f} = \alpha \hat{g} + \beta \hat{h}$
- (c)  $\int_a^b f(x)dx = \int_a^b \hat{f}(x)dx$  (This is true for the fuzzy  $r$ -partition ( $r \geq 1$ ) of  $[a, b]$  only.)
- (d) Let  $A_1, \dots, A_n$  be an  $h$ -uniform Ruspini partition of  $[a, b]$ , where  $h = (b - a)/(n - 1)$  and  $n > 3$ . Let  $s : [a, b] \rightarrow \mathbb{R}$  be a continuous function such that one of the following two conditions are fulfilled:
  - (i)  $s$  is  $2h$ -periodical and for all  $x \in [0, h]$ ,  $s(x_k - x) = -s(x_k + x)$ , where  $k = 2, \dots, n - 1$
  - (ii)  $s$  is  $h$ -periodical and  $\int_{x_{k-1}}^{x_k} s(x)dx = 0$ , where  $k = 2, \dots, n - 1$ .

Then, for  $x \in [x_2, x_{n-1}]$ ,

$$\hat{f} = \widehat{f+s}.$$

The last property is known as *noise removal*. This phrase implies that both functions  $f$  (non-noisy) and  $f + s$  (noisy) have the same inverse  $F$ -transform. The noise is represented by  $s$  and characterized by conditions (i) or (ii). We illustrate this property in Fig. 7.5.

## 7.4 Discrete F-Transform

The discrete case of the  $F$ -transform, for which an original function  $f$  is defined (may be computed) on a finite set  $P = \{p_1, \dots, p_l\} \subseteq [a, b]$ , was introduced in [7.1]. We will adapt the mentioned definition to the case of a generalized fuzzy partition of  $[a, b]$ .

We assume that the domain  $P$  of the function  $f$  is *sufficiently dense with respect to the fixed partition*, i. e.,

$$(\forall k)(\exists j)A_k(p_j) > 0.$$

Then, the (discrete)  $F$ -transform of  $f$  is defined as follows.

### Definition 7.6

Let  $A_1, \dots, A_n$ , for  $n > 2$ , be the basic functions that form a generalized fuzzy partition of  $[a, b]$ , and let func-

tion  $f$  be defined on the set  $P = \{p_1, \dots, p_l\} \subseteq [a, b]$ , which is sufficiently dense with respect to the partition. We say that the  $n$ -tuple of real numbers  $(F_1, \dots, F_n)$  is the discrete  $F$ -transform of  $f$  with respect to  $A_1, \dots, A_n$  if

$$F_k = \frac{\sum_{j=1}^l f(p_j)A_k(p_j)}{\sum_{j=1}^l A_k(p_j)}. \quad (7.9)$$

It is not difficult to demonstrate that the components of the discrete  $F$ -transform have similar properties to those listed in Sect. 7.3.1.

In the discrete case, we define the inverse  $F$ -transform on the same set  $P$  on which the original function is defined.

**Definition 7.7**

Let  $A_1, \dots, A_n$ , for  $n > 2$ , be the basic functions that form a generalized fuzzy partition of  $[a, b]$ , and let function  $f$  be defined on the set  $P = \{p_1, \dots, p_l\} \subseteq [a, b]$ , which is sufficiently dense with respect to the partition. Moreover, let  $\mathbf{F}[f] = (F_1, \dots, F_n)$  be the discrete  $F$ -transform of  $f$  w.r.t.  $A_1, \dots, A_n$ . Then, the function  $\hat{f} : P \rightarrow \mathbb{R}$  represented by

$$\hat{f}(p_j) = \frac{\sum_{k=1}^n F_k A_k(p_j)}{\sum_{k=1}^n A_k(p_j)} \quad (7.10)$$

is the inverse discrete  $F$ -transform of  $f$ .

**Remark 7.3**

If a fuzzy partition of  $[a, b]$  fulfills the generalized Ruspini condition (7.2) with  $r \geq 1$ , i.e., for all  $p_j \in P$ ,  $\sum_{k=1}^n A_k(p_j) = r$ , then the inversion formula (7.10) can be simplified to

$$\hat{f}(p_j) = \frac{1}{r} \sum_{k=1}^n F_k A_k(p_j)$$

## 7.5 $F$ -Transforms of Functions of Two Variables

The direct and inverse  $F$ -transform of a function of two (and more) variables is a direct generalization of the case of one variable. We introduce it briefly and refer to [7.1] for more details.

Suppose that the universe is a rectangle  $[a, b] \times [c, d] \subseteq \mathbb{R} \times \mathbb{R}$  and that  $x_1 < \dots < x_n$  are the fixed nodes of  $[a, b]$  and  $y_1 < \dots < y_m$  are the fixed nodes of  $[c, d]$  such that  $x_1 = a$ ,  $x_n = b$ ,  $y_1 = c$ ,  $y_m = d$  and  $n, m \geq 2$ . Let us formally extend the set of nodes by setting  $x_0 = a$ ,  $y_0 = c$ ,  $x_{n+1} = b$ , and  $y_{m+1} = d$ . Assume that  $A_1, \dots, A_n$  are the basic functions that form a generalized fuzzy partition of  $[a, b]$  and  $B_1, \dots, B_m$  are basic functions that form a generalized fuzzy partition of  $[c, d]$ . Then, the rectangle  $[a, b] \times [c, d]$  is partitioned into fuzzy sets  $A_k \times B_l$  with the membership functions  $(A_k \times B_l)(x, y) = A_k(x)B_l(y)$ ,  $k = 1, \dots, n$ ,  $l = 1, \dots, m$ . Let  $C([a, b] \times [c, d])$  be the set of continuous functions of two variables on the domain and  $f \in C([a, b] \times [c, d])$ .

**Definition 7.8**

Let  $A_1, \dots, A_n$  be the basic functions that form a generalized fuzzy partition of  $[a, b]$  and  $B_1, \dots, B_m$  be the basic functions that form a generalized fuzzy partition of  $[c, d]$ . Let  $f$  be any function from  $C([a, b] \times [c, d])$ . We say that the  $n \times m$ -matrix of real numbers  $\mathbf{F}[f] = (F_{kl})_{n \times m}$  is the (integral)  $F$ -transform of  $f$  with respect

or (in the case of Ruspini partition, i.e.,  $r = 1$ ) to

$$\hat{f}(p_j) = \sum_{k=1}^n F_k A_k(p_j).$$

Analogous to Theorem 7.1, we can show that the inverse discrete  $F$ -transform  $\hat{f}$  can approximate the original discrete function  $f$  on  $P$  with arbitrary precision [7.1]. Moreover, the properties (a)–(c) that are listed in Sect. 7.3.2 have valid discrete analogies.

An interesting comparison between the discrete  $F$ -transform and the least-square approximation was made in [7.20]. It was demonstrated that the discrete  $F$ -transform is invariant with respect to the interpolating and least-squares approximation of the set  $\{(p_j, f(p_j)) \mid j = 1, \dots, l\}$ . This means that the best approximation of  $f$  on  $P$  in the form of  $\sum_{i=1}^n \alpha_i A_i$ , where  $n \leq l$ , has the same direct discrete  $F$ -transform as the original  $f$ .

to  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$  if for each  $k = 1, \dots, n$ ,  $l = 1, \dots, m$ ,

$$F_{kl} = \frac{\int_c^d \int_a^b f(x, y) A_k(x) B_l(y) dx dy}{\int_c^d \int_a^b A_k(x) B_l(y) dx dy}. \quad (7.11)$$

The components  $F_{kl}$  (7.11) have properties (adapted to the case of two variables) similar to those listed in Sect. 7.3.1. For example, the property (e) has the following form (we assume that  $A_1, \dots, A_n$  form an  $h_1$ -uniform Ruspini partition of  $[a, b]$  and  $B_1, \dots, B_m$  form an  $h_2$ -uniform Ruspini partition of  $[c, d]$ )

$$\begin{aligned} & \int_c^d \int_a^b f(x, y) dx dy \\ &= \frac{h_1 h_2}{4} (F_{11} + F_{1m} + F_{n1} + F_{nn}) \\ &+ \frac{h_1 h_2}{2} \left( \sum_{k=2}^{n-1} F_{k1} + \sum_{k=2}^{n-1} F_{km} + \sum_{l=2}^{m-1} F_{1l} + \sum_{l=2}^{m-1} F_{nl} \right) \\ &+ h_1 h_2 \sum_{k=2}^{n-1} \sum_{l=2}^{m-1} F_{kl}. \end{aligned}$$

In the discrete case, when an original function  $f$  is known only at points  $(p_i, q_j) \in [a, b] \times [c, d]$ , where  $i =$

$1, \dots, N$  and  $j = 1, \dots, M$ , the (discrete)  $F$ -transform of  $f$  can be introduced in a manner analogous to the case of a function of one variable. This case is important for applications of the  $F$ -transform to image processing [7.8, 9, 18, 24–26].

### Definition 7.9

Let a function  $f$  be given at nodes  $(p_i, q_j) \in [a, b] \times [c, d]$ , for which  $i = 1, \dots, N$  and  $j = 1, \dots, M$ , and  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$ , where  $n < N$  and  $m < M$ , be the basic functions that form generalized fuzzy partitions of  $[a, b]$  and  $[c, d]$ , respectively. Suppose that sets  $P$  and  $Q$  of these nodes are sufficiently dense with respect to the chosen partitions. We say that the  $n \times m$ -matrix of real numbers  $\mathbf{F}[f] = (F_{kl})_{nm}$  is the discrete  $F$ -transform of  $f$  with respect to  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$  if

$$F_{kl} = \frac{\sum_{j=1}^M \sum_{i=1}^N f(p_i, q_j) A_k(p_i) B_l(q_j)}{\sum_{j=1}^M \sum_{i=1}^N A_k(p_i) B_l(q_j)} \quad (7.12)$$

holds for all  $k = 1, \dots, n$ ,  $l = 1, \dots, m$ .

## 7.6 $F^1$ -Transform

In [7.16], a higher degree  $F$ -transform was introduced for the purpose for advanced applications in time series and image processing [7.26, 27]. In this section, we give a description of the  $F^1$ -transform, which has working applications, and refer to [7.16] for the  $F^m$ -transform for which  $m > 1$ .

Throughout this section, we assume that  $A_1, \dots, A_n$ ,  $n > 2$  is an  $h$ -uniform generalized fuzzy partition of  $[a, b]$  such that there exists a generating function  $A_0 : [-1, 1] \rightarrow [0, 1]$  such that for all  $k = 1, \dots, n$ ,  $A_k$  is defined by (7.3) (the illustration is in Fig. 7.3).

Let  $k$  be a fixed integer from  $\{1, \dots, n\}$ , and let  $L_2(A_k)$  be a normed space of square-integrable functions  $f : [x_{k-1}, x_{k+1}] \rightarrow \mathbb{R}$ , where the norm  $\|f\|_k$  is given by

$$\|f\|_k = \sqrt{\frac{\int_{x_{k-1}}^{x_{k+1}} f^2(x) A_k(x) dx}{\int_{x_{k-1}}^{x_{k+1}} A_k(x) dx}}.$$

By  $L_2(A_1, \dots, A_n)$  we denote a set of functions  $f : [a, b] \rightarrow \mathbb{R}$  such that for all  $k = 1, \dots, n$ ,  $f|_{[x_{k-1}, x_{k+1}]} \in L_2(A_k)$ , where  $f|_{[x_{k-1}, x_{k+1}]}$  is the restriction of  $f$  on  $[x_{k-1}, x_{k+1}]$ .

For any function  $f$  from  $L_2(A_1, \dots, A_n)$  we define the  $F^1$ -transform of  $f$  with respect to  $A_1, \dots, A_n$  as the

The inverse  $F$ -transform of a function of two variables is a simple extension of (7.7). It will be given below for the continuous version of a function.

### Definition 7.10

Let  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$  be the basic functions that form generalized fuzzy partitions of  $[a, b]$  and  $[c, d]$ , respectively. Let  $f$  be a function from  $C([a, b] \times [c, d])$  and  $\mathbf{F}[f]$  be the  $F$ -transform of  $f$  with respect to  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$ . Then, the function  $\hat{f} : [a, b] \times [c, d] \rightarrow \mathbb{R}$  represented by

$$\hat{f}(x, y) = \frac{\sum_{k=1}^n \sum_{l=1}^m F_{kl} A_k(x) B_l(y)}{\sum_{k=1}^n \sum_{l=1}^m A_k(x) B_l(y)} \quad (7.13)$$

is called the *the inverse  $F$ -transform*.

Similar to the case of a function of one variable, we can prove that the inverse  $F$ -transform  $\hat{f}$  can approximate the original continuous function  $f$  with arbitrary precision, and the (adapted) properties (a)–(c), which are listed in Sect. 7.3.2, are fulfilled.

vector of linear functions

$$\mathbf{F}^1[f] = (c_{1,0} + c_{1,1}(x - x_1), \dots, c_{n,0} + c_{n,1}(x - x_n)), \quad (7.14)$$

where for every  $k = 1, \dots, n$ ,

$$c_{k,0} = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x) A_k(x) dx}{hs_0}, \quad c_{k,1} = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x)(x - x_k) A_k(x) dx}{\int_{x_{k-1}}^{x_{k+1}} (x - x_k)^2 A_k(x) dx}, \quad (7.15)$$

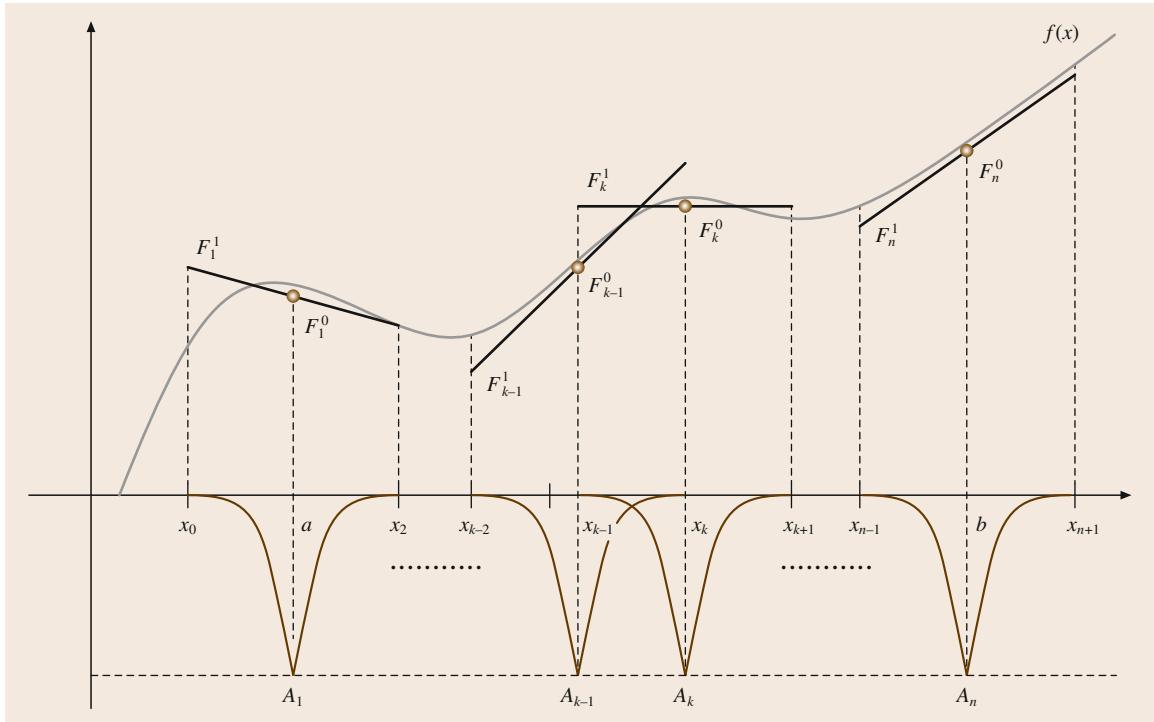

and

$$s_0 = \int_{-1}^1 A_0(x) dx.$$

The  $k$ th component of the vector  $\mathbf{F}^1[f]$  is denoted by  $F_k^1[f]$ .

The following is a list of properties of the  $F^1$ -transform of  $f$  with respect to a generalized fuzzy partition of  $[a, b]$ . They are particular cases of the properties of the  $F^m$ -transform proved in [7.16]:

- (a) Let  $F_k$  and  $c_{k,0} + c_{k,1}(x - x_k)$ , for  $k = 1, \dots, n$ , be respective  $k$ th components of  $\mathbf{F}^1[f]$  and  $\mathbf{F}[f]$ . Then,  $F_k = c_{k,0}$ .

**Fig. 7.6** Function  $f$ , its  $F^1$ -transform components  $F_1^1, \dots, F_k^1, \dots, F_n^1$  (linear segments) and its  $F^0$ -transform components  $F_1^0, \dots, F_k^0, \dots, F_n^0$  (star nodes) (after [7.16])

- (b) If for all  $x \in [a, b]$ ,  $f(x) = d + cx$ , then all the components of  $F^1$ -transform of  $d + cx$  are equal to  $(d + cx_k) + c(x - x_k)$ ,  $k = 1, \dots, n$ .
- (c) If  $f = \alpha g + \beta h$ , then  $\mathbf{F}^1[f] = \alpha \mathbf{F}^1[g] + \beta \mathbf{F}^1[h]$ .
- (d)  $c_{k,0} + c_{k,1}(x - x_k) = \min \|f(x) - (d + c(x - x_k))\|_k$ ,  $k = 1, \dots, n$ , where  $\min$  is considered over the set of functions of the form  $(d + c(x - x_k))$ .
- (e) If  $f$  is four times continuously differentiable on  $[a, b]$ , then

$$c_{k,0} = f(x_k) + O(h^2),$$

$$c_{k,1} = f'(x_k) + O(h), \quad k = 1, \dots, n.$$

In Fig. 7.6, we show a schematic representation of the  $F^1$ -transform components of a generic function  $f$ .

Finally, we give simplified expressions of  $F^1$ -transform components with respect to an  $h$ -uniform triangular fuzzy partition [7.16]

$$c_{k,0} = \frac{\int_{x_{k-1}}^{x_{k+1}} f(x) A_k(x) dx}{h}, \quad (7.16)$$

$$c_{k,1} = \frac{12 \int_{x_{k-1}}^{x_{k+1}} f(x)(x - x_k) A_k(x) dx}{h^3}, \quad (7.17)$$

where  $k = 1, \dots, n$ .

## 7.7 Applications

In this section, we consider applications of the  $F$ -transform and  $F^1$ -transform to image processing.

### 7.7.1 Image Compression and Reconstruction

A method of lossy image compression and reconstruction using fuzzy relations was proposed in [7.19]. The

dominant idea was a choice of suitable granulation (represented by a fuzzy relation) of an image domain. We will refer to this method as FEQ.  $F$ -transform image compression (FTR) is based on the same idea of granulation but connects it with fuzzy partitions [7.1, 9]. In the cited papers, two approaches were proposed: a uniform fuzzy partition of the entire domain [7.1] and a two-step partition [7.9] in which initially the entire do-

main is partitioned into blocks and second, each block is uniformly partitioned into fuzzy sets. Both approaches were compared with JPEG and other compression techniques (including FEQ) [7.9], and the conclusion was that the *F*-transform-based method is slightly worse than JPEG but better than FEQ. Two further improvements of the *F*-transform-based compression have been proposed in [7.18, 28], where an advantage over JPEG was achieved in many cases.

In this section, after reiterating the principles of image compression and reconstruction using the *F*-transform and its inverse, we explain how a proper choice of a fuzzy partition improves the quality of the reconstructed image. A detailed elaboration and comparison with other existing techniques is in [7.18, 28] and will be presented in subsequent papers.

### Principles of Image Compression Using the *F*-Transform

Let a grayscale image of size  $N \times M$  pixels be represented by a function of two variables  $u : N \times M \rightarrow [0, 1]$ . The value  $u(i, j)$  represents the intensity range of each pixel in the gray scale. The problem of image compression is to reduce the image's size to save space or transmission time. A desirable size  $n \times m$  (where  $n < N$  and  $m < M$ ) of a compressed image can be obtained from the *compression ratio*,  $\rho = nm/(NM)$ . If a compression method is lossy (JPEG, FEQ, and the *F*-transform, for example), then the respective reconstruction  $\hat{u}$  to a full size image is compared with the original image using the two quality indices **PSNR** (peak signal-to-noise ratio) and **RMSE** (root-mean-square error), where

$$\text{PSNR} = 20 \ln \frac{255}{\text{RMSE}},$$

and

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^N \sum_{j=1}^M [u(i, j) - \hat{u}(i, j)]^2}{NM}}.$$

### Simple *F*-Transform Compression

In [7.1], we proposed representing a compressed image by the  $n \times m$  matrix  $\mathbf{U}$  of *F*-transform components

$$\mathbf{U} = \begin{pmatrix} U_{11} & \dots & U_{1m} \\ \vdots & \vdots & \vdots \\ U_{n1} & \dots & U_{nm} \end{pmatrix},$$

computed over uniform fuzzy partitions (usually, triangular)  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$  of the entire domains

$[1, N]$  and  $[1, M]$ , respectively

$$U_{kl} = \frac{\sum_{j=1}^M \sum_{i=1}^N u(i, j) A_k(i) B_l(j)}{\sum_{j=1}^M \sum_{i=1}^N A_k(i) B_l(j)}, \\ k = 1, \dots, n; \quad l = 1, \dots, m.$$

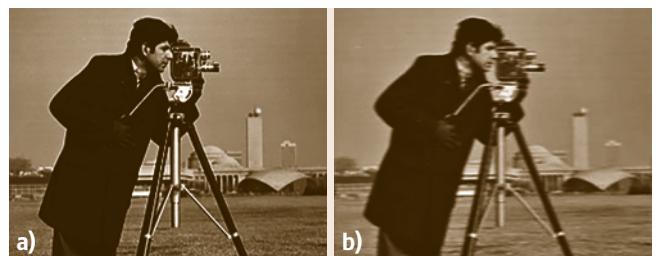

We proposed reconstructing  $\mathbf{U}$  to a full-size image using the inverse *F*-transform of  $u$  such that

$$\hat{u}(i, j) = \sum_{k=1}^n \sum_{l=1}^m U_{kl} A_k(i) B_l(j).$$

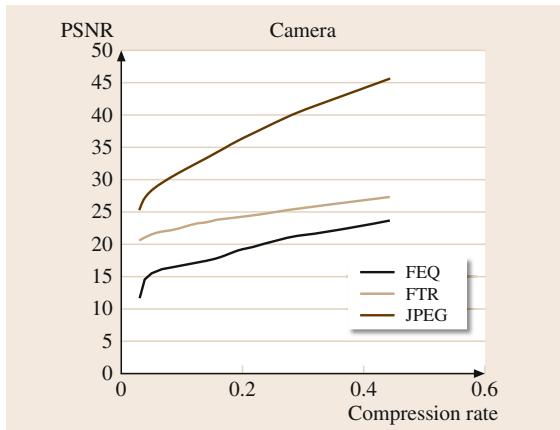

This method does not take advantage of any property of the original image and therefore, its quality is not very high. Let us illustrate it on the image *Cameraman* taken from the Corel Gallery. In Fig. 7.7, we show the original image and its reconstruction using the simple *F*-transform compression described above. The compression ratio is  $\rho = 0.25$ , and  $\text{PSNR} = 25.422$  (compare with  $\text{PSNR} = 38.8$  for JPEG with a similar compression ratio).

### *F*-Transform Compression with Block Decomposition

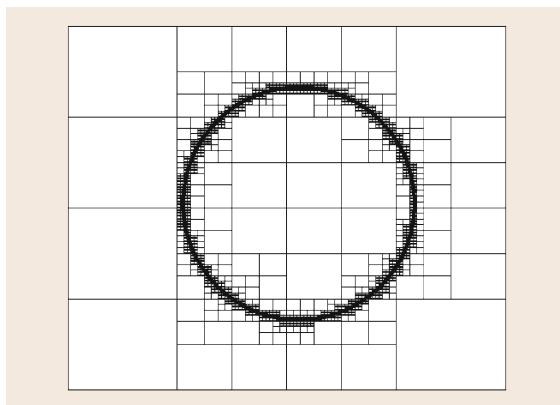

This *F*-transform-based compression [7.9] was inspired by the JPEG method in which, at first, the entire domain was decomposed into blocks and then, each block was compressed according to a compression ratio. In [7.9], the same principle is used. In the first step, a decomposition into blocks of the same size is performed, where the size (chosen experimentally) is such that a certain quality of approximation by the inverse *F*-transform should be guaranteed (Theorem 7.1). Each block is then uniformly partitioned into cosine-shaped fuzzy sets and compressed by the simple *F*-transform method according to a compression ratio. In comparison with the simple *F*-transform compression, this method considers the peculiarities of the original images when making

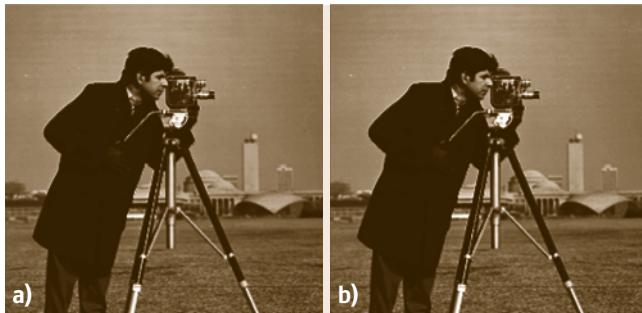

**Fig. 7.7a,b** Original image *Cameraman* (a) and its reconstruction after applying the simple *F*-transform compression (b) with  $\text{PSNR} = 25.422$

**Fig. 7.8** The **PSNR** values of the image *Cameraman* compressed using three methods: FEQ, the *F*-transform with block decomposition, and JPEG (after [7.29])

**Fig. 7.9** The quad tree algorithm and the generalized fuzzy partition on its base

**Fig. 7.10a,b** Two reconstructions of the image *Cameraman* after applying the advanced *F*-transform compression (the ratio is 0.188) with the histogram restoring (a) and without it (b). The **PSNR** values are 29 (a) and 30 (b)

the block decomposition. In Fig. 7.8, we show the **PSNR** quality measure of the image *Cameraman* compressed using three methods: FEQ, *F*-transform with block decomposition and JPEG. It is easily observed that the JPEG method is still better than the *F*-transform with block decomposition, whereas the latter is better than FEQ. However, for the particular image *Cameraman* and the compression ratio  $\rho = 0.25$ , the value of **PSNR** of the *F*-transform with block decomposition is similar to that of the simple *F*-transform compression: 25.0676 versus 25.422, respectively. This means that the uniform partition, even when applied to both steps independently, is not effective with respect to the quality estimated by **PSNR**. In the next subsection, we propose an *F*-transform compression method [7.18] that is almost nonlossy and is based on a nonuniform generalized partition adapted to each particular image.

### Advanced Image Compression

If we analyze the properties of the *F*-transform (Sect. 7.3.1), then it is immediate from (a) that the more the function behaves like a constant, the better is the approximation quality of the inverse *F*-transform. Thus, the following recommendation regarding the choice of a proper generalized fuzzy partition can be made:

- A generalized fuzzy partition of the domain  $[1, N] \times [1, M]$  into fuzzy sets  $A_k \times B_l$ , where  $k = 1, \dots, n$  and  $l = 1, \dots, m$ , should guarantee that the difference between extremal values of the image over each  $A_k \times B_l$  is not greater than  $\varepsilon > 0$  or (if the preceding condition cannot be fulfilled) the area of  $A_k \times B_l$  is not greater than  $\delta > 0$ .

There are several algorithms that can produce a generalized fuzzy partition with the mentioned property. In [7.18], we used the quad tree algorithm for this purpose; see the illustration in Fig. 7.9.

Let us add that the advanced image compression algorithm [7.18] uses the following two tricks to increase the quality of the reconstructed image:

- Preserve sharp edges
- Restore the histogram of the original image.

Figure 7.10 shows how the histogram restoration influences the quality of the reconstructed image. In Fig. 7.11, we see that the **PSNR** values of the advanced *F*-transform and the JPEG are almost equal.

## 7.7.2 Image Fusion

Image fusion aims to integrate complementary distorted multisensor, multitemporal, and/or multiview scenes into one new image that contains the *best* parts of each scene. Thus, the primary problem in image fusion is to find the least distorted scene for every pixel.

A local focus measure is traditionally used for the selection of an undistorted scene. The scene that maximizes the focus measure is selected. Usually, the focus measure is a measure of high-frequency occurrences in the image spectrum. This measure is used when a source of distortion is connected with blurring, which suppresses high frequencies in an image. In this case, it is desirable that a focus measure decreases with an increase in blurring.

There are various fusion methodologies that are currently in use. They can be classified according to the primary technique: aggregation operators [7.22], fuzzy methods [7.30], optimization methods (e.g., neural networks and genetic algorithms [7.29]), and multiscale decomposition methods based on various transforms (e.g., discrete wavelet transforms; [7.31]).

The *F*-transform approach to image fusion was proposed in [7.32, 33]. The primary idea is a combination of (at least) two fusion operators, both of which are based on the *F*-transform. The first fusion operator is applied to the *F*-transform components of scenes and is based on a robust partition of the scene domain. The second fusion operator is applied to the residuals of scenes with respect to

inverse *F*-transforms with fused components and is based on a finer partition of the same domain. Although this approach is not explicitly based on focus measures, it uses the fusion operator, which is able to choose an undistorted scene among the available blurred scenes.

### Principles of Image Fusion Using the *F*-Transform

In this subsection, we present a short overview of the two methods of fusion that were proposed in [7.32, 33] and introduce a new method [7.34] that is a weighted combination of those two. We will demonstrate that the new method is computationally more effective than the first two.

The *F*-transform fusion is based on a certain decomposition of an image. We assume that the image  $u$  is a discrete real function  $u = u(x, y)$  defined on the  $N \times M$  array of pixels  $P = \{(i, j) \mid i = 1, \dots, N, j = 1, \dots, M\}$  such that  $u : P \rightarrow \mathbb{R}$ . Moreover, let fuzzy sets  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$ , where  $2 \leq n \leq N, 2 \leq m \leq M$ , establish uniform Ruspini partitions of  $[1, N]$  and  $[1, M]$ , respectively. We begin with the following representation of  $u$  on  $P$ ,

$$u(x, y) = u_{nm}(x, y) + e(x, y), \quad (7.18)$$

$$e(x, y) = u(x, y) - u_{nm}(x, y), \quad (7.19)$$

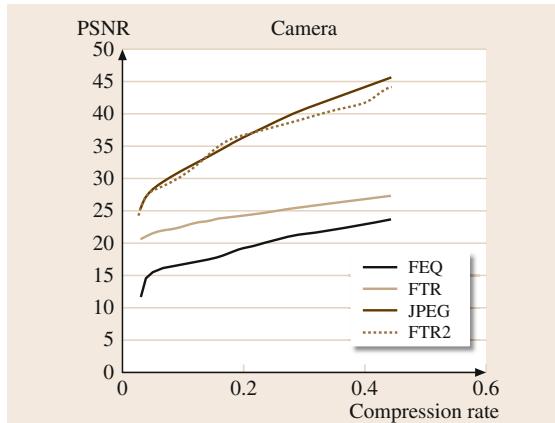

where  $u_{nm}$  is the inverse *F*-transform of  $u$  and  $e$  is the respective first difference. If we replace  $e$  in (7.18) by its inverse *F*-transform  $e_{NM}$  with respect to the finest partition of  $[1, N] \times [1, M]$ , the above representation can then be rewritten as follows,

$$u(x, y) = u_{nm}(x, y) + e_{NM}(x, y). \quad (7.20)$$

We call (7.20) a *one-level decomposition* of  $u$  on  $P$ . If  $u$  is smooth, then the function  $e_{NM}$  is small (this claim follows from the property (e) in Sect. 7.3.1), and we can stop at this level. In the opposite case, we continue with the decomposition of the first difference  $e$  in (7.18). We decompose  $e$  into its inverse *F*-transform  $e_{n'm'}$  (with respect to a finer fuzzy partition of  $[1, N] \times [1, M]$  with  $n' : n < n' \leq N$  and  $m' : m < m' \leq M$  basic functions) and the second difference  $e'$ . Thus, we obtain the *second-level decomposition* of  $u$  on  $P$

$$u(x, y) = u_{nm}(x, y) + e_{n'm'}(x, y) + e'(x, y),$$

$$e'(x, y) = e(x, y) - e_{n'm'}(x, y).$$

**Fig. 7.11** The PSNR values of the image *Camerman* compressed using four methods: FEQ, the *F*-transform with block decomposition, the advanced *F*-transform, and JPEG

In the same manner, we can obtain a *higher level decomposition* of  $u$  on  $P$

$$\begin{aligned} u(x, y) &= u_{n_1 m_1}(x, y) + e_{n_2 m_2}^{(1)}(x, y) + \dots \\ &\quad + e_{n_{k-1} m_{k-1}}^{(k-2)}(x, y) + e^{(k-1)}(x, y), \end{aligned} \quad (7.21)$$

where

$$\begin{aligned} 0 < n_1 &\leq n_2 \leq \dots \leq n_{k-1} \leq N, \\ 0 < m_1 &\leq m_2 \leq \dots \leq m_{k-1} \leq M, \\ e^{(1)}(x, y) &= u(x, y) - u_{n_1 m_1}(x, y), \\ e^{(i)}(x, y) &= e^{(i-1)}(x, y) - e_{n_i m_i}^{(i-1)}(x, y), \\ i &= 2, \dots, k-1. \end{aligned} \quad (7.22)$$

### Three Algorithms for Image Fusion

In [7.33], we proposed two algorithms:

1. The *simple F-transform-based fusion algorithm (SA)* and
2. The *complete F-transform-based fusion algorithm (CA)*.

The principal role in the fusion algorithms **CA** and **SA** is played by the *fusion operator*  $\kappa : \mathbb{R}^K \rightarrow \mathbb{R}$ , which is defined as follows:

$$\kappa(x_1, \dots, x_K) = x_p, \text{ if } |x_p| = \max(|x_1|, \dots, |x_K|). \quad (7.23)$$

### The Simple F-Transform-Based Fusion Algorithm

In this subsection, we present a *block* description of the **SA** without technical details, which can be found in [7.33]. We assume that  $K \geq 2$  input (channel) images  $c_1, \dots, c_K$  with various types of degradation are given. Our aim is to recognize undistorted parts in the given images and to fuse them into one image. The algorithm is based on the decompositions given in (7.20), which are applied to each channel image:

1. Choose values  $n$  and  $m$  such that  $2 \leq n \leq N, 2 \leq m \leq M$  and create a fuzzy partition of  $[1, N] \times [1, M]$  by fuzzy sets  $A_k \times B_l$ , where  $k = 1, \dots, n$  and  $l = 1, \dots, m$ .
2. Decompose the input images  $c_1, \dots, c_K$  into inverse  $F$ -transforms and error functions according to the one-level decomposition (7.20).
3. Apply the fusion operator (7.23) to the respective  $F$ -transform components of  $c_1, \dots, c_K$ , and obtain the fused  $F$ -transform components of a new image.

4. Apply the fusion operator to the respective  $F$ -transform components of the error functions  $e_i, i = 1, \dots, K$ , and obtain the fused  $F$ -transform components of a new error function.
5. Reconstruct the fused image from the inverse  $F$ -transforms with the fused components of the new image and the fused components of the new error function.

The **SA**-based fusion is very efficient if we can guess values  $n$  and  $m$  that characterize a proper fuzzy partition. Usually, this is performed manually according to the user's skills. The dependence on fuzzy partition parameters can be considered as a primary shortcoming of this otherwise effective algorithm. Two recommendations follow from our experience:

- For complex images (with many small details), higher values of  $n$  and  $m$  yield better results.
- If a triangular shape for a basic function is chosen, than the generic choice of  $n$  and  $m$  is such that the corresponding values of  $n_p$  and  $m_p$  are equal to 3 (recall that  $n_p$  is the number of points that are covered by every full basic function  $A_k$ ).

### The Complete F-Transform-Based Fusion Algorithm

The **CA**-based fusion does not depend on the choice of only one fuzzy partition (as in the case of the **SA**) because it runs through a sequence (7.22) of increasing values of  $n$  and  $m$ . The algorithm is based on the decomposition presented in (7.21), which is applied to each channel image. The description of the **CA** is similar to that of the **SA** except for step 4, which is repeated in a cycle. Therefore, the quality of fusion is high, but the implementation of the **CA** is rather slow and memory consuming, especially for large images. For an illustration, Fig. 7.12, Tables 7.1 and 7.2.

**Table 7.1** Basic characteristics of the three algorithms applied to the image *Balls*

Image	Resolution	Time (s)			Memory (MB)		
		CA	SA	ESA	CA	SA	ESA
Balls	$1600 \times 1200$	340	1.2	36	270	58	152

**Table 7.2** MSE (mean-square error) and PSNR characteristics of the three fusion methods applied to the image *Balls*

Image set	MSE			PSNR		
	CA	SA	ESA	CA	SA	ESA
Balls	1.28	6.03	0.86	48.91	43.81	52.57

**Fig. 7.12a–c** The **SA** (a), **CA** (b) and **ESA** (c) fusions of the image *Balls*. The **ESA** fusion has the best quality (Table 7.2)

### Enhanced Simple Fusion Algorithm

In [7.34], we proposed an algorithm that is as fast as the **SA** and as efficient as the **CA**. We aimed at achieving the following goals:

- Avoid running through a long sequence of possible partitions (as in the case of **CA**).
- Automatically adjust the parameters of the fusion algorithm according to the level of blurring and the location of blurred areas in input images.

The algorithm adds another run of the *F*-transform over the first difference (7.18). The explanation is as follows: the first run of the *F*-transform is aimed at edge detection in each input image, whereas the second run propagates only sharp edges (and their local areas) to the fused image. We refer to this algorithm as to *enhanced simple algorithm* (**ESA**) and give its informal description:

```

for all input (channel) images do
    Compute the inverse F-transform
    Compute the first absolute difference between the
    original image and the inverse F-transform of it
    Compute the second absolute difference between
    the first one and its inverse F-transform and set
    them as the pixel weights
end for
for all pixels in an image do
    Compute the value of sow – the sum of the weights
    over all input images
    for all input images do
        Compute the value of wr – the ratio between the
        weight of a current pixel and sow
end for
    Compute the fused value of a pixel in the resulting
    image as a weighted (by wr) sum of input image
    values
end for
```

The primary advantages of the **ESA** are:

- *Time* – the execution time is smaller than for the **CA** (Table 7.1).

- *Quality* – the quality of the **ESA** fusion is better than that of the **SA** and for particular cases (Table 7.2), it is better than that of the **CA**.

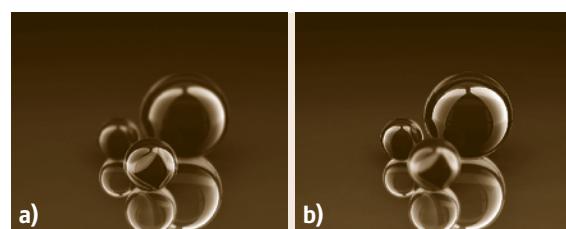

Because of space limitations, we present only one illustration of the *F*-transform fusion performed using the three algorithms, **SA**, **CA**, and **ESA**. We chose the image *Balls* with geometric figures to demonstrate that our fusion methods are able to reconstruct edges. In Fig. 7.13, two (channel) inputs of the image *Balls* are given, and in Fig. 7.12, three fusions of the same image are demonstrated.

In Table 7.1, we demonstrate that the complexity (measured by the execution time or by the memory used) of the **ESA** is greater than the complexity of the **SA** and less than the complexity of the **CA**.

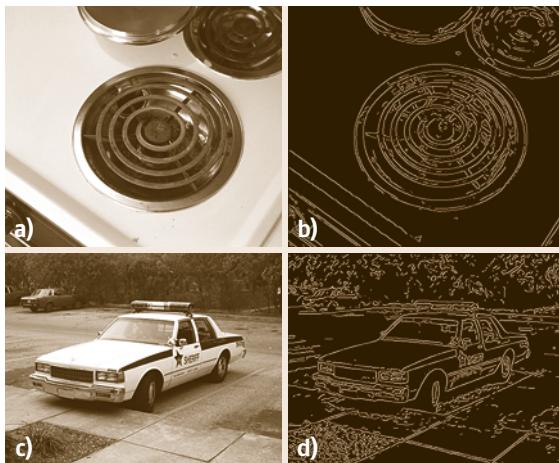

In Table 7.2, we demonstrate that for the particular image *Balls*, the quality of fusion (measured by the values of **MSE** and **PSNR**) of the **ESA** result is better (the **MSE** value is smaller) than the quality of the **SA** result and even than the quality of the **CA** result.

### 7.7.3 $F^1$ -Transform Edge Detector

Edge detection is inevitable in image processing. In particular, it is a first step in feature extraction and image segmentation. We focused on the Canny edge detector [7.35], which is widely used in computer vision. It was developed to ensure three basic criteria: good detection, good localization, and minimal response. In

**Fig. 7.13a,b** Two inputs for the image *Balls*. The central ball is blurred in (a), and conversely, it is the only sharp ball in (b)

**Fig. 7.14a–d** Original images (a,c) and their  $F^1$ -transform edges (b,d)

these aspects, the Canny detector can be considered an *optimal* edge detector. In [7.26], we proposed using the  $F^1$ -transform with the purpose of simplifying the first two steps of the Canny algorithm. Below, we provide the details of our proposal.

The Canny algorithm is a multistep procedure for detecting edges as the local maxima of the gradient magnitude. The first step, performed using a Gaussian filter, is image smoothing and filtering noise. The second step is computation of a gradient of the image function to find the local maxima of the gradient magnitude and the gradient's direction at each point. This step is performed using a convolution of the original image with directional masks (edge detection operators, such as those of *Roberts*, *Prewitt*, and *Sobel*, are some examples of these filters). The next step is called nonmaximum suppression [7.36], and it selects those points whose gradient magnitudes are maximal in the corresponding gradient direction. The final step is tracing edges and hysteresis thresholding, which leads to preserving the continuity of edges.

In our experiment, we removed the first two steps in the Canny algorithm and replaced them by computation of approximate gradient values using the  $F^1$ -transform. The reason is that the  $F^1$ -transform (similar to the ordinary  $F$ -transform) filters out noise when computing approximate values of the first partial derivatives given by (7.15). We assume that the image is represented by a discrete function  $u : P \rightarrow \mathbb{R}$  of two vari-

ables, where  $P = \{(i, j) \mid i = 1, \dots, N, j = 1, \dots, M\}$  is an  $N \times M$  array of pixels, and the fuzzy sets  $A_1, \dots, A_n$  and  $B_1, \dots, B_m$  establish a uniform triangular fuzzy partition of  $[1, N]$  and  $[1, M]$ , respectively.

Let  $x_1, \dots, x_N \in [1, N]$  and  $y_1, \dots, y_M \in [1, M]$  be the  $h_x$  and  $h_y$ -equidistant nodes of  $[1, N]$  and  $[1, M]$ , respectively.

According to property (e) in Sect. 7.6, the coefficients  $c_{k,1}$  of the linear polynomials of the  $F^1$ -transform components are approximate values of the first partial derivatives of the image function at nodes  $(x_k, y_l)$  (for simplicity, we assume  $k = 2, \dots, n-1$  and  $l = 2, \dots, m$ ), where by (7.17) and (7.5) the following hold,

$$c_{k,1}(y_l) = \frac{12}{h_x^3 h_y} \sum_{i=1}^N \sum_{j=1}^M u(i, j)(i - x_k) A_k(i) B_l(j) ,$$

$$c_{l,1}(x_k) = \frac{12}{h_x h_y^3} \sum_{i=1}^N \sum_{j=1}^M u(i, j)(j - y_l) A_k(i) B_l(j) .$$

Then, we can write approximations of the first partial derivatives as the respective inverse  $F$ -transforms

$$G_x(i, j) \approx \sum_{k=1}^n \sum_{l=1}^m c_{k,1}(y_l) A_k(i) B_l(j) ,$$

and

$$G_y(i, j) \approx \sum_{k=1}^n \sum_{l=1}^m c_{l,1}(x_k) A_k(i) B_l(j) .$$

All other steps of the Canny algorithm – namely, finding the local maxima of the gradient magnitude and its direction, nonmaximum suppression, tracing edges through the image and hysteresis thresholding – are the same as in the original procedure.

In the two examples in Fig. 7.14, we demonstrate the results of the  $F^1$ -transform edge detector on images chosen from the dataset available at [ftp://figment.csee.usf.edu/pub/ROC/edge\\_comparison\\_dataset.tar.gz](ftp://figment.csee.usf.edu/pub/ROC/edge_comparison_dataset.tar.gz).

We observe that many thin edges/lines are detected as well as their connectedness and smoothness. Moreover, the following properties are retained:

- Smoothness of circular lines
- Concentricity of circles
- Smoothness of sharp connections.

## 7.8 Conclusions

In this chapter, the theory of the  $F$ -transform has been discussed from the perspective of the latest developments and applications. The importance of a proper choice of fuzzy partition has been stressed. Various fuzzy partitions have been considered, including the most general partition (currently known). The definition

of the  $F$ -transform has been adapted to the generalized fuzzy partition, and the main properties of the  $F$ -transform have been re-established. The applications to image processing, namely image compression, fusion and edge detection, have been discussed with sufficient technical details.

# 8. Fuzzy Linear Programming and Duality

# Fuzzy Linear

Jaroslav Ramík, Milan Vlach

The chapter is concerned with linear programming problems whose input data may be fuzzy while the values of variables are always real numbers. We propose a rather general approach to these types of problems, and present recent results for problems in which the notions of feasibility and optimality are based on the fuzzy relations of possibility and necessity. Special attention is devoted to the weak and strong duality.

Formulation of an abstract model applicable to a complex decision problem usually involves a tradeoff between the accuracy of the problem description and the tractability of the resulting model. One of the widespread models of decision problems is based on the assumption of linearity of constraints and optimization criteria, in spite of the fact that, in most instances of real decision problems, not all constraints and optimization criteria are linear. Fortunately, in many such cases, solutions of decision problems obtained through linear programming are exact or numerically tractable approximations. Given the practical relevance of linear programming, it is not surprising that attempts to extend linear programming theory to problems involving fuzzy data have been appearing since the early days of fuzzy sets. To obtain a meaningful extension of linear programming to problems involving fuzzy data, one has to specify a suitable class of permitted fuzzy numbers, introduce fundamental arithmetic operations with such fuzzy numbers, define inequalities between fuzzy numbers, and clarify the meaning of feasibility and optimality. Because this can be done in many different ways, we can hardly expect a unique extension that would be so clean and clear like the theory of linear programming without fuzzy data. Instead, there exist several variants of the theory for fuzzy linear programming, the re-

sults of which resemble in various degrees some of the useful results established in the conventional linear programming.

Certainly, the most influential papers for the early development of optimization theory for problems with fuzzy data were papers written by *Bellman* and *Zadeh* [8.1], and *Zimmermann* [8.2]. As pointed out in a recent paper by *Dubois* [8.3], fuzzy optimization that is based on the Bellman and Zadeh, and Zimmermann ideas comes down to max–min bottleneck optimization. Thus, strictly speaking, the fuzzy linear programming problems are not necessarily linear in the standard sense.

Throughout the chapter, we assume that some or all of the input data defining the problem may be fuzzy while the values of variables are always real numbers. For problems with fuzzy decision variables, see e.g. [8.4]. Moreover, we not always satisfy the requirement of the symmetric model of [8.1, 2] which demands that the constraints and criteria are to be treated in the same way. In general, we take into consideration the fact that in many situations, in practice, the degree of feasibility may be essentially different from the degree of optimality attainment.

The structure of the chapter is briefly described as follows. In the next section, we first recall the basic results of the conventional linear programming, espe-

cially the results on duality. As a canonical problem we consider the problem of the form: Given real numbers  $b_1, b_2, \dots, b_m, c_1, c_2, \dots, c_n, a_{11}, a_{12}, \dots, a_{mn}$ ,

$$\begin{aligned} & \text{maximize} && c_1x_1 + c_2x_2 + \dots + c_nx_n \\ & \text{subject to} && a_{i1}x_1 + a_{i2}x_2 + \dots + a_{in}x_n \leq b_i, \\ & && i = 1, 2, \dots, m, \\ & && x_j \geq 0, \quad j = 1, 2, \dots, n. \end{aligned}$$

Then we review the basic notions and terminology of fuzzy set theory, which we need for precise formulation and description of results of linear programming problems involving fuzzy data. After these necessary preliminaries, in Sect. 3, we introduce and study fuzzy linear programming problems. We focus attention on analogous canonical form, namely on the following

problem

$$\begin{aligned} & \text{maximize} && \tilde{c}_1x_1 + \tilde{c}_2x_2 + \dots + \tilde{c}_nx_n \\ & \text{subject to} && \tilde{a}_{i1}x_1 + \tilde{a}_{i2}x_2 + \dots + \tilde{a}_{in}x_n \tilde{P} \tilde{b}_i, \\ & && i = 1, 2, \dots, m, \\ & && x_j \geq 0, \quad j = 1, 2, \dots, n, \end{aligned}$$

where  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$ , and  $\tilde{b}_i$  are fuzzy quantities and the meanings of *subject to* and *maximize* are based on the standard possibility and necessity relations introduced in [8.5]. The final section is devoted to duality theory for fuzzy linear programming problems. First, we recall some of the early approaches that are based on the ideas of Bellman and Zadeh [8.1], and Zimmermann [8.2]. Then we present recent results of Ramík [8.6, 7].

## 8.1 Preliminaries

### 8.1.1 Linear Programming

Linear programming is concerned with optimization problems whose objective functions are linear in the unknowns and whose constraints are linear inequalities or linear equalities in the unknowns. The form of a linear programming problem may differ from one problem to another but, fortunately, there are several standard forms to which any linear programming problem can be transformed. We shall use the following canonical form.

Given real numbers  $b_1, b_2, \dots, b_m, c_1, c_2, \dots, c_n, a_{11}, a_{12}, \dots, a_{mn}$ ,

$$\text{maximize} \quad c_1x_1 + c_2x_2 + \dots + c_nx_n \quad (8.1)$$

$$\begin{aligned} & \text{subject to} && a_{i1}x_1 + a_{i2}x_2 + \dots + a_{in}x_n \leq b_i, \\ & && i = 1, 2, \dots, m, \\ & && x_j \geq 0, \\ & && j = 1, 2, \dots, n. \end{aligned} \quad (8.2)$$

The set of all  $n$ -tuples  $(x_1, x_2, \dots, x_n)$  of real numbers that simultaneously satisfy inequalities (8.2) and (8.3) is called the *feasible region* of problem (8.1)–(8.3) and the elements of feasible region are called *feasible solutions*. A feasible solution  $\hat{x}$  such that no other feasible solution  $x$  satisfies

$$c_1x_1 + c_2x_2 + \dots + c_nx_n > c_1\hat{x}_1 + c_2\hat{x}_2 + \dots + c_n\hat{x}_n$$

is called an *optimal solution* of (8.1)–(8.3), and the set of all optimal solutions is called the *optimal region*.

Using the same data  $b_1, b_2, \dots, b_m, c_1, c_2, \dots, c_n, a_{11}, a_{12}, \dots, a_{mn}$ , we can associate with problem (8.1)–(8.3) another linear programming problem, namely, the problem

$$\text{minimize} \quad y_1b_1 + y_2b_2 + \dots + y_mb_m \quad (8.4)$$

$$\begin{aligned} & \text{subject to} && y_1a_{1j} + y_2a_{2j} + \dots + y_ma_{mj} \geq c_j, \\ & && j = 1, 2, \dots, n, \end{aligned} \quad (8.5)$$

$$\begin{aligned} & && y_i \geq 0, \\ & && i = 1, 2, \dots, m. \end{aligned} \quad (8.6)$$

Analogously to the case of maximization, we say that the set of all  $m$ -tuples  $(y_1, y_2, \dots, y_m)$  of real numbers that simultaneously satisfy inequalities (8.5) and (8.6) is the feasible region of problem (8.4)–(8.6), and that an element  $\hat{y}$  of the feasible region such that no other element  $y$  of the feasible region satisfies

$$b_1y_1 + b_2y_2 + \dots + b_my_m < b_1\hat{y}_1 + b_2\hat{y}_2 + \dots + b_m\hat{y}_m$$

is an optimal solution of (8.4)–(8.6).

The problem (8.1)–(8.3) is then called the *primal problem* and the associated problem (8.4)–(8.6) is called the *dual problem* to (8.1)–(8.3). However, this terminology is relative because if we rewrite the dual problem into the form of the equivalent primal problem

and again construct the corresponding dual, then we obtain a linear programming problem which is equivalent to the original primal problem. In other words, the dual to the dual is the primal. Consequently, it is just the matter of convenience which of these problems is taken as the primal problem.

The main theoretical results on linear programming are concerned with mutual relationship between the primal problem and its dual problem. They can be summarized as follows, see also [8.8, 9].

Let  $\mathbb{R}^n$  and  $\mathbb{R}_+^n$  denote the set of real  $n$ -vectors and real nonnegative  $n$ -vectors equipped by the usual euclidean distance. For  $n = 1$ , we simplify the notation to  $\mathbb{R}$  and  $\mathbb{R}_+$ . The scalar product of vectors  $x$  and  $y$  from  $\mathbb{R}^n$  is denoted by  $xy$ :

1. If  $x$  is a feasible solution of the primal problem and if  $y$  is a feasible solution of the dual problem, then  $cx \leq yb$ .
2. If  $\bar{x}$  is a feasible solution of the primal problem, and if  $\bar{y}$  is a feasible solution of the dual problem, and if  $c\bar{x} = \bar{y}b$ , then  $\bar{x}$  is optimal for the primal problem and  $\bar{y}$  is optimal for the dual problem.
3. If the feasible region of the primal problem is nonempty and the objective function  $x \mapsto cx$  is not bounded above on it, then the feasible region of the dual problem is empty.
4. If the feasible region of the dual problem is nonempty and the objective function  $y \mapsto yb$  is not bounded below on it, then the feasible region of the primal problem is empty.

It turns out that the following deeper results concerning mutual relation between the primal and dual problems hold:

5. If either of the problem (8.1)–(8.3) or (8.4)–(8.6) has an optimal solution, so does the other, and the corresponding values of the objective functions are equal.
6. If both problems (8.1)–(8.3) and (8.4)–(8.6) have feasible solutions, then both of them have optimal solutions and the corresponding optimal values are equal.
7. A necessary and sufficient condition that feasible solutions  $x$  and  $y$  of the primal and dual problems are optimal is that

$$x_j > 0 \Rightarrow yA^j = c_j, \quad 1 \leq j \leq n,$$

$$x_j = 0 \Leftarrow yA^j > c_j, \quad 1 \leq j \leq n,$$

$$y_i > 0 \Rightarrow A_i x = b_i, \quad 1 \leq i \leq m,$$

$$y_i = 0 \Leftarrow A_i x < b_i, \quad 1 \leq i \leq m,$$

where  $A^j$  and  $A_i$  stand for the  $j$ -th column and  $i$ -th row of  $A = \{a_{ij}\}$ , respectively.

It is also well known that the essential duality results of linear programming can be expressed as a saddle-point property of the Lagrangian function, see [8.10]:

8. Let  $L: \mathbb{R}_+^n \times \mathbb{R}_+^m \rightarrow \mathbb{R}$  be the *Lagrangian function* for the primal problem (8.1)–(8.3), that is,  $L(x, y) = cx + y(b - Ax)$ . The necessary and sufficient condition that  $\bar{x} \in \mathbb{R}_+^n$  be an optimal solution of the primal problem (8.1)–(8.3) and  $\bar{y} \in \mathbb{R}_+^m$  be an optimal solution of the dual problem (8.4)–(8.6) is that  $(\bar{x}, \bar{y})$  be a saddle point of  $L$ ; that is, for all  $x \in \mathbb{R}_+^n$  and  $y \in \mathbb{R}_+^m$ ,

$$L(x, y) \leq L(\bar{x}, y) \leq L(\bar{x}, \bar{y}). \quad (8.7)$$

## 8.1.2 Sets and Fuzzy Sets

A well-known fact about subsets of a given set is that their properties and their mutual relations can be studied by means of their characteristic functions. However, these two notions are different, and the notion of characteristic function of a subset of a set is more complicated than that of a subset of a set. Indeed, because the characteristic function  $\chi_A$  of a subset  $A$  of a fixed given set  $X$  is a mapping from  $X$  into the set  $\{0, 1\}$ , we not only need the underlying set  $X$  and its subset  $A$  but also one additional set; in particular, the set  $\{0, 1\}$ . In addition, we also need the notion of an ordered pair and the notion of the Cartesian product of sets because functions are specially structured binary relations; in this case, special subsets of  $X \times \{0, 1\}$ .

The phrases *the membership function of a fuzzy set* ... or *the fuzzy set defined by membership function* ... (and similar ones), which are very common in the fuzzy set literature, clearly indicate that a *fuzzy set* and its *membership function* are different mathematical objects. If we introduce fuzzy sets by means of their membership functions, that is, by replacing the range  $\{0, 1\}$  of characteristic functions with the unit interval  $[0, 1]$  of real numbers ordered by the standard ordering  $\leq$ , then we are tacitly assuming that the membership functions of fuzzy sets on  $X$  are related to fuzzy sets on  $X$  in an analogous way as the characteristic functions of subsets of  $X$  are related to subsets of  $X$ . What are those objects that we call fuzzy sets on  $X$  in set-theoretic terms? Obviously, they are more complex than just subsets of  $X$  because the class of functions mapping  $X$  into the lattice  $([0, 1], \leq)$  is much richer than the class of functions mapping  $X$  into  $\{0, 1\}$ . We follow the opinion

that fuzzy sets are special-nested families of subsets of a set, see [8.11].

### Definition 8.1

A *fuzzy subset* of a nonempty set  $X$  (or a *fuzzy set* on  $X$ ) is a family  $\{A_\alpha\}_{\alpha \in [0,1]}$  of subsets of  $X$  such that  $A_0 = X$ ,  $A_\beta \subset A_\alpha$  whenever  $0 \leq \alpha \leq \beta \leq 1$ , and  $A_\beta = \bigcap_{0 \leq \alpha < \beta} A_\alpha$  whenever  $0 < \beta \leq 1$ .

### Definition 8.2

If  $A = \{A_\alpha\}_{\alpha \in [0,1]}$  is a fuzzy subset of  $X$ , then the *membership function* of  $A$  is the function  $\mu_A$  from  $X$  into the unit interval  $[0, 1]$  defined by  $\mu_A(x) = \sup\{\alpha : x \in A_\alpha\}$ .

### Remark 8.1

It is worth noting that by defining a fuzzy subset of a set  $X$  as a special family of subsets of  $X$ , we can easily avoid certain troublesome phrases. For example, we are used to say *a subset  $A$  of  $X$*  and not *a subset  $\chi_A : X \rightarrow \{0, 1\}$  of a set  $X$* . Similarly, it is more natural to say *a fuzzy subset  $A$  of  $X$*  than to say *a fuzzy subset  $\mu_A : X \rightarrow [0, 1]$  in  $X$* . Moreover, if a fuzzy set on  $X$  would be defined as a function  $\mu$  from  $X$  to  $[0, 1]$ , then we would obtain statements like *fuzzy set  $\mu$  is function  $\mu$* , or *a fuzzy set  $\mu$  is convex if and only if  $\mu$  is quasi-concave*.

Let  $A$  be a subset of a set  $X$  and let  $\{A_\alpha\}_{\alpha \in [0,1]}$  be the family of subsets of  $X$  defined by  $A_0 = X$  and  $A_\alpha = A$  for each positive  $\alpha$  from  $[0, 1]$ . It can easily be seen that this family is a fuzzy set on  $X$  and that its membership function is equal to the characteristic function of  $A$ ; see [8.12, 13] for details. This one-to-one correspondence between the characteristic functions of subsets of  $X$  and the membership functions of certain fuzzy sets on  $X$  provides an embedding of the set of subsets of  $X$  into the set of fuzzy sets on  $X$ . Consequently, we can view subsets of  $X$  as special fuzzy sets on  $X$ . When we need to distinguish the latter from the other fuzzy sets on  $X$ , we call them the *crisp fuzzy sets* on  $X$ . Moreover, we can also view the elements of  $X$  as a special fuzzy sets on  $X$  by additionally employing the one-to-one correspondence that assigns to each element  $x$  of  $X$  the singleton  $\{x\}$ . When we need to distinguish an element  $x \in X$  from the crisp fuzzy sets on  $X$  corresponding to  $\{x\}$ , we write  $k(x)$  for the latter.

We denote the collection of all fuzzy sets on  $X$  by  $\mathcal{F}(X)$ . When  $A$  is from  $\mathcal{F}(X)$  and  $\mu_A$  is the membership function of  $A$ , then we use the following terminol-

ogy. The value  $\mu_A(x)$  is called the *membership degree* of  $x$  in  $A$ . The set  $\{x \in X : \mu_A(x) = 1\}$  is called the *core* of  $A$ . If the core of  $A$  is nonempty, then  $A$  is said to be *normalized*. The *complement* of  $A$  is the fuzzy set  $c(A)$  on  $X$  whose membership function is  $\mu_{c(A)}(x) = 1 - \mu_A(x)$ . For each  $\alpha \in [0, 1]$ , the set  $\{x \in X : \mu_A(x) \geq \alpha\}$  is called the  *$\alpha$ -cut* of  $A$  and is denoted by  $[A]_\alpha$ . If  $X$  is a nonempty subset of a real finite-dimensional normed space, then a fuzzy set  $A$  in  $X$  is called *closed*, *bounded*, *compact*, or *convex* if the  $\alpha$ -cut  $[A]_\alpha$  is a closed, bounded, compact or convex subset of  $X$  for every  $\alpha \in (0, 1]$ , respectively.

Following the terminology of [8.7], we say that a fuzzy subset  $A$  of  $\mathbb{R}$  is a *fuzzy quantity* whenever  $A$  is normal, compact, and its membership function  $\mu_A$  is semistrictly quasiconcave in the following sense: The membership function  $\mu_A$  of  $A$  is *semistrictly quasiconcave* on  $\mathbb{R}$  if there exist  $a, b, c, d \in \mathbb{R}$ ,  $-\infty < a \leq b \leq c \leq d < +\infty$ , such that

$$\begin{aligned}\mu_A(t) &= 0 && \text{if } t < a \text{ or } t > d, \\ \mu_A &\quad \text{is strictly increasing on the interval } [a, b], \\ \mu_A(t) &= 1 && \text{if } b \leq t \leq c, \\ \mu_A &\quad \text{is strictly decreasing on the interval } [c, d].\end{aligned}$$

The set of all fuzzy quantities is denoted by  $\mathcal{F}_0(\mathbb{R})$ . Note that  $\mathcal{F}_0(\mathbb{R})$  contains well-known classes of fuzzy numbers: crisp (real) numbers, crisp intervals, triangular fuzzy numbers, trapezoidal, and bell-shaped fuzzy numbers etc. However,  $\mathcal{F}_0(\mathbb{R})$  does not contain fuzzy sets with *stair-like* membership functions.

Recall that the binary relations on  $X$  are subsets of the Cartesian product  $X \times X$  and that the fuzzy sets on  $X \times X$  are called the *fuzzy binary relation* on  $X$ , or simply *fuzzy relation* on  $X$ . Because the binary relations on  $X$  are subsets of  $X \times X$ , we can view them as special fuzzy relations on  $X$ ; namely, as those fuzzy relations on  $X$  whose membership functions are equal to the characteristic functions of the corresponding binary relations. Again, we call them *crisp*. Since the membership functions of fuzzy sets provide a mathematical tool for introducing grades in the notion of set membership, the fuzzy relations on  $X$  can be used for introducing grades in comparison of elements of  $X$ . However, if we need to compare not only elements of  $X$  but also fuzzy sets on  $X$ , then we need binary relations and fuzzy binary relations on the set of fuzzy sets on  $X$ , that is, on  $\mathcal{F}(X) \times \mathcal{F}(X)$ .

Let  $R$  be a fuzzy relation on  $X$  and let  $Q$  be a fuzzy relation on  $\mathcal{F}(X)$ , that is,  $R$  belongs to  $\mathcal{F}(X \times X)$  and  $Q$  belongs to  $\mathcal{F}(\mathcal{F}(X) \times \mathcal{F}(X))$ . We say that  $Q$  is a *fuzzy*

extension (or briefly an *extension*) of  $R$  from  $X$  to  $\mathcal{F}(X)$  if, for each pair  $x$  and  $y$  in  $X$ ,

$$\mu_Q(k(x), k(y)) = \mu_R(x, y). \quad (8.8)$$

Because the set of the conventional binary relations on  $X$  can be embedded into the set of fuzzy relation on  $X$ , we also obtained from (8.8) extensions of conventional binary relations on  $X$  to fuzzy relations on  $\mathcal{F}(X)$ .

## 8.2 Fuzzy Linear Programming

As mentioned in the beginning, we can hardly expect that some unique extension of the conventional linear programming to problems with fuzzy data can be established which would be so clean and clear like the theory of the conventional linear programming in finite-dimensional spaces. This can also be easily seen from the current literature where we can find a number of different extensions, the results of which resemble in various degrees some of the useful results established in the conventional linear programming.

When dealing with problems that arise from the canonical linear programming problem (8.1)–(8.3) by permitting the input data  $c_j$ ,  $a_{ij}$ , and  $b_i$  in (8.1)–(8.3) to be fuzzy quantities, we distinguish the fuzzy quantities from real numbers by writing the tilde above the corresponding symbol. Thus, we write  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$ , and  $\tilde{b}_i$  and consequently  $\mu_{\tilde{c}_j} : \mathbb{R} \rightarrow [0, 1]$ ,  $\mu_{\tilde{a}_{ij}} : \mathbb{R} \rightarrow [0, 1]$  and  $\mu_{\tilde{b}_i} : \mathbb{R} \rightarrow [0, 1]$ , respectively, for  $i \in \mathcal{M} = \{1, 2, \dots, m\}$  and  $j \in \mathcal{N} = \{1, 2, \dots, n\}$ . When the tilde is omitted, it signifies that the corresponding data or values of variables are considered to be real numbers. Notice that if  $\tilde{c}_j$  and  $\tilde{a}_{ij}$  are fuzzy quantities, then, for every  $(x_1, x_2, \dots, x_n)$  from  $\mathbb{R}^n$ , the fuzzy subsets  $\tilde{c}_1x_1 + \dots + \tilde{c}_nx_n$  and  $\tilde{a}_{i1}x_1 + \dots + \tilde{a}_{in}x_n$  of  $\mathbb{R}$  defined by the extension principle are again fuzzy quantities. Also notice that it is possible to consider the conventional linear programming problems as special cases of such fuzzy problems because the real numbers can be identified with crisp fuzzy quantities.

As the canonical fuzzy counterpart of the canonical linear programming problem (8.1)–(8.3), we consider the problem

$$\begin{aligned} & \text{maximize } \tilde{c}_1x_1 + \dots + \tilde{c}_nx_n \\ & \text{subject to } (\tilde{a}_{i1}x_1 + \dots + \tilde{a}_{in}x_n) \tilde{P}_i \tilde{b}_i, \quad i \in \mathcal{M}, \\ & \qquad \qquad \qquad x_j \geq 0, \quad j \in \mathcal{N}, \end{aligned} \quad (8.9)$$

where, for each  $i \in \mathcal{M}$ , the fuzzy quantities  $\tilde{a}_{i1}x_1 + \dots + \tilde{a}_{in}x_n$  and  $\tilde{b}_i$  from  $\mathcal{F}_0(\mathbb{R})$  are compared by a fuzzy relation  $\tilde{P}_i$  on  $\mathcal{F}_0(\mathbb{R})$ , and where the meanings of *subject to* and *maximize*, that is, the meanings of feasibility and optimality, remain to be specified.

Primarily, we shall study the case in which all  $\tilde{P}_i$  appearing in the constraints of problem (8.9) are the same. Namely, let  $\tilde{P}$  be a fuzzy relation on  $\mathcal{F}_0(\mathbb{R})$  and let us assume that  $\tilde{P}_i = \tilde{P}$  for all  $i \in \mathcal{M}$ . Then (8.9) simplifies to

$$\begin{aligned} & \text{maximize } \tilde{c}_1x_1 + \dots + \tilde{c}_nx_n \\ & \text{subject to } (\tilde{a}_{i1}x_1 + \dots + \tilde{a}_{in}x_n) \tilde{P} \tilde{b}_i, \quad i \in \mathcal{M}, \\ & \qquad \qquad \qquad x_j \geq 0, \quad j \in \mathcal{N}, \end{aligned} \quad (8.10)$$

where the meaning of *feasibility* and *optimality* are specified as follows.

- *Feasibility:* Let  $\beta$  be a positive number from  $[0, 1]$ . By a  $\beta$ -*feasible region* of problem (8.10) we understand the  $\beta$ -cut of the fuzzy subset  $\tilde{X}$  of  $\mathbb{R}^n$  whose membership function  $\mu_{\tilde{X}}$  is given by

$$\mu_{\tilde{X}}(x) = \begin{cases} \min_{1 \leq i \leq m} \mu_{\tilde{P}}(\tilde{a}_{i1}x_1 + \dots + \tilde{a}_{in}x_n, \tilde{b}_i) & \text{if } x_j \geq 0 \text{ for all } j \in \mathcal{N}, \\ 0 & \text{otherwise.} \end{cases} \quad (8.11)$$

The elements of  $\beta$ -feasible region are called  $\beta$ -*feasible solutions* of problem (8.10), and  $\tilde{X}$  defined by (8.11) is called the *feasible region* of problem (8.10). It is worth mentioning that when the data in (8.10) are crisp, then  $\tilde{X}$  become the feasible region of the canonical linear programming problem (8.1)–(8.3).

- *Optimality:* When specifying the meaning of optimization, we have to take into account that the set of fuzzy values of the objective function is not linearly ordered, and that the relation for making comparison of elements of this set may be independent of that used in the notion of feasibility. We propose to use the notion of  $\alpha$ -efficient ( $\alpha$ -nondominated) solution of the fuzzy linear programming (FLP) problem. (Some other approaches can be found in the literature; for example, see [8.6].)

First, we observe that a feasible solution  $\hat{x}$  of non-fuzzy problem (8.1)–(8.3) is optimal exactly when

there is no other feasible solution  $x$  such that  $cx > c\bar{x}$ . This suggests the introduction of a suitable fuzzy extensions of  $>$ . Let  $\tilde{Q}$  be a fuzzy relation on  $\mathbb{R}$  and let  $\alpha \in (0, 1]$ . If  $\tilde{a}$  and  $\tilde{b}$  are fuzzy quantities, then we write

$$\tilde{a} \tilde{Q}_\alpha \tilde{b}, \text{ if } \mu_{\tilde{Q}}(\tilde{a}, \tilde{b}) \geq \alpha \quad (8.12)$$

and call  $\tilde{Q}_\alpha$  the  $\alpha$ -relation on  $\mathbb{R}$  associated to  $\tilde{Q}$ . We also write

$$\tilde{a} \tilde{Q}_\alpha^* \tilde{b}, \text{ if } (\tilde{a} \tilde{Q}_\alpha \tilde{b} \text{ and } \mu_{\tilde{Q}}(\tilde{b}, \tilde{a}) < \alpha), \quad (8.13)$$

and call  $\tilde{Q}_\alpha^*$  the strict  $\alpha$ -relation on  $\mathbb{R}$  associated to  $\tilde{Q}$ . Now let  $\alpha$  and  $\beta$  be positive numbers from  $[0, 1]$ . We say that a  $\beta$ -feasible solution  $\hat{x}$  of (8.10) is  $(\alpha, \beta)$ -maximal solution of (8.10) if there is no  $\beta$ -feasible solution  $x$  of (8.10) different from  $\hat{x}$  such that

$$\begin{aligned} \tilde{c}_1 \hat{x}_1 &+ \tilde{c}_2 \hat{x}_2 + \cdots + \tilde{c}_n \hat{x}_n \tilde{Q}_\alpha^* \tilde{c}_1 x_1 \\ &+ \tilde{c}_2 x_2 + \cdots + \tilde{c}_n x_n. \end{aligned} \quad (8.14)$$

### Remark 8.2

Note that  $\tilde{Q}_\alpha$  and  $\tilde{Q}_\alpha^*$  are binary relations on the set of fuzzy quantities  $\mathcal{F}_0(\mathbb{R})$  that are constructed from fuzzy relation  $\tilde{Q}$  at the level  $\alpha \in (0, 1]$ , and that relation  $\tilde{Q}_\alpha^*$  is the strict relation associated with the relation  $\tilde{Q}_\alpha$ . Also notice that if  $\tilde{a}$  and  $\tilde{b}$  are crisp fuzzy numbers corresponding to real numbers  $a$  and  $b$ , respectively, and  $\tilde{Q}$  is a fuzzy extension of relation  $\leq$ , then  $a \tilde{Q}_\alpha b$  holds if and only if  $a \leq b$  does. Then, for  $\alpha \in (0, 1)$ ,  $a \tilde{Q}_\alpha^* b$  if and only if  $a < b$ .

Significance and usefulness of duality results for linear programming problems with fuzzy data depend crucially on the choice of fuzzy relations  $\tilde{P}$  and  $\tilde{Q}$  appearing in the definition of feasibility and optimality. In what follows, we use the natural extensions of binary relations  $\leq$  and  $\geq$  on  $\mathbb{R}$  to fuzzy relations on  $\mathcal{F}(\mathbb{R})$  that are based on the possibility and necessity relations Pos and Nec defined on  $\mathcal{F}(\mathbb{R})$  by

$$\begin{aligned} \mu_{\text{Pos}}(\tilde{a}, \tilde{b}) &= \sup\{\min(\mu_{\tilde{a}}(x), \mu_{\tilde{b}}(y), \mu_R(x, y)) \mid x, y \in \mathbb{R}\}, \end{aligned} \quad (8.15)$$

$$\begin{aligned} \mu_{\text{Nec}}(\tilde{a}, \tilde{b}) &= \inf\{\max(1 - \mu_{\tilde{a}}(x), 1 - \mu_{\tilde{b}}(y), \\ &\quad \mu_R(x, y)) \mid x, y \in \mathbb{R}\}. \end{aligned} \quad (8.16)$$

Equivalently, we write  $\tilde{a} \leq^{\text{Pos}} \tilde{b}$  and  $\tilde{a} \prec^{\text{Nec}} \tilde{b}$ , instead of  $\mu_{\text{Pos}}(\tilde{a}, \tilde{b})$  and  $\mu_{\text{Nec}}(\tilde{a}, \tilde{b})$ , respectively, and by  $\tilde{a} \succeq^{\text{Pos}} \tilde{b}$  we mean  $\tilde{b} \leq^{\text{Pos}} \tilde{a}$ .

The proofs of the following propositions can be found in [8.7].

### Proposition 8.1

Let  $\tilde{a}, \tilde{b} \in \mathcal{F}_0(\mathbb{R})$  be fuzzy quantities. Then, for each  $\alpha \in (0, 1)$ , we have

$$\mu_{\text{Pos}}(\tilde{a}, \tilde{b}) \geq \alpha \text{ iff } \inf[\tilde{a}]_\alpha \leq \sup[\tilde{b}]_\alpha, \quad (8.17)$$

$$\mu_{\text{Nec}}(\tilde{a}, \tilde{b}) \geq \alpha \text{ iff } \sup[\tilde{a}]_{1-\alpha} \leq \inf[\tilde{b}]_{1-\alpha}. \quad (8.18)$$

Let  $\tilde{d} \in \mathcal{F}_0(\mathbb{R})$  be a fuzzy quantity, let  $\beta \in [0, 1]$ , and let  $\tilde{d}^L(\beta)$  and  $\tilde{d}^R(\beta)$  be defined by

$$\begin{aligned} \tilde{d}^L(\beta) &= \inf\{t \mid t \in [\tilde{d}]_\beta\} = \inf[\tilde{d}]_\beta, \\ \tilde{d}^R(\beta) &= \sup\{t \mid t \in [\tilde{d}]_\beta\} = \sup[\tilde{d}]_\beta. \end{aligned} \quad (8.19)$$

### Proposition 8.2

- i) Let  $\tilde{P} = \leq^{\text{Pos}}$  and let  $\beta \in [0, 1]$ . A vector  $x = (x_1, \dots, x_n)$  is a  $\beta$ -feasible solution of the FLP problem (8.10) if and only if it is a nonnegative solution of the system of inequalities

$$\sum_{j \in \mathcal{N}} \tilde{a}_{ij}^L(\beta) x_j \leq \tilde{b}_i^R(\beta), \quad i \in \mathcal{M}.$$

- ii) Let  $\tilde{P} = \prec^{\text{Nec}}$ . A vector  $x = (x_1, \dots, x_n)$  is a  $\beta$ -feasible solution of the FLP problem (8.10) if and only if it is a nonnegative solution of the system of inequalities

$$\sum_{j \in \mathcal{N}} \tilde{a}_{ij}^R(1 - \beta) x_j \leq \tilde{b}_i^L(1 - \beta), \quad i \in \mathcal{M}.$$

The following proposition is a simple consequence of the above results applied to the particular fuzzy relations  $\tilde{P} = \leq^{\text{Pos}}$  and  $\tilde{P} = \prec^{\text{Nec}}$ .

### Proposition 8.3

Let  $\tilde{a}$  and  $\tilde{b}$  be fuzzy quantities,  $\alpha \in (0, 1]$ .

- i) Let  $\tilde{P} = \leq^{\text{Pos}}$  be a fuzzy relation on  $\mathbb{R}$  defined by (8.15). Then

$$\begin{aligned} \tilde{a} \tilde{P}_\alpha \tilde{b} &\text{ iff } \tilde{a}^L(\alpha) \leq \tilde{b}^R(\alpha), \\ \tilde{a} \tilde{P}_\alpha^* \tilde{b} &\text{ iff } \tilde{a}^R(\alpha) < \tilde{b}^L(\alpha). \end{aligned} \quad (8.20)$$

- ii) Let  $\tilde{P} = \prec^{\text{Nec}}$  be a fuzzy relation on  $\mathbb{R}$  defined by (8.16). Then

$$\begin{aligned} \tilde{a} \tilde{P}_\alpha \tilde{b} &\text{ iff } \tilde{a}^R(1-\alpha) \leq \tilde{b}^L(1-\alpha), \\ \tilde{a} \tilde{P}_\alpha^* \tilde{b} &\text{ iff } \tilde{a}^R(1-\alpha) \leq \tilde{b}^L(1-\alpha) \text{ and} \\ &\quad \tilde{a}^L(1-\alpha) < \tilde{b}^R(1-\alpha). \end{aligned} \tag{8.21}$$

As to the *optimal* solution of **FLP** problem, we obtain the following result, see also [8.7].

#### Proposition 8.4

Let  $\alpha, \beta \in (0, 1)$  and let  $\tilde{X}$  be a feasible region of the **FLP** problem (8.10) with  $\tilde{P} = \preceq^{\text{Pos}}$ . Let  $c_j$  be such that

$\tilde{c}_j^L(\alpha) \leq c_j \leq \tilde{c}_j^R(\alpha)$  for all  $j \in \mathcal{N}$ . If  $x^* = (x_1^*, \dots, x_n^*)$  is an optimal solution of the LP problem

$$\begin{aligned} &\text{maximize} \quad \sum_{j \in \mathcal{N}} c_j x_j \\ &\text{subject to} \quad \sum_{j \in \mathcal{N}} \tilde{a}_{ij}^L(\beta) x_j \leq \tilde{b}_i^R(\beta), \quad i \in \mathcal{M}, \\ &\quad x_j \geq 0, \quad j \in \mathcal{N}, \end{aligned} \tag{8.22}$$

then  $x^*$  is an  $(\alpha, \beta)$ -maximal solution of the **FLP** problem (8.10).

## 8.3 Duality in Fuzzy Linear Programming

### 8.3.1 Early Approaches

#### Dual Pairs of Rödder and Zimmermann

One of the early approaches to duality in linear programming problems involving fuzziness is due to *Rödder* and *Zimmermann* [8.14]. To be able to state the problems considered by Rödder and Zimmermann concisely, we first observe that conditions (8.7) bring up the pair of optimization problems

$$\text{maximize}_{y \geq 0} \min L(x, y) \quad \text{subject to } x \in \mathbb{R}_+^n, \tag{8.23}$$

$$\text{minimize}_{x \geq 0} \max L(x, y) \quad \text{subject to } y \in \mathbb{R}_+^m. \tag{8.24}$$

Let  $\mu$  and  $\mu'$  be the real-valued functions on  $\mathbb{R}_+^n$  and  $\mathbb{R}_+^m$ , respectively, and let  $\{\nu_x\}_{x \in \mathbb{R}_+^n}$  and  $\{\nu'_y\}_{y \in \mathbb{R}_+^m}$  be families of real-valued functions on  $\mathbb{R}_+^n$  and  $\mathbb{R}_+^m$ , respectively. Furthermore, let  $\varphi_y$  and  $\psi_x$  be real-valued functions on  $\mathbb{R}_+^n$  and  $\mathbb{R}_+^m$  defined by

$$\varphi_y(x) = \min(\mu(x), \nu_x(y)), \tag{8.25}$$

$$\psi_x(y) = \min(\mu'(y), \nu'_y(x)). \tag{8.26}$$

Now let us consider the following pair of families of optimization problems

Family  $\{P_y\}$ : Given  $y \in \mathbb{R}_+^m$ ,

$$\text{maximize } \varphi_y(x) \quad \text{subject to } x \in \mathbb{R}_+^n.$$

Family  $\{D_x\}$ : Given  $x \in \mathbb{R}_+^n$ ,

$$\text{maximize } \psi_x(y) \quad \text{subject to } y \in \mathbb{R}_+^m.$$

Motivated and supported by economic interpretation, *Rödder* and *Zimmermann* [8.14] propose to specify

functions  $\mu$  and  $\mu'$  and families  $\{\nu_x\}$  and  $\{\nu'_y\}$  as follows: Given an  $m \times n$  matrix  $A$ ,  $m \times 1$  vector  $b$ ,  $1 \times n$  vector  $c$ , and real numbers  $\gamma$  and  $\delta$ , define the functions  $\mu, \mu', \nu_x$  and  $\nu'_y$  by

$$\begin{aligned} \mu(x) &= \min(1, 1 - (\gamma - cx)), \\ \mu'(y) &= \min(1, 1 - (yb - \delta)); \end{aligned} \tag{8.27}$$

$$\begin{aligned} \nu_x(y) &= \max(0, y(b - Ax)), \\ \nu'_y(x) &= \max(0, (yA - c)x). \end{aligned} \tag{8.28}$$

Strictly speaking, we do not obtain a duality scheme as conceived by Kuhn because there is no relationship between the numbers  $\gamma$  and  $\delta$ . Indeed, if the family  $\{P_y\}_{y \geq 0}$  is considered to be the primal problem, then we have the situation in which the primal problem is completely specified by data  $A, b, c$ , and  $\gamma$ . However, these data are not sufficient for specification of family  $\{D_x\}_{x \geq 0}$  because the definition of  $\{D_x\}_{x \geq 0}$  requires knowledge of  $\delta$ . Thus, from the point of view that the dual problem is to be constructed only on the basis of the primal problem data, every choice of  $\delta$  determines a certain family dual to  $\{P_y\}_{y \geq 0}$ . In this sense, we could say that every choice of  $\delta$  gives a duality, the  $\delta$ -duality. Analogously, if the primal problem is  $\{D_x\}_{x \geq 0}$ , then every choice of  $\gamma$  determines some family  $\{P_y\}_{y \geq 0}$  dual to  $\{D_x\}_{x \geq 0}$ , and we obtain the  $\gamma$ -duality. In other words, for every  $\gamma, \delta$ , we obtain  $(\gamma, \delta)$ -duality. It is worth noticing that families  $\{P_y\}$  and  $\{D_x\}$  consist of uncountably many linear optimization problems. Moreover, every problem of each of these families may have uncountably many optimal solutions. Consequently, the solution of the problem given by family  $\{P_y\}_{y \geq 0}$  is the family  $\{X(y)\}_{y \geq 0}$  of subsets of  $\mathbb{R}_+^n$  where  $X(y)$  is the set of maximizers of  $\varphi_y$  over  $\mathbb{R}_+^n$ . Analogously, the family

$\{Y(x)\}_{x \geq 0}$  of maximizers of  $\psi_x$  over  $\mathbb{R}_+^m$  is the solution of problem given by family  $\{D_x\}_{x \geq 0}$ . Rödder and Zimmermann propose to replace the families  $\{P_y\}$  and  $\{D_x\}$  by the families  $\{P'_y\}$  and  $\{D'_x\}$  of problems defined as follows

- Family  $\{P'_u\}$ : For every  $u \geq 0$ ,

$$\begin{aligned} & \text{maximize } \lambda \\ & \text{subject to } \lambda \leq 1 + cx - \gamma \\ & \quad \lambda \leq u(b - Ax) \\ & \quad x \geq 0, \end{aligned} \tag{8.29}$$

- Family  $\{D'_x\}$ : For every  $x \geq 0$ ,

$$\begin{aligned} & \text{minimize } \eta \\ & \text{subject to } \eta \geq ub - \delta - 1 \\ & \quad \eta \geq (c - uA)x \\ & \quad u \geq 0. \end{aligned} \tag{8.30}$$

They call these families of optimization problems the *fuzzy dual pair* and claim that the families  $\{P_y\}$  and  $\{D_x\}$  become families  $\{P'_y\}$  and  $\{D'_x\}$  when  $\mu, \mu', v_x$  and  $v'_y$  are defined by (8.27) and (8.28). To see that this claim cannot be substantiated, it suffices to observe that the value of function  $\varphi_y$  cannot be greater than 1, whereas the value of  $\lambda$  is not bounded above whenever  $A$  and  $b$  are such that both  $cx$  and  $-yAx$  are positive for some  $x \in \mathbb{R}_+^n$ .

To obtain a valid conversion, one needs to add the inequalities  $\lambda \leq 1$  and  $\eta \geq -1$  to the constraints. Thus, it seems that more suitable choice of functions  $v_x$  and  $v'_y$  in the Rödder and Zimmermann duality scheme would be

$$v_x(y) = \min(1, 1 + y(b - Ax)), \tag{8.31}$$

$$v'_y(x) = \min(1, 1 + (yA - c)x). \tag{8.32}$$

Another objection to the Rödder and Zimmermann model arises from the fact that the duality results for the proposed fuzzy dual pair do not reduce to the standard duality results for the crisp scenario, that is, for  $\lambda = 1, \eta = -1$ . Again an easy remedy is to work with  $v_x$  and  $v'_y$  defined by (8.31) and (8.32) instead of  $v_x$  and  $v'_y$  from (8.28). Similar approaches can be found in [8.15, 16].

### Dual Pairs of Bector and Chandra

In contrast to the usual practice, in the Rödder and Zimmermann model, the range of membership functions  $\mu$

and  $\mu'$  is  $(-\infty, 1]$ , and the range of membership functions  $v_x$  and  $v'_y$  is  $[0, \infty)$  or  $[1, \infty)$  instead of usual  $[0, 1]$ . Bector and Chandra [8.17] proposed to replace the relations  $\leq$  and  $\geq$  appearing in the dual pair of linear programming problems by suitable fuzzy relations on  $\mathbb{R}$ . In particular, the inequality  $\leq$  appearing in the  $i$ -th constraint of the primal problem (8.1)–(8.3) is replaced by the fuzzy relation  $\leq_i$  whose membership function  $\mu_{\leq i}: \mathbb{R} \times \mathbb{R} \rightarrow [0, 1]$  is defined by

$$\mu_{\leq i}(\alpha, \beta) = \begin{cases} 1 & \text{if } \alpha \leq \beta \\ 1 - \frac{\alpha - \beta}{p_i} & \text{if } \beta < \alpha \leq \beta + p_i \\ 0 & \text{if } \beta + p_i < \alpha \end{cases},$$

where  $p_i$  is a positive number. Analogously, the inequality  $\geq$  appearing in the  $j$ -th constraint of the dual problem (8.4)–(8.6) is replaced by the fuzzy relation  $\geq_j$  with the membership function

$$\mu_{\geq j}(\alpha, \beta) = \begin{cases} 1 & \text{if } \alpha \geq \beta \\ 1 - \frac{\beta - \alpha}{q_j} & \text{if } \beta > \alpha \geq \beta - q_j \\ 0 & \text{if } \beta - q_j > \alpha \end{cases},$$

where  $q_j$  is a positive number. The degree of satisfaction with which  $x \in \mathbb{R}^n$  fulfills the  $i$ -th fuzzy constraint  $A_i x \leq_i b_i$  of the primal problem is expressed by the fuzzy subset of  $\mathbb{R}^n$  whose membership function  $\mu_i$  is defined by  $\mu_i(x) = \mu_{\leq i}(A_i x, b_i)$ , and the degree of satisfaction with which  $y \in \mathbb{R}^m$  fulfills the  $j$ -th fuzzy constraint  $y A^j \geq_j c_j$  of the dual problem is expressed by the fuzzy subset of  $\mathbb{R}^m$  whose membership function  $\mu_j$  is defined by  $\mu_j(y) = \mu_{\geq j}(y A^j, c_j)$ .

Similarly, we can express the degree of satisfaction with a prescribed aspiration level  $\gamma$  of the objective function value  $c x$  by the fuzzy subset of  $\mathbb{R}^n$  given by  $\mu_0(x) = \mu_{\leq 0}(c x, \gamma)$  where, for the tolerance given by a positive number  $p_0$ , the membership function  $\mu_{\leq 0}$  is defined by

$$\mu_{\leq 0}(\alpha, \beta) = \begin{cases} 1 & \text{if } \alpha \leq \beta \\ 1 - \frac{\beta - \alpha}{p_0} & \text{if } \beta > \alpha \geq \beta - p_0 \\ 0 & \text{if } \beta - p_0 > \alpha . \end{cases}$$

Analogously, for the degree of satisfaction with the aspiration level  $\delta$  and tolerance  $q_0$  in the dual problem, we have  $\mu_0(y) = \mu_{\leq 0}(\delta, y b)$  where

$$\mu_{\leq 0}(\alpha, \beta) = \begin{cases} 1 & \text{if } \alpha \leq \beta \\ 1 - \frac{\alpha - \beta}{q_0} & \text{if } \beta < \alpha \leq \beta + q_0 \\ 0 & \text{if } \beta + q_0 < \alpha . \end{cases}$$

This leads to the following pair of linear programming problems.

Given positive numbers  $p_0, p_1, \dots, p_m$ , and a real number  $\gamma$ , maximize  $\lambda$  subject to

$$\begin{aligned} (\lambda - 1)p_0 &\leq cx - \gamma, \\ (\lambda - 1)p_i &\leq b_i - A_i x, \quad 1 \leq i \leq m, \\ 0 \leq \lambda &\leq 1, \quad x \geq 0. \end{aligned} \quad (8.33)$$

Given positive numbers  $q_0, q_1, \dots, q_n$ , and a real number  $\delta$ , minimize  $-\eta$  subject to

$$\begin{aligned} (\eta - 1)q_0 &\leq \delta - yb, \\ (\eta - 1)q_j &\leq yA^j - c_j, \quad 1 \leq j \leq n, \\ 0 \leq \eta &\leq 1, \quad y \geq 0. \end{aligned} \quad (8.34)$$

Bector and Chandra call this pair the *modified fuzzy pair of primal dual linear programming problems*, and they show that if  $x, \lambda$ , and  $u, \eta$  are feasible solutions of the corresponding problems, then

$$\begin{aligned} &(\lambda - 1) \sum_{i=1}^m u_i p_i + (\eta - 1) \sum_{j=1}^n q_j x_j \\ &\leq \sum_{i=1}^m u_i b_i - \sum_{j=1}^n c_j x_j, \\ &(\lambda - 1)p_0 + (\eta - 1)q_0 \\ &\leq \sum_{j=1}^n c_j x_j - \sum_{i=1}^m u_i b_i + (\delta - \gamma). \end{aligned}$$

It follows that, for the crisp scenario  $\lambda = 1$  and  $\eta = 1$ , we have

$$\sum_{j=1}^n c_j x_j \leq \sum_{i=1}^m u_i b_i \leq \sum_{j=1}^n c_j x_j + (\delta - \gamma).$$

Moreover, for  $\gamma \leq \delta$ , feasible solutions  $\bar{x}, \bar{\lambda}$  and  $\bar{u}, \bar{\eta}$  are optimal if

- $(\bar{\lambda} - 1) \sum_{i=1}^m \bar{u}_i p_i + (\bar{\eta} - 1) \sum_{j=1}^n \bar{q}_j \bar{x}_j$   
 $= \sum_{i=1}^m \bar{u}_i b_i - \sum_{j=1}^n \bar{c}_j \bar{x}_j,$
- $(\bar{\lambda} - 1)p_0 + (\bar{\eta} - 1)q_0$   
 $= \sum_{j=1}^n \bar{c}_j \bar{x}_j - \sum_{i=1}^m \bar{u}_i b_i + (\delta - \gamma).$

Again we see that the dual problem is not stated by using only the data available in the primal problem. Indeed, if problem (8.33) is considered to be the primal problem, then to state its dual problem one needs

additional information; namely, a number  $\delta$  and numbers  $q_0, q_1, \dots, q_n$ ; if problem (8.34) is considered to be primal, then one needs a number  $\gamma$  and numbers  $p_0, p_1, \dots, p_m$ .

### Dual Pairs of Verdegay

Verdegay's approach to duality in fuzzy linear problems presented in [8.18] is based on two natural ideas: (i) Solutions to problems involving fuzziness should be fuzzy; (ii) the dual problem to a problem with fuzziness only in constraints should involve fuzziness only in the objective.

The primal problem considered in [8.19] has the form

$$\begin{aligned} &\text{maximize } cx \\ &\text{subject to } A_i x \preceq_i b_i, \quad i = 1, 2, \dots, m \\ &\quad x \geq 0, \end{aligned} \quad (8.35)$$

where the valued relation  $\preceq_i$  in the  $i$ th constraint is the same as in the previous section, that is,

$$\mu_{\preceq}^i(\alpha, \beta) = \begin{cases} 1 & \text{if } \alpha \leq \beta \\ 1 - \frac{\alpha - \beta}{p_i} & \text{if } \beta < \alpha \leq \beta + p_i \\ 0 & \text{if } \beta + p_i < \alpha. \end{cases}$$

The fuzzy solution of problem (8.35) is given by the fuzzy subset of  $\mathbb{R}^n$  whose each  $\gamma$ -cut,  $0 < \gamma \leq 1$ , is the solution set of the problem

$$\begin{aligned} &\text{maximize } cx \\ &\text{subject to } \mu_{\preceq}^i(A_i x, b_i) \geq \gamma, \quad i = 1, 2, \dots, m \\ &\quad x \geq 0. \end{aligned} \quad (8.36)$$

Consequently, we obtain the following problem of parametric linear programming.

For  $0 < \gamma \leq 1$ ,

$$\begin{aligned} &\text{maximize } cx \\ &\text{subject to } A_i x \leq b_i + (1 - \gamma)p_i, \quad i = 1, 2, \dots, m \\ &\quad x \geq 0. \end{aligned} \quad (8.37)$$

Consider now the ordinary dual problem to (8.37), that is, for  $0 < \gamma \leq 1$ ,

$$\begin{aligned} &\text{minimize } \sum_{i=1}^m u_i(b_i + (1 - \gamma)p_i) \\ &\text{subject to } uA \geq c \\ &\quad u \geq 0. \end{aligned} \quad (8.38)$$

This suggests to introduce variables  $y_1, y_2, \dots, y_m$  by

$$y_i = b_i + \delta p_i, \quad i = 1, 2, \dots, m$$

with  $\delta = 1 - \gamma$ , and consider the family of problems: Given  $0 < \delta \leq 1$  and  $u \geq 0$  with  $uA \geq c$ ,

$$\begin{aligned} & \text{minimize} \sum_{i=1}^m u_i y_i \\ & \text{subject to } y_i \geq b_i + \delta p_i, \quad i = 1, 2, \dots, m. \end{aligned} \quad (8.39)$$

Consequently, in terms of the membership functions  $\mu_{\leq}^i$ , we obtain the family of problems: Given  $0 < \delta \leq 1$  and  $u \geq 0$  with  $uA \geq c$ ,

$$\begin{aligned} & \text{minimize} \sum_{i=1}^m u_i y_i \\ & \text{subject to } \mu_{\leq}^i(y_i, b_i) \leq 1 - \delta, \quad i = 1, 2, \dots, m. \end{aligned} \quad (8.40)$$

### 8.3.2 More General Approach

In this section, we return to the general canonical FLP problem, that is, to the problem

$$\begin{aligned} & \text{maximize } \tilde{c}_1 x_1 \tilde{+} \cdots \tilde{+} \tilde{c}_n x_n \\ & \text{subject to } (\tilde{a}_{i1} x_1 \tilde{+} \cdots \tilde{+} \tilde{a}_{in} x_n) \tilde{P} \tilde{b}_i, \quad i \in \mathcal{M}, \\ & \quad x_j \geq 0, \quad j \in \mathcal{N}. \end{aligned} \quad (8.41)$$

We will call it the *primal FLP problem* and denote it by  $\mathfrak{P}$ . The feasible region of  $\mathfrak{P}$  is introduced by (8.11) and the meaning of  $(\alpha, \beta)$ -maximal solution is explained in (8.14) and (8.22).

To introduce the dual problem to problem  $\mathfrak{P}$ , we first define a suitable notion of duality for fuzzy relations on  $\mathcal{F}(X)$ . Let  $\Phi$  and  $\Psi$  be mappings from  $\mathcal{F}(X \times X)$  into  $\mathcal{F}(\mathcal{F}(X) \times \mathcal{F}(X))$ , and let  $\Theta$  be a nonempty subset of  $\mathcal{F}(X \times X)$ . We say that mapping  $\Phi$  is *dual* to mapping  $\Psi$  on  $\Theta$ , if

$$\Phi(c(P)) = c(\Psi(P)) \quad (8.42)$$

for each  $P \in \Theta$ . Moreover, if  $P$  is in  $\Theta$  and  $\Phi$  is *dual* to  $\Psi$  on  $\Theta$ , then we say that the fuzzy relation  $\Phi(P)$  on  $\mathcal{F}(X)$  is *dual* to fuzzy relation  $\Psi(P)$ .

The *dual FLP problem* (denoted by  $\mathfrak{D}$ ) to problem  $\mathfrak{P}$  is formulated as

$$\begin{aligned} & \text{minimize } \tilde{b}_1 y_1 \tilde{+} \cdots \tilde{+} \tilde{b}_m y_m \\ & \text{subject to } \tilde{c}_j \tilde{Q} (\tilde{a}_{1j} y_1 \tilde{+} \cdots \tilde{+} \tilde{a}_{mj} y_m), \quad j \in \mathcal{N}, \\ & \quad y_i \geq 0, \quad i \in \mathcal{M}. \end{aligned} \quad (8.43)$$

Here,  $\tilde{P}$  and  $\tilde{Q}$  are dual fuzzy relations to each other, particularly  $\tilde{P} = \leq^{\text{Pos}}$ ,  $\tilde{Q} = \prec^{\text{Nec}}$ , or,  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{Q} = \leq^{\text{Pos}}$ . In problem  $\mathfrak{P}$ , *maximization* is considered with respect to fuzzy relation  $\tilde{P}$ , in problem  $\mathfrak{D}$ , *minimization* is considered with respect to fuzzy relation  $\tilde{Q}$ . The pair of FLP problems  $\mathfrak{P}$  and  $\mathfrak{D}$ , that is, (8.41) and (8.43), is called the *primal-dual pair of FLP problems*. Now, we introduce a concept of feasible region of problem  $\mathfrak{D}$ , which is a modification of the feasible region of primal problem  $\mathfrak{P}$ , see also [8.20].

Let  $\mu_{\tilde{a}_{ij}}$  and  $\mu_{\tilde{c}_j}$ ,  $i \in \mathcal{M}, j \in \mathcal{N}$ , be the membership functions of fuzzy quantities  $\tilde{a}_{ij}$  and  $\tilde{c}_j$ , respectively. Let  $\tilde{P}$  be a fuzzy extension of a binary relation  $P$  on  $\mathbb{R}$ . A fuzzy set  $\tilde{Y}$ , whose membership function  $\mu_{\tilde{Y}}$  is defined for all  $y \in \mathbb{R}^m$  by

$$\mu_{\tilde{Y}}(y) = \begin{cases} \min\{\mu_{\tilde{P}}(\tilde{c}_1, \tilde{a}_{11} y_1 \tilde{+} \cdots \tilde{+} \tilde{a}_{m1} y_m), \\ \dots, \mu_{\tilde{P}}(\tilde{c}_n, \tilde{a}_{1n} y_1 \tilde{+} \cdots \tilde{+} \tilde{a}_{mn} y_m)\} \\ \quad \text{if } y_i \geq 0 \text{ for all } i \in \mathcal{M}, \\ 0 \quad \text{otherwise,} \end{cases} \quad (8.44)$$

is called a *fuzzy set of feasible region* or shortly *feasible region* of dual FLP problem (8.43). Moreover, if  $\beta \in (0, 1]$ , then the vectors belonging to  $[\tilde{Y}]_\beta$  are called  $\beta$ -*feasible solutions* of problem (8.43).

By the parallel way, we define an *optimal solution* of the dual FLP problem  $\mathfrak{D}$ .

Let  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$ , and  $\tilde{b}_i$ ,  $i \in \mathcal{M}, j \in \mathcal{N}$ , be fuzzy quantities on  $\mathbb{R}$ . Let  $\tilde{Q}$  be a fuzzy relation on  $\mathcal{F}(\mathbb{R})$  that is a fuzzy extension of the usual binary relation  $\leq$  on  $\mathbb{R}$ , and let  $\alpha, \beta \in (0, 1]$ . A  $\beta$ -feasible solution of (8.43)  $y \in [\tilde{Y}]_\beta$  is called the  $(\alpha, \beta)$ -*minimal solution* of (8.43) if there is no  $y' \in [\tilde{Y}]_\beta, y' \neq y$ , such that

$$\begin{aligned} & \tilde{b}_1 y'_1 \tilde{+} \tilde{b}_2 y'_2 \tilde{+} \cdots \tilde{+} \tilde{b}_m y'_m \tilde{Q}_\alpha^* \tilde{b}_1 y_1 \tilde{+} \tilde{b}_2 y_2 \\ & \tilde{+} \cdots \tilde{+} \tilde{b}_m y_m. \end{aligned} \quad (8.45)$$

where  $\tilde{Q}_\alpha^*$  is the strict  $\alpha$ -relation on  $\mathbb{R}$  associated to  $\tilde{Q}$ .

Let  $P$  be the usual binary operation  $\leq$  on  $\mathbb{R}$ . Now, we shall investigate FLP problems (8.36) and (8.43) with pairs of dual fuzzy relations in the constraints, particularly  $\tilde{P} = \leq^{\text{Pos}}$ ,  $\tilde{Q} = \prec^{\text{Nec}}$ , or,  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{Q} = \leq^{\text{Pos}}$ . The values of objective functions  $\tilde{z}$  and  $\tilde{w}$  are *maximized* and *minimized* with respect to fuzzy relation  $\tilde{P}$  and  $\tilde{Q}$ , respectively.

The feasible region of the primal FLP problem  $\mathfrak{P}$  is denoted by  $\tilde{X}$ , the feasible region of the dual FLP problem  $\mathfrak{D}$  by  $\tilde{Y}$ . Clearly,  $\tilde{X}$  is a fuzzy subset of  $\mathbb{R}^n$ ,  $\tilde{Y}$  is a fuzzy subset of  $\mathbb{R}^m$ .

Note that in the crisp case, that is, when the parameters  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$ , and  $\tilde{b}_i$  are crisp fuzzy quantities, then by (8.15) and (8.16), the relations  $\preceq^{\text{Pos}}$  and  $\prec^{\text{Nec}}$  coincide with  $\leq$ . Hence,  $\mathfrak{P}$  and  $\mathfrak{D}$  forms a primal–dual pair of linear programming problems in the classical sense. The following proposition is a useful modification of Proposition 8.4 and gives a sufficient conditions for  $y^*$  to be an  $(\alpha, \beta)$ -minimal solution of the FLP problem (8.43).

### Proposition 8.5

Let  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$  and  $\tilde{b}_i$  be fuzzy quantities for all  $i \in \mathcal{M}$  and  $j \in \mathcal{N}$ ,  $\alpha, \beta \in (0, 1)$ . Let  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{P} = \preceq^{\text{Pos}}$ . Let  $b_i$  be such that  $\tilde{b}_i^L(\alpha) \leq b_i \leq \tilde{b}_i^R(\alpha)$  for all  $i \in \mathcal{M}$ . If  $y^* = (y_1^*, \dots, y_m^*)$  is an optimal solution of the LP problem

$$\begin{aligned} & \text{minimize} \sum_{i \in \mathcal{M}} b_i y_i \\ & \text{subject to} \sum_{i \in \mathcal{M}} \tilde{a}_{ij}^R(\beta) y_i \geq \tilde{c}_j^L(\beta), \quad j \in \mathcal{N}, \\ & \quad y_i \geq 0, \quad i \in \mathcal{M}, \end{aligned} \quad (8.46)$$

then  $y^*$  is a  $(\alpha, \beta)$ -minimal solution of the FLP problem (8.43).

### Dual Pairs of Ramík

When presenting duality theorems obtained by Ramík in [8.21] (see also [8.7]), we always present two versions: i) for fuzzy relation  $\preceq^{\text{Pos}}$  and ii) for fuzzy relation  $\prec^{\text{Nec}}$ . In order to prove duality results we assume that the level of satisfaction  $\alpha$  of the objective function is equal to the level of satisfaction  $\beta$  of the constraints. Otherwise, the duality theorems in our formulation do not hold. The proofs of the following theorems can be found in [8.7].

### Theorem 8.1 First Weak Duality Theorem

Let  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$  and  $\tilde{b}_i$  be fuzzy quantities,  $i \in \mathcal{M}$  and  $j \in \mathcal{N}$ ,  $\alpha \in (0, 1)$ .

- i) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \preceq^{\text{Pos}}$ , and  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \prec^{\text{Nec}}$ . If a vector  $x = (x_1, \dots, x_n) \geq 0$  belongs to  $[\tilde{X}]_\alpha$  and  $y = (y_1, \dots, y_m) \geq 0$  belongs to  $[\tilde{Y}]_{1-\alpha}$ , then

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^R(\alpha) x_j \leq \sum_{i \in \mathcal{M}} \tilde{b}_i^R(\alpha) y_i. \quad (8.47)$$

- ii) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \preceq^{\text{Pos}}$ . If a vector  $x = (x_1, \dots, x_n) \geq 0$  belongs to  $[\tilde{X}]_{1-\alpha}$  and  $y = (y_1, \dots, y_m) \geq 0$  belongs to  $[\tilde{Y}]_\alpha$ , then

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^L(\alpha) x_j \leq \sum_{i \in \mathcal{M}} \tilde{b}_i^L(\alpha) y_i. \quad (8.48)$$

### Theorem 8.2 Second Weak Duality Theorem

Let  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$  and  $\tilde{b}_i$  be fuzzy quantities for all  $i \in \mathcal{M}$  and  $j \in \mathcal{N}$ ,  $\alpha \in (0, 1)$ .

- i) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \preceq^{\text{Pos}}$ ,  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \prec^{\text{Nec}}$ . If for some  $x = (x_1, \dots, x_n) \geq 0$  belonging to  $[\tilde{X}]_\alpha$  and  $y = (y_1, \dots, y_m) \geq 0$  belonging to  $[\tilde{Y}]_{1-\alpha}$  it holds

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^R(\alpha) x_j = \sum_{i \in \mathcal{M}} \tilde{b}_i^R(\alpha) y_i, \quad (8.49)$$

then  $x$  is an  $(\alpha, \alpha)$ -maximal solution of the FLP problem (8.36) and  $y$  is an  $(1-\alpha, 1-\alpha)$ -minimal solution of the FLP problem  $\mathfrak{D}$ , (8.43).

- ii) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \preceq^{\text{Pos}}$ . If for some  $x = (x_1, \dots, x_n) \geq 0$  belonging to  $[\tilde{X}]_{1-\alpha}$  and  $y = (y_1, \dots, y_m) \geq 0$  belonging to  $[\tilde{Y}]_\alpha$  it holds

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^L(\alpha) x_j = \sum_{i \in \mathcal{M}} \tilde{b}_i^L(\alpha) y_i, \quad (8.50)$$

then  $x$  is an  $(1-\alpha, 1-\alpha)$ -maximal solution of the FLP problem  $\mathfrak{P}$ , (8.36) and  $y$  is an  $(\alpha, \alpha)$ -minimal solution of the FLP problem  $\mathfrak{D}$ , (8.43).

### Remark 8.3

In the crisp case, Theorems 8.1 and 8.2 are the standard linear programming weak duality theorems.

### Remark 8.4

Let  $\alpha \geq 0.5$ . Then  $[\tilde{X}]_\alpha \subset [\tilde{X}]_{1-\alpha}$ ,  $[\tilde{Y}]_\alpha \subset [\tilde{Y}]_{1-\alpha}$ , hence in the first weak duality theorem we can change the assumptions as follows:  $x \in [\tilde{X}]_\alpha$  and  $y \in [\tilde{Y}]_\alpha$ .

However, the statements of the theorem remain unchanged. The same holds for the second weak duality theorem.

Finally, let us direct our attention to the *strong duality*. Motivated by the pairs of Propositions 8.4 and 8.5, in Theorem 8.2, we consider a pair of dual LP problems corresponding to FLP problems (8.36) and (8.43) with fuzzy relations  $\tilde{P} = \preceq^{\text{Pos}}$ ,  $\tilde{Q} = \prec^{\text{Nec}}$ ,  $\alpha = \beta$

$$\begin{aligned} & \text{maximize} \sum_{j \in \mathcal{N}} \tilde{c}_j^R(\alpha) x_j \\ (\text{P1}) \text{ subject to } & \sum_{j \in \mathcal{N}} \tilde{a}_{ij}^L(\alpha) x_j \leq \tilde{b}_i^R(\alpha), \quad i \in \mathcal{M}, \\ & x_j \geq 0, \quad j \in \mathcal{N}, \end{aligned} \quad (8.51)$$

$$\begin{aligned} & \text{minimize} \sum_{i \in \mathcal{M}} \tilde{b}_i^R(\alpha) y_i \\ (\text{D1}) \text{ subject to } & \sum_{i \in \mathcal{M}} \tilde{a}_{ij}^L(\alpha) y_i \geq \tilde{c}_j^R(\alpha), \quad j \in \mathcal{N}, \\ & y_i \geq 0, \quad i \in \mathcal{M}. \end{aligned} \quad (8.52)$$

Moreover, we consider a pair of dual LP problems with fuzzy relations  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{P}^D = \preceq^{\text{Pos}}$

$$\begin{aligned} & \text{maximize} \sum_{j \in \mathcal{N}} \tilde{c}_j^L(\alpha) x_j \\ (\text{P2}) \text{ subject to } & \sum_{j \in \mathcal{N}} \tilde{a}_{ij}^R(\alpha) x_j \leq \tilde{b}_i^L(\alpha), \quad i \in \mathcal{M}, \\ & x_j \geq 0, \quad j \in \mathcal{N}, \\ & \text{minimize} \sum_{i \in \mathcal{M}} \tilde{b}_i^L(\alpha) y_i \\ (\text{D2}) \text{ subject to } & \sum_{i \in \mathcal{M}} \tilde{a}_{ij}^R(\alpha) y_i \geq \tilde{c}_j^L(\alpha), \quad j \in \mathcal{N}, \\ & y_i \geq 0, \quad i \in \mathcal{M}. \end{aligned} \quad (8.53) \quad (8.54)$$

Notice that (P1) and (D1) are classical dual linear programming problems and the same holds for (P2) and (D2).

### Theorem 8.3 Strong Duality Theorem

Let  $\tilde{c}_j$ ,  $\tilde{a}_{ij}$ , and  $\tilde{b}_i$  be fuzzy quantities for all  $i \in \mathcal{M}$  and  $j \in \mathcal{N}$ .

- i) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \preceq^{\text{Pos}}$ ,  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \prec^{\text{Nec}}$ . If for some  $\alpha \in (0, 1)$ ,  $[\tilde{X}]_\alpha$  and  $[\tilde{Y}]_{1-\alpha}$  are nonempty, then there exists  $x^*$  – an  $(\alpha, \alpha)$ -maximal solution of the FLP problem  $\mathfrak{P}$ , and there exists  $y^*$  – an  $(1-\alpha, 1-\alpha)$ -minimal solution of the FLP problem  $\mathfrak{D}$  such that

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^R(\alpha) x_j^* = \sum_{i \in \mathcal{M}} \tilde{b}_i^R(\alpha) y_i^*. \quad (8.55)$$

- ii) Let  $\tilde{X}$  be a feasible region of the FLP problem (8.36) with  $\tilde{P} = \prec^{\text{Nec}}$ ,  $\tilde{Y}$  be a feasible region of the FLP problem (8.43) with  $\tilde{Q} = \preceq^{\text{Pos}}$ . If for some  $\alpha \in (0, 1)$ ,  $[\tilde{X}]_{1-\alpha}$  and  $[\tilde{Y}]_\alpha$  are nonempty, then there exists  $x^*$  – an  $(1-\alpha, 1-\alpha)$ -maximal solution of the FLP problem  $\mathfrak{P}$ , and  $y^*$  – an  $(\alpha, \alpha)$ -minimal solution of the FLP problem  $\mathfrak{D}$  such that

$$\sum_{j \in \mathcal{N}} \tilde{c}_j^L(\alpha) x_j^* = \sum_{i \in \mathcal{M}} \tilde{b}_i^L(\alpha) y_i^*. \quad (8.56)$$

### Remark 8.5

In the crisp case, Theorem 8.3 is the standard linear programming (strong) duality theorem.

### Remark 8.6

Let  $\alpha \geq 0.5$ . Then  $[\tilde{X}]_\alpha \subset [\tilde{X}]_{1-\alpha}$ ,  $[\tilde{Y}]_\alpha \subset [\tilde{Y}]_{1-\alpha}$ , hence in the strong duality theorem, we can assume  $x \in [\tilde{X}]_\alpha$  and  $y \in [\tilde{Y}]_\alpha$ . Evidently, the statement of the theorem remains unchanged.

### Remark 8.7

Theorem 8.3 provides only the existence of the  $(\alpha, \alpha)$ -maximal solution (or  $(1-\alpha, 1-\alpha)$ -maximal solution) of the FLP problem  $\mathfrak{P}$ , and  $(1-\alpha, 1-\alpha)$ -minimal solution ( $(\alpha, \alpha)$ -minimal solution) of the FLP problem  $\mathfrak{D}$  such that (8.55) or (8.56) holds. However, the proof of the theorem gives also the method for finding the solutions by solving linear programming problems (P1) and (D1).

## 8.4 Conclusion

The leading idea of this chapter is based on the fact that, in many cases, the solutions of decision problems obtained through linear programming are numerically tractable approximations of the original nonlinear problems. Because of the practical relevance of linear programming and taking into account a vast literature on this subject, we extended linear programming theory to problems involving fuzzy data. To obtain a meaningful extension of linear programming to problems involving fuzzy data, we specified a suitable class of permitted fuzzy values called fuzzy quantities or fuzzy numbers, introduced fundamental arithmetic operations with such fuzzy numbers, defined inequalities between fuzzy numbers, and clarified

the meaning of feasibility and optimality concepts. On the other hand, we did not deal with linear programming problems involving fuzzy variables. In the literature, it has been done in many different ways, here we focused on such variants of the theory for fuzzy linear programming the results of which resemble in various degrees some of the useful results established in the conventional linear programming. The final and main section of this work has been devoted to duality theory for fuzzy linear programming problems. We recalled some of the early approaches that are based on the ideas of Bellman and Zadeh, and Zimmermann, and then we presented our own recent results.

# 9. Basic Solutions of Fuzzy Coalitional Games

# Basic Solutions of Fuzzy Coalitional Games

**Tomáš Kroupa, Milan Vlach**

This chapter is concerned with basic concepts of solution for coalitional games with fuzzy coalitions in the case of finitely many players and transferable utility. The focus is on those solutions which preoccupy the main part of cooperative game theory (the core and the Shapley value). A detailed discussion or just the comprehensive overview of current trends in fuzzy games is beyond the reach of this chapter. Nevertheless, we mention current developments and briefly discuss other solution concepts.

The theory of cooperative games builds and analyses mathematical models of situations in which players can form coalitions and make binding agreements on how to share results achieved by these coalitions. One of the basic models of cooperative games is a *cooperative game in coalitional form* (briefly a *coalitional game* or a *game*). Following Osborne and Rubinstein [9.1] we assume that the data specifying a coalitional game are composed of:

- A nonempty set  $\Omega$  (the set of players) and a nonempty set  $X$  (the set of consequences),
- A mapping  $V$  that assigns to every subset  $S$  of  $\Omega$  a subset  $V(S)$  of  $X$ , and
- A family  $\{\succ_i\}_{i \in \Omega}$  of binary relations on  $X$  (players' preference relations).

The set  $\Omega$  of all players is usually referred to as the *grand coalition*, subsets of  $\Omega$  are called *coalitions*, and the mapping  $V$  is called the *characteristic function* (or *coalition function*) of the game.

This definition provides a rather general framework for analyzing many classes of coalitional games. The games of this type are usually called coalitional games *without side payments* or *without transferable payoff* (or *utility*). Obviously, for many purposes, this framework is too general because it neither specifies some useful structure of the set of consequences nor properties of preference relations. At the same

time, this framework is also too restrictive because of requiring that the domain of the characteristic function must be the system of all subsets of the player set.

In this chapter, we are mainly concerned with coalitional games in which the number of players is finite. The number of players will be denoted by  $n$  and, without loss of generality, the players will be named by integers  $1, 2, \dots, n$ . In other words, we set  $\Omega = N$  where  $N = \{1, 2, \dots, n\}$ . Moreover, we assume that the sets  $V(S)$  of consequences are subsets of the  $n$ -dimensional real linear space  $\mathbb{R}^n$ , and that each player  $i$  prefers  $(x_1, \dots, x_n)$  to  $(y_1, \dots, y_n)$  if and only if  $x_i > y_i$ . Furthermore, we significantly restrict the generality by considering only the so-called coalitional games with transferable payoff or utility. This class of games is a subclass of games without transferable utility that is characterized by the property: for each coalition  $S$ , there exists a real number  $v(S)$  such that

$$V(S) = \left\{ x \in \mathbb{R}^n : \sum_{i \in S} x_i \leq v(S) \text{ and } x_j = 0 \text{ if } j \notin S \right\}.$$

Evidently, each such game can be identified with the corresponding real-valued function  $v$  defined on the system of all subsets of  $N$ .

In coalitional games, whether with transferable or nontransferable utility, each player has only two alter-

natives of participation in a nonempty coalition: full participation or no participation. This assumption is too restrictive in many situations, and there has been a need for models that give players the possibility of participation in some or all intermediate levels between these two extreme involvements.

The first mathematical models in the form of coalitional games in which the players are permitted to participate in a coalition not only fully or not at all but also partially were proposed by *Butnariu* [9.2] and *Aubin* [9.3]. *Aubin* notices that the idea of partial participation in a coalition was used already in the *Shapley–Shubik* paper on market games [9.4]. In these models, the subsets of  $N$  no longer represent every possible coalition. Instead, a notion of a coalition has to be introduced that makes it possible to represent the partial membership degrees.

It has become customary to assume that a membership degree of player  $i \in N$  is determined by a number  $a_i$  in the unit interval  $I = [0, 1]$ , and to call the resulting vector  $a = (a_1, \dots, a_n) \in I^n$  a *fuzzy coalition*. The

$n$ -dimensional cube  $I^n$  is thus identified with the set of all fuzzy coalitions. Every subset  $S$  of  $N$ , that is, every coalition  $S$ , can be viewed as an  $n$ -vector from  $\{0, 1\}^n$  whose  $i$ th components is 1 when  $i \in S$  and 0 when  $i \notin S$ . These special fuzzy coalitions are often called *crisp* coalitions. Hence, we may think of the set of all fuzzy coalitions  $I^n$  as the convex closure of the set  $\{0, 1\}^n$  of all crisp coalitions. This leads to the notion of an  $n$ -player coalitional game with fuzzy coalitions and transferable utility (briefly a *fuzzy game*) as a bounded function  $v: I^n \rightarrow \mathbb{R}$  satisfying  $v(0) = 0$ .

It turns out that most classes of coalitional games with transferable utility and most solution concepts have natural counterparts in the theory of fuzzy games with transferable utility. Therefore, in what follows, we start with the classical case (Sect. 9.1) and then deal with the fuzzy case (Sect. 9.2). Taking into account that, in comparison with the classical case, the theory of fuzzy games is relatively less developed, we focus attention on two well-established solution concepts of fuzzy games: the core and the Shapley value.

## 9.1 Coalitional Games with Transferable Utility

We know from the beginning of this chapter that from the mathematical point of view, every  $n$ -player coalitional game with transferable utility can be identified with a real-valued function  $v$  defined on the system of all subsets of the set  $N = \{1, 2, \dots, n\}$ . For convenience, we assume that always  $v(\emptyset) = 0$ .

It is customary to interpret the value  $v(S)$  of the characteristic function  $v$  at coalition  $S$  as the worth of coalition  $S$  or the total payoff that coalition  $S$  will be able to distribute among its members, provided exactly the coalition  $S$  forms. However, equally well, the number  $v(S)$  may represent the total cost of reaching some common goal of coalition  $S$  that must be shared by the members of  $S$ ; or some other quantity, depending on the application field. In conformity with the players preferences stated previously, we usually assume that  $v(S)$  represents the total payoff that  $S$  can distribute among its members.

Since the preferences are fixed, we denote the game given through  $N$  and  $v$  by  $(N, v)$ , or simply  $v$ , and the collection of all games with fixed  $N$  by  $G_N$ . The sum  $v + w$  of games from  $G_N$  defined by  $(v + w)(S) = v(S) + w(S)$  for each coalition  $S$  is again a game from  $G_N$ . Moreover, if multiplication of  $v \in G_N$  by a real number  $\alpha$  is defined by  $(\alpha v)(S) = \alpha v(S)$  for each coali-

tion  $S$ , then  $\alpha v$  also belongs to  $G_N$ . An important and well-known fact is that  $G_N$  endowed with these two algebraic operations is a real linear space.

### Example 9.1 Simple games

If the range of a game  $v$  is the two-element set  $\{0, 1\}$  only, then the game can be viewed as a model of a voting system where each coalition  $A \subseteq N$  is either *winning* ( $v(A) = 1$ ) or *loosing* ( $v(A) = 0$ ). Then it is natural to assume that the game also satisfies *monotonicity*; that is, if coalition  $A$  is winning and  $B$  is a coalition with  $A \subseteq B$ , then  $B$  is also winning. It is also natural to consider only games with at least one winning coalition. Thus, we define a *simple game* [9.5, Section 2.2.3] to be a  $\{0, 1\}$ -valued coalitional game  $v$  such that the grand coalition is winning and  $v(A) \leq v(B)$ , whenever  $A \subseteq B$  for each  $A, B \subseteq N$ .

We say that a game  $v$  is *superadditive* if  $v(A \cup B) \geq v(A) + v(B)$ , for every disjoint pair of coalitions  $A, B \subseteq N$ . Consequently, in a superadditive game, it may be advantageous for members of disjoint coalitions  $A$  and  $B$  to form coalition  $A \cup B$  because every pair of disjoint coalitions can obtain jointly at least as much as they could have obtained separately. Consequently, it is ad-

vantageous to form the largest possible coalitions, that is, the grand coalition.

The strengthening of the property of superadditivity is the assumption of nondecreasing marginal contribution of a player to each coalition with respect to coalition inclusion: a game  $v$  is said to be *convex* whenever

$$v(A \cup \{i\}) - v(A) \leq v(B \cup \{i\}) - v(B)$$

for each  $i \in N$  and every  $A \subseteq B \subseteq N \setminus \{i\}$ . It can be directly checked that convexity of  $v$  is equivalent to

$$\begin{aligned} v(A \cup B) + v(A \cap B) &\geq v(A) + v(B) \\ \text{for every } A, B \subseteq N. \end{aligned}$$

### Example 9.2

Let  $B$  be a nonempty coalition in a simple game  $(N, v)$ . Then the game  $v_B$  given by

$$v_B(A) = \begin{cases} 1, & A \supseteq B, \\ 0, & \text{otherwise,} \end{cases} \quad A \subseteq N,$$

is a convex simple game.

### Example 9.3 Bankruptcy game [9.6]

Let  $e > 0$  be the total value of assets held in a bankruptcy estate of a debtor and let  $N$  be the set of all creditors. Furthermore, let  $d_i > 0$  be the debt to creditor  $i \in N$ . Assume that  $e \leq \sum_{i \in N} d_i$ . The *bankruptcy game* is then the game such that, for every  $A \subseteq N$ ,

$$v(A) = \max \left( 0, e - \sum_{i \in N \setminus A} d_i \right).$$

It can be shown that the bankruptcy game is convex.

There is a variety of solution concepts for coalitional games with  $n$  players. Some, like the core, stable set or bargaining set, may consist of sets of real  $n$ -vectors, while others offer as a solution of a game a single real  $n$ -vector.

### 9.1.1 The Core

Let  $v$  be an  $n$ -player coalitional game with transferable utility. The *core* of  $v$  is the set of all efficient payoff vectors  $x \in \mathbb{R}^n$  upon which no coalition can improve,

that is,

$$C(v) = \left\{ x \in \mathbb{R}^n \mid \begin{array}{l} \sum_{i \in N} x_i = v(N) \\ \text{and } \sum_{i \in A} x_i \geq v(A) \text{ for each } A \subseteq N \end{array} \right\}. \quad (9.1)$$

The Bondareva–Shapley theorem [9.5, Theorem 3.1.4] gives a necessary and sufficient condition for the core nonemptiness in terms of the so-called balanced systems. It is easy to see that the core of every game is a (possibly empty) convex polytope. Moreover, the core of a convex game is always nonempty and its vertices can be explicitly characterized [9.7].

### 9.1.2 The Shapley Value

Let  $f = (f_1, f_2, \dots, f_n)$  be a mapping that assigns to every game  $v$  from some collection of games from  $G_N$  a real  $n$ -vector  $f(v) = (f_1(v), f_2(v), \dots, f_n(v))$ . Following the basic interpretation of values of a characteristic functions as the total payoff, we can interpret the values of components of such a function as payoffs to individual players in game  $v$ .

Let  $\mathcal{A}$  be a nonempty collection of games from  $G_N$ . A *solution function on  $\mathcal{A}$*  is a mapping  $f$  from  $\mathcal{A}$  into the  $n$ -dimensional real linear space  $\mathbb{R}^n$ . If the domain  $\mathcal{A}$  of  $f$  is not explicitly specified, then it is assumed to be  $G_N$ . The collection of such mappings is too broad to contain only the mappings that lead to sensible solution concepts. Hence, to obtain reasonable solution concepts we have to require that the solution functions have some reasonable properties. One of the natural properties in many contexts is the following property of efficiency.

#### Property 9.1 Efficiency

A solution function  $f$  on a subset  $\mathcal{A}$  of  $G_N$  is *efficient on  $\mathcal{A}$*  if  $f_1(v) + f_2(v) + \dots + f_n(v) = v(N)$  for every game  $v$  from  $\mathcal{A}$ .

This property can be interpreted as a combination of the requirements of the *feasibility* defined by  $f_1(v) + f_2(v) + \dots + f_n(v) \leq v(N)$  and *collective rationality* defined by  $f_1(v) + f_2(v) + \dots + f_n(v) \geq v(N)$ .

In addition to satisfying the efficiency condition, solution functions are required to satisfy a number of other desirable properties. To introduce some of them, we need further definitions.

Player  $i$  from  $N$  is a *null* player in game  $v$  if  $v(S \cup \{i\}) = v(S)$  for every coalition  $S$  that does not con-

tain player  $i$ ; that is, participation of a null player in a coalition does not contribute anything to the coalition in question.

Player  $i$  from  $N$  is a *dummy* player in game  $v$  if  $v(S \cup \{i\}) = v(S) + v(\{i\})$  for every coalition  $S$  that does not contain player  $i$ ; that is, a dummy player contributes to every coalition the same amount, his or her value of the characteristic function.

Players  $i$  and  $j$  from  $N$  are *interchangeable* in game  $v$  if  $v(S \cup \{i\}) = v(S \cup \{j\})$  for every coalition  $S$  that contains neither player  $i$  nor player  $j$ . In other words, two players are interchangeable if they can replace each other in every coalition that contain one of them.

#### Property 9.2 Null player

A solution function  $f$  satisfies the *null player property* if  $f_i(v) = 0$  whenever  $v \in G_N$  and  $i$  is a null player in  $v$ .

#### Property 9.3 Dummy player

A solution function  $f$  satisfies the *dummy player property* if  $f_i(v) = v(\{i\})$  whenever  $v \in G_N$  and  $i$  is a dummy player in  $v$ .

#### Property 9.4 Equal treatment

A solution function  $f$  satisfies the *equal treatment property* if  $f_i(v) = f_j(v)$  for every  $v \in G_N$  and every pair of players  $i, j$  that are interchangeable in  $v$ .

These three properties are quite reasonable and attractive, especially from the point of fairness and impartiality: a player who contributes nothing should get nothing; a player who contributes the same amount to every coalition cannot expect to get anything else than he or she contributed; and two players who contribute the same to each coalition should be treated equally by the solution function.

The next property reflects the natural requirement that the solution function should be independent of the players' names. Let  $v$  be a game from  $G_N$  and  $\pi: N \rightarrow N$  be a permutation of  $N$ , and let the image of coalition  $S$  under  $\pi$  be denoted by  $\pi(S)$ . It is obvious that, for every  $v \in G_N$ , the function  $\pi v$  defined on  $G_N$  by  $(\pi v)(S) = v(\pi(S))$  is again a game from  $G_N$ . Apparently, the game  $\pi v$  differs from game  $v$  only in players' names; they are interchanged by the permutation  $\pi$ .

#### Property 9.5 Anonymity

A solution function  $f$  is said to be *anonymous* if, for

every permutation  $\pi$  of  $N$ , we have  $f_i(\pi v) = f_{\pi(i)}(v)$  for every game  $v \in G_N$  and every player  $i \in N$ .

When a game consists of two independent games played separately by the same players or if a game is split into a sum of games, then it is natural to require the following property of additivity.

#### Property 9.6 Additivity

A solution function  $f$  on  $G_N$  is said to be *additive* if  $f(u + v) = f(u) + f(v)$  for every pair of games  $u$  and  $v$  from  $G_N$ .

The requirement of additivity differs from the previous conditions in one important aspect. It involves two different games that may or may not be mutually dependent. In contrast, the dummy player and equal treatment properties involve only one game, and the anonymity property involves only those games which are completely determined by a single game.

#### Remark 9.1

The terminology introduced in the literature for various properties of players and solution functions is not completely standardized. For example, some authors use the term *dummy player* and *symmetric players* (or *substitutes*), for what we call null player and interchangeable players, respectively. Moreover, the term *symmetry* is sometimes used for our equal treatment and sometimes for our anonymity.

One of the most studied and most influential single-valued solution concept for coalitional games with transferable utility is the Shapley solution function or briefly the Shapley value, proposed by Shapley in 1953 [9.8]. The simplest way of introducing the Shapley value is to define it explicitly by the following well-known formula for calculation of its components.

#### Definition 9.1

The Shapley value on a subset  $\mathcal{A}$  of  $G_N$  is a solution function  $\varphi$  on  $\mathcal{A}$  whose components  $\varphi_1(v), \varphi_2(v), \dots, \varphi_n(v)$  at game  $v \in \mathcal{A}$  are defined by

$$\varphi_i(v) = \sum_{S: i \in S} \frac{(s-1)!(n-s)!}{n!} [v(S) - v(S \setminus \{i\})], \quad (9.2)$$

where the sum is meant over all coalitions  $S$  containing player  $i$ , and  $s$  generically stands for the number of players in coalition  $S$ .

To clarify the basic idea behind this definition, we first recall the notion of players' marginal contributions to coalitions.

### Definition 9.2

For each player  $i$  and each coalition  $S$ , a *marginal contribution* of player  $i$  to coalition  $S$  in game  $v$  from  $G_N$  is the number  $m_i^v(S)$  defined by

$$m_i^v(S) = \begin{cases} v(S) - v(S \setminus \{i\}) & \text{if } i \in S \\ v(S \cup \{i\}) - v(S) & \text{if } i \notin S \end{cases} .$$

Now imagine a procedure for dividing the total payoff  $v(N)$  among the members of  $N$  in which the players enter a room in some prescribed order and each player receives his or her marginal contribution as payoff to the coalition of players already being in the room. Suppose that the prescribed order is  $(\pi(1), \pi(2), \dots, \pi(n))$  where  $\pi: N \rightarrow N$  is a fixed permutation of  $N$ . Then the procedure under consideration determines the payoffs to individual players as follows: before the first player  $\pi(1)$  entered the room, there was the empty coalition waiting in the room. After player  $\pi(1)$  enters, the coalition in the room becomes  $\{\pi(1)\}$  and the player receives  $v(\{\pi(1)\}) - v(\emptyset)$ . Similarly, before the second player  $\pi(2)$  entered, there was coalition  $\{\pi(1)\}$  waiting in the room. After player  $\pi(2)$  enters, coalition  $\{\pi(1), \pi(2)\}$  is formed in the room and player  $\pi(2)$  receives  $v(\{\pi(1), \pi(2)\}) - v(\{\pi(1)\})$ . This continues till the last player  $\pi(n)$  enters and receives  $v(N) - v(N \setminus \{\pi(n)\})$ .

Let  $S_i^\pi$  denote the coalition of players preceding player  $i$  in the order given by  $(\pi(1), \pi(2), \dots, \pi(n))$ ; that is,  $S_i^\pi = \{\pi(1), \pi(2), \dots, \pi(j-1)\}$  where  $j$  is the uniquely determined member of  $N$  such that  $i = \pi(j)$ . Because there are  $n!$  possible orders, the arithmetical average of the marginal contributions of player  $i$  taken over all possible orderings is equal to the number  $(1/n!) \sum m_i^v(S_i^\pi)$  where the sum is understood over all permutations  $\pi$  of  $N$ . This number is exactly the  $i$ -th component of the Shapley value. Therefore, in addition to the equality (9.2) we also have the equality

$$\varphi_i(v) = \frac{1}{n!} \sum_{\pi} m_i^v(S_i^\pi) \quad (9.3)$$

for computing the components of the Shapley value.

In addition to satisfying the condition of efficiency, the Shapley value has a number of other useful properties. In particular, it satisfies all properties 9.2–9.6. Remarkably, no other solution function on  $G_N$  satisfies

the properties of null player, equal treatment, and additivity at the same time.

### Theorem 9.1 Shapley

For each  $N$ , there exists a unique solution function on  $G_N$  satisfying the properties of efficiency, null player, equal treatment, and additivity; this solution function is the Shapley value introduced by Definition 9.1.

The standard proof of this basic result follows from the following facts:

- The collection  $\{u_T : T \neq \emptyset, T \subseteq N\}$  of *unanimity games* defined by

$$u_T(S) = \begin{cases} 1 & \text{if } T \subseteq S \\ 0 & \text{otherwise ,} \end{cases} \quad (9.4)$$

form a base of the linear space  $G_N$ .

- The null player and equal treatment properties guarantee that  $\varphi$  is determined uniquely on multiples of unanimity games.
- The property of additivity (combined with the fact that the unanimity games form a basis) makes it possible to extend  $\varphi$  in a unique way to the whole space  $G_N$ .

In addition to the original axiomatization by Shapley, there exist several equally beautiful alternative axiomatizations of the Shapley value that do not use the property of additivity [9.9, 10].

### 9.1.3 Probabilistic Values

Let us fix some player  $i$  and, for every coalition  $S$  that does not contain player  $i$ , denote by  $\alpha_i(S)$  the number  $s!(n-s-1)!/n!$ . The family  $\{\alpha_i(S) : S \subseteq N \setminus \{i\}\}$  is a probability distribution over the set of coalitions not containing player  $i$ . Because the  $i$ -th component of the Shapley value can be computed by

$$\varphi_i(v) = \sum_{S \subseteq N \setminus \{i\}} \alpha_i(S) [v(S \cup \{i\}) - v(S)] ,$$

we see that the  $i$ -th component of the Shapley value is the expected marginal contribution of player  $i$  with respect to the probability measure  $\{\alpha_i(S) : S \subseteq N \setminus \{i\}\}$  and that the Shapley value belongs to the following class of solution functions:

### Definition 9.3

A solution function  $f$  on a subset  $\mathcal{A}$  of  $G_N$  is called *probabilistic on  $\mathcal{A}$*  if, for each player  $i$ , there ex-

ists a probability distribution  $\{p_i(S) : S \subseteq N \setminus \{i\}\}$  on the collection of coalitions not containing  $i$  such that

$$f_i(v) = \sum_{S \subseteq N \setminus \{i\}} p_i(S)[v(S \cup \{i\}) - v(S)] \quad (9.5)$$

for every  $v \in \mathcal{A}$ .

The family of probabilistic solution functions embraces an enormous number of functions [9.11]. The efficient probabilistic solution functions are often called *quasivalues*, and the anonymous probabilistic solution functions are called *semivalues*. Since the Shapley value is anonymous and efficient on  $G_N$ , we know that it is both a quasivalue and a semivalue on  $G_N$ . Moreover, the Shapley value is the only probabilistic solution function with these properties.

### Theorem 9.2 Weber

If  $N$  has at least three elements, then the Shapley value is the unique probabilistic solution function on  $G_N$ , that is, anonymous and efficient.

Another widely known probabilistic solution function is the function proposed originally only for voting games by *Banzhaf* [9.12].

### Definition 9.4

The *Banzhaf value* on  $G_N$  is a solution function  $\psi$  on  $G_N$  whose components at game  $v$  are defined by

$$\psi_i(v) = \sum_{S \subseteq N \setminus \{i\}} \frac{1}{2^{n-1}} [v(S \cup \{i\}) - v(S)]. \quad (9.6)$$

Again, by simple computation, we can verify that the Banzhaf solution is a probabilistic solution function. Consequently, the  $i$ -th component of the Banzhaf solution is the expected marginal contribution of player  $i$  with respect to the probability measure  $\{\beta_i(S) : S \subseteq N \setminus \{i\}\}$ , where  $\beta_i(S) = 1/2^{n-1}$  for each subset  $S$  of  $N \setminus \{i\}$ . From the probabilistic point of view, the Banzhaf solution is based on the assumption that each player  $i$  is equally likely to join any subcoalition of  $N \setminus \{i\}$ . On the other hand, the Shapley value is based on the assumption that the coalition the player  $i$  enters is equally likely to be of any size  $s$ ,  $0 \leq s \leq n-1$ , and that all coalitions of this size are equally likely.

## 9.2 Coalitional Games with Fuzzy Coalitions

Since the publication of *Aubin*'s seminal paper [9.3], cooperative scenarios allowing for players' fractional membership degrees in coalitions have been studied. In such situations, the subsets of  $N$  no longer model every possible coalition. Instead, a notion of coalitions has to be introduced that makes it possible to represent the partial membership degrees. It has become customary to assume that a membership degree of player  $i \in N$  is determined by a number  $a_i$  in the unit interval  $I = [0, 1]$ , and to call the resulting vector  $a = (a_1, \dots, a_n) \in I^n$  a *fuzzy coalition*. (The choice of  $I^n$  is not the only possible choice, see [9.13] or the discussion in [9.14].) The  $n$ -dimensional cube  $I^n$  is thus identified with the set of all fuzzy coalitions. Every subset  $A$  of  $N$ , that is, every classical coalition, can be viewed as a vector  $\mathbb{1}_A \in \{0, 1\}^n$  with coordinates

$$(\mathbb{1}_A)_i = \begin{cases} 1 & \text{if } i \in A, \\ 0 & \text{otherwise.} \end{cases}$$

These special fuzzy coalitions are also called *crisp* coalitions. When  $A = \{i\}$  is a singleton, we write simply  $\mathbb{1}_i$  in place of  $\mathbb{1}_{\{i\}}$ . Hence, we may think

of the set of all fuzzy coalitions  $I^n$  as the convex closure of the set  $\{0, 1\}^n$  of all crisp coalitions; see [9.14] for further explanation of this convexification process.

Several definitions of fuzzy games appear in the literature [9.3, 15]. We adopt the one used by *Azrieli* and *Lehrer* [9.13]. However, note that the authors of [9.13] use a slightly more general definition, since they consider a fuzzy coalition  $a$  to be any nonnegative real vector such that  $a \leq q$ , where  $q \in \mathbb{R}^n$  is a given non-negative vector.

### Definition 9.5

An  $n$ -player game (with fuzzy coalitions and transferable utility) is a bounded function  $v: I^n \rightarrow \mathbb{R}$  satisfying  $v(\mathbb{1}_\emptyset) = 0$ .

If we want to emphasize the dependence of Definition 9.5 on the number  $n$  of players, then we write  $(I^n, v)$  in place of  $v$ . Further, by  $\bar{v}$  we denote the restriction of  $v$  to all crisp coalitions

$$\bar{v}(A) = v(\mathbb{1}_A), \quad A \subseteq N. \quad (9.7)$$

Hence, every game with fuzzy coalitions  $v$  induces a classical coalition game  $\bar{v}$  with transferable utility.

Most solution concepts of the cooperative game theory have been generalized to games with fuzzy coalitions. A *payoff vector* is any vector  $x$  with  $n$  real coordinates,  $x = (x_1, \dots, x_n) \in \mathbb{R}^n$ . In a particular game with fuzzy coalitions  $(I^n, v)$ , each player  $i \in N$  obtains the amount of utility  $x_i$  as a result of his cooperative activity. Consequently, a fuzzy coalition  $a \in I^n$  gains the amount

$$\langle a, x \rangle = \sum_{i=1}^n a_i x_i,$$

which is just the weighted average of the players' payoffs  $x$  with respect to their participation levels in the fuzzy coalition  $a$ . By a *feasible payoff* in game  $(I^n, v)$ , we understand a payoff vector  $x$  with  $\langle \mathbb{1}_N, x \rangle \leq v(\mathbb{1}_N)$ .

The following general definition captures most solution concepts for games with fuzzy coalitions.

### Definition 9.6

Let  $\Gamma_N$  be a class of all games with fuzzy coalitions  $(I^n, v)$  and let  $\Lambda_N$  be its nonempty subclass. A *solution* on  $\Lambda_N$  is a function  $\sigma$  that associates with each game  $(I^n, v)$  in  $\Lambda_N$  a subset  $\sigma(I^n, v)$  of the set

$$\{x \in \mathbb{R}^n \mid \langle \mathbb{1}_N, x \rangle \leq v(\mathbb{1}_N)\}$$

of all feasible payoffs in game  $(I^n, v)$ .

The choice of  $\sigma$  is governed by all thinkable rules of economic rationality. Every solution  $\sigma$  is thus determined by a system of restrictions on the set of all feasible payoff vectors in the game. For example, we may formulate a set of axioms for  $\sigma$  to satisfy or single out inequalities making the payoffs in  $\sigma(I^n, v)$  stable, in some sense.

#### 9.2.1 Multivalued Solutions

##### Core

The core is a solution concept  $\sigma$  defined on the whole class of games with fuzzy coalitions  $\Gamma_N$ . We present the definition that appeared in [9.3].

### Definition 9.7

Let  $N = \{1, \dots, n\}$  be the set of all players and  $v \in \Gamma_N$ . The *core* of  $v$  is a set

$$C(v) = \{x \in \mathbb{R}^n \mid \langle \mathbb{1}_N, x \rangle = v(\mathbb{1}_N), \langle a, x \rangle \geq v(a), \text{ for every } a \in I^n\}. \quad (9.8)$$

In words, the core of  $v$  is the set of all payoff vectors  $x$  such that no coalition  $a \in I^n$  is better off when accepting any other payoff vector  $y \notin C(v)$ . This is a consequence of the two conditions in (9.8): *Pareto efficiency*  $\langle \mathbb{1}_N, x \rangle = v(\mathbb{1}_N)$  requires that the profit of the grand coalition is distributed among all the players in  $N$  and *coalitional rationality*  $\langle a, x \rangle \geq v(a)$  means that no coalition  $a \in I^n$  accepts less than is its profit  $v(a)$ .

Observe that the core  $C(v)$  of a game with fuzzy coalitions  $v$  is an intersection of uncountably many halfspaces  $\langle a, x \rangle \geq v(a)$  with the affine hyperplane  $\langle \mathbb{1}_N, x \rangle = v(\mathbb{1}_N)$ . This implies that the core is a possibly empty compact convex subset of  $\mathbb{R}^n$ , since  $C(v)$  is included in the core (9.1) of a classical coalition game  $\bar{v}$  given by (9.7). In this way, we may think of the Aubin's core  $C(v)$  as a refinement of the classical core (9.1).

A payoff  $x$  in the core  $C(v)$  must meet uncountably many restrictions represented by all coalitions  $I^n$ . This raises several questions:

1. When is  $C(v)$  nonempty/empty?
2. When is  $C(v)$  reducible to the intersection of finitely many sets only?
3. For every  $a \in I^n$ , is there a core element  $x \in C(v)$  giving coalition  $a$  exactly its worth  $v(a)$ ?
4. Is there an allocation rule for assigning payoffs in  $C(v)$  to fuzzy coalitions?

*Azrieli and Lehrer* formulated a necessary and a sufficient condition for the core nonemptiness [9.13], thus generalizing the well-known Bondareva–Shapley theorem for classical coalition games. We will need an additional notion in order to state their result. The *strong superadditive cover* of a game  $v \in \Gamma_N$  is a game  $\hat{v} \in \Gamma_N$  such that, for every  $a \in I^n$ ,

$$\begin{aligned} \hat{v}(a) &= \sup \left\{ \sum_{k=1}^{\ell} \lambda_k v(a^k) \mid \ell \in \mathbb{N}, a^i \leq a, \lambda_i \geq 0, \right. \\ &\quad \left. \sum_{k=1}^{\ell} \lambda_k a^k = a, \quad i = 1, \dots, \ell \right\}. \end{aligned}$$

The nonemptiness of  $C(v)$  depends on value of  $\hat{v}$  at one point only.

### Theorem 9.3 Azrieli and Lehrer [9.13]

Let  $v \in \Gamma_N$ . The core  $C(v)$  is nonempty if and only if  $v(\mathbb{1}_N) = \hat{v}(\mathbb{1}_N)$ .

The above theorem answers Question 1. Nevertheless, it may be difficult to check the condition  $v(\mathbb{1}_N) =$

$\hat{v}(\mathbb{1}_N)$ . Can we simplify this task for some classes of games? In particular, can we show that the shape of the core is simpler on some class of games? This leads naturally to Question 2. *Branzei et al.* [9.16] showed that the class of games for which this holds true is the class of convex games. We say that a game  $v \in \Gamma_N$  is *convex*, whenever the inequality

$$v(a+c) - v(a) \leq v(b+c) - v(b) \quad (9.9)$$

is satisfied for every  $a, b, c \in I^n$  such that  $b + c \in I^n$  and  $a \leq b$ . A word of caution is in order here: in general, as shown in [9.13], the convexity of the game  $v \in \Gamma_N$  does not imply and is not implied by the convexity of  $v$  as an  $n$ -place real function. The game-theoretic convexity captures the economic principle of nondecreasing marginal utility. Interestingly, this property makes it possible to simplify the structure of  $C(v)$ .

#### Theorem 9.4 Branzei et al. [9.12]

Let  $v \in \Gamma_N$  be a convex game. Then  $C(v) \neq \emptyset$  and, moreover,  $C(v)$  coincides with the core  $C(\bar{v})$  of the classical coalition game  $\bar{v}$ .

The previous theorem, which solves Question 2, provides in fact the complete characterization of core on the class of convex games with fuzzy coalitions. Indeed, since the game  $\bar{v}$  is convex, we can use the result of *Shapley* [9.7] to describe the shape of  $C(v) = C(\bar{v})$ .

The point 3 motivates the following definition. A game  $v \in \Gamma_N$  is said to be *exact* whenever for every  $a \in I^n$ , there exists  $x \in C(v)$  such that  $\langle a, x \rangle = v(a)$ . The class of exact games can be explicitly described [9.13].

#### Theorem 9.5

Let  $v \in \Gamma_N$ . Then the following properties are equivalent:

- i)  $v$  is exact;
- ii)  $v(a) = \min \{\langle a, x \rangle | x \in C(v)\}$ ;
- iii)  $v$  is simultaneously
  - a) a concave, positively homogeneous function on  $I^n$ , and
  - b)  $v(\lambda a + (1-\lambda)\mathbb{1}_N) = \lambda v(a) + (1-\lambda)v(\mathbb{1}_N)$ , for every  $a \in I^n$  and every  $0 \leq \lambda \leq 1$ .

The second equivalent property enables us to generate many examples of exact games – it is enough to take the minimum of a family of linear functions, each of which coincides at point  $\mathbb{1}_N$ .

Question 4 amounts to asking for the existence of allocation rules in the sense of *Lehrer* [9.17] or dynamic procedures for approximating the core elements by *Wu* [9.18]. A bargaining procedure for recovering the elements of the Aubin's core  $C(v)$  is discussed in [9.19], where the authors present the so-called Cimmino-style bargaining scheme. For a game  $v \in \Gamma_N$  and some *initial payoff*  $x^0 \in \mathbb{R}^n$ , the goal is to recover a sequence of payoffs converging to a core element, provided that  $C(v) \neq \emptyset$ . We consider a probability measure that captures the bargaining power of coalitions  $a \in I^n$ : a *coalitional assessment* is any complete probability measure  $v$  on  $I^n$ . In what follows, we will require that  $v$  is such that, for every Lebesgue measurable set  $A \subseteq I^n$ ,

$$v(A) > 0, \quad \text{whenever } A \text{ is open or } \mathbb{1}_N \in A. \quad (9.10)$$

Let  $x \in \mathbb{R}^n$  be an arbitrary payoff and  $a \in I^n$ . We denote

$$C_a(v) = \begin{cases} \{y \in \mathbb{R}^n | \langle a, y \rangle \geq v(a)\} & a \in I^n \setminus \{\mathbb{1}_N\}, \\ \{y \in \mathbb{R}^n | \langle \mathbb{1}_N, y \rangle = v(\mathbb{1}_N)\} & a = \mathbb{1}_N. \end{cases}$$

What happens when payoff  $x$  is accepted by  $a$ , that is,  $x \in C_a(v)$ ? Then coalition  $a$  has no incentive to bargain for another payoff. On the contrary, if  $x \notin C_a(v)$ , then  $a$  may seek the payoff  $P_{ax} \in C_a(v)$  such that  $P_{ax}$  is the closest to  $x$  in some sense. Specifically, we will assume that  $P_{ax}$  minimizes the Euclidean distance of  $x$  from set  $C_a(v)$ . This yields the formula

$$\begin{aligned} P_{ax} &= \arg \min_{y \in C_a(v)} \|y - x\| \\ &= \begin{cases} x + \frac{\max\{0, v(a) - \langle a, x \rangle\}}{\|a\|^2} a & a \in I^n \setminus \{\mathbb{1}_\emptyset, \mathbb{1}_N\}, \\ x + \frac{v(\mathbb{1}_N) - \langle \mathbb{1}_N, x \rangle}{n} \mathbb{1}_N & a = \mathbb{1}_N, \\ x & a = \mathbb{1}_\emptyset, \end{cases} \end{aligned}$$

where  $\|\cdot\|$  is the Euclidean norm. After all coalitions  $a \in I^n$  have raised their requests on the new payoff  $P_{ax}$ , we will average their demands with respect to the coalitional assessment  $v$  in order to obtain a new proposal payoff vector  $Px$ . Hence,  $Px$  is computed as

$$Px = \int_I P_{ax} dv(a).$$

The integral on the right-hand side is well defined, whenever  $v$  is Lebesgue measurable. The amalgamated

projection operator  $P$  is the main tool in the *Cimmino-style bargaining procedure*: an initial payoff  $x^0$  is arbitrary, and we put  $x^k = Px^{k-1}$ , for each  $k = 1, 2, \dots$

### Theorem 9.6

Let  $v \in \Gamma_N$  be a continuous game with fuzzy coalitions and let  $v$  be a coalitional assessment satisfying (9.10):

1. If the sequence  $(x^k)_{k \in \mathbb{N}}$  generated by the Cimmino procedure is bounded and

$$\lim_{k \rightarrow \infty} \int_{[0,1]^n} \|x^k - P_a x^k\| dv(a) = 0, \quad (9.11)$$

then  $C(v) \neq \emptyset$  and  $\lim_{k \rightarrow \infty} x^k \in C(v)$ .

2. If the sequence  $(x^k)_{k \in \mathbb{N}}$  is unbounded or (9.11) does not hold, then  $C(v) = \emptyset$ .

The interested reader is invited to consult [9.19] for further details and numerical experiments.

## 9.2.2 Single-Valued Solutions

### Shapley value

Aubin defined Shapley value on spaces of games with fuzzy coalitions possessing nice analytical properties [9.3, 14, Chapter 13.4]. Specifically, let a function  $v : \mathbb{R}^n \rightarrow \mathbb{R}$  be positively homogeneous and Lipschitz in the neighborhood of  $\mathbb{1}_N$ . Such functions are termed *generalized sharing games with side payments* by Aubin [9.14, Chap. 13.4]. The restriction of  $v$  onto the cube  $I^n$  is clearly a game with fuzzy coalitions and therefore we would not make any distinction between  $v$  and its restriction to  $I^n$ . In addition, assume that function  $v$  is continuously differentiable at  $\mathbb{1}_N$  and denote by  $\mathcal{G}_N^1$  the class of all such games with fuzzy coalitions. Hence, we may put

$$\sigma(v) = \nabla v(\mathbb{1}_N), \quad v \in \mathcal{G}_N^1. \quad (9.12)$$

Each coordinate  $\sigma_i(v)$  of the gradient vector  $\sigma(v)$  captures the marginal contribution of player  $i \in N$  to the grand coalition  $\mathbb{1}_N$ . As pointed out by Aubin, the gradient measures the roles of the players as pivots in game  $v$ . Moreover, the operator  $\sigma$  given by (9.12) can be considered as a generalized Shapley value on the class of games  $\mathcal{G}_N^1$  (cf. Theorem 9.1): Aubin proved [9.14, Chapter 13.4] that the operator defined by (9.12) satisfies

$$\langle \mathbb{1}_N, \sigma(v) \rangle = v(\mathbb{1}_N),$$

for every game  $v \in \mathcal{G}_N^1$ , and

$$\sigma_i(\pi v) = \sigma_{\pi(i)}(v),$$

for every player  $i \in N$  and every permutation  $\pi$  of  $N$ . Moreover,  $\sigma$  fulfills a certain variant of the Dummy Property.

When defining a value on games with fuzzy coalitions, many other authors [9.15, 20] proceed in the following way: a classical cooperative game is extended from the set of all crisp coalitions to the set of all fuzzy coalitions. The main issue is to decide on the nature of this extension procedure and to check that the extended game with fuzzy coalitions inherits all or at least some properties of the function that is extended (such as superadditivity or convexity). Clearly, there are as many choices for the extension as there are possible interpolations of a real function on  $\{0, 1\}^n$  to the cube  $[0, 1]^n$ .

Tsurumi et al. [9.20] used the Choquet integral as an extension. Specifically, for every  $a \in I^n$ , let  $V_a = \{a_i | a_i > 0, i \in N\}$  and let  $n_a = |V_a|$ . Without loss of generality, we may assume that the elements of  $V_a$  are ordered and write them as  $b_1 < \dots < b_{n_a}$ . Further, put  $[a]_y = \{i \in N | a_i \geq y\}$ , for each  $a \in I^n$  and for each  $y \in [0, 1]$ .

### Definition 9.8

A game with fuzzy coalitions  $(I^n, v)$  is a *game with Choquet integral form* whenever

$$v(a) = \sum_{i=1}^{n_a} \bar{v}([a]_{b_i}) (b_i - b_{i-1}), \quad a \in I^n,$$

where  $b_0 = 0$ . Let  $\Gamma_N^C$  be the class of all games with Choquet integral form.

In the above definition the function  $v$  is the so-called Choquet integral [9.21] of  $a$  with respect to the restriction  $\bar{v}$  of  $v$  to all crisp coalitions. It was shown that every game  $v \in \Gamma_N^C$  is monotone whenever  $\bar{v}$  is monotone [9.20, Lemma 2] and that  $v$  is a continuous function on  $I^n$  [9.20, Theorem 2]. The authors define a mapping

$$f : \Gamma_N^C \rightarrow ([0, \infty)^n)^{I^n},$$

which is called a *Shapley function*, by the following assignment

$$f_i(v)(a) = \sum_{i=1}^{n_a} f_i^0(\bar{v})([a]_{b_i}) (b_i - b_{i-1}), \\ i \in N, v \in \Gamma_N^C, a \in I^n,$$

where

$$\begin{aligned} f_i^0(\bar{v})(B) \\ = \sum_{\substack{A \subseteq B \\ i \in A}} \frac{(|A|-1)!(|B|-|A|)!}{|B|!} (\bar{v}(A) - \bar{v}(A \setminus \{i\})) , \\ B \subseteq N , \end{aligned}$$

whenever  $i \in B$ , and  $f_i^0(\bar{v})(B) = 0$ , otherwise. Observe that  $f_i(v)(a)$  is the Choquet integral of  $a$  with respect to  $f_i^0(v)$  and that  $f_i^0(\bar{v})(B)$  is the Shapley value of  $\bar{v}$  with the grand coalition  $N$  replaced with the coalition  $B$ . Before we show that the Shapley function has some expected properties, we prepare the following definitions. Let  $a \in I^n$  and  $i, j \in N$ . For each  $b \in I^n$  with  $b \leq a$ , define a vector  $b_{ij}^a$  whose coordinates are

$$(b_{ij}^a)_k = \begin{cases} b_i \wedge a_j & k = i , \\ b_j \wedge a_i & k = j , \\ b_k & \text{otherwise} , \end{cases} \quad k \in N .$$

For an arbitrary  $b \in I^n$ , put

$$(b'_{ij}[a])_k = \begin{cases} b_j & k = i , \\ b_i & k = j , \\ b_k & \text{otherwise} , \end{cases} \quad k \in N .$$

Clearly, we have both  $b_{ij}^a \leq a$  and  $b'_{ij}[a] \leq a$ . The following theorem is proved in [9.20].

### Theorem 9.7

The operator  $f : \Gamma_N^C \rightarrow ([0, \infty)^n)^{I^n}$  has the following properties:

1. If  $v \in \Gamma_N^C$  and  $a \in I^n$ , then

$$\sum_{i \in N} f_i(v)(a) = v(a) \quad \text{and} \quad f_j(v)(a) = 0 ,$$

for every  $j \in N$  such that  $a_j = 0$ .

2. If  $v \in \Gamma_N^C$ ,  $a \in I^n$ , and  $b \in I^n$  such that  $v(b \wedge c) = v(b)$ , for every  $c \in I^n$  with  $c \leq a$ , then

$$f_i(v)(a) = f_i(v)(b) \quad \text{for every } i \in N .$$

3. If  $v \in \Gamma_N^C$ ,  $a \in I^n$ ,  $a_{ij}^a$  is such that  $v(a_{ij}^a \wedge c) = v(b)$ , for every  $c \in I^n$  with  $c \leq a$ , and  $v(b) = v(b'_{ij})$  for every  $b \in I^n$  with  $b \leq a_{ij}^a$ , then

$$f_i(v)(a) = f_j(v)(a) .$$

4. If  $v, w \in \Gamma_N^C$ , then  $v + w \in \Gamma_N^C$ , and

$$f_i(v + w)(a) = f_i(v)(a) + f_i(w)(a) ,$$

for every  $i \in N$  and every  $a \in I^n$ .

The previous theorem thus says that the Shapley function  $f$  on the class of games  $\Gamma_N^C$  has the properties analogous to the Shapley value: efficiency, the carrier property, symmetry, and additivity.

*Butnariu and Kroupa* [9.15] studied a value operator on the class of fuzzy games  $(I^n, v)$  satisfying

$$v(a) = \sum_{t \in [0,1]} \psi(t)v(a^t), \quad a \in I^n ,$$

where  $\psi : [0,1] \rightarrow \mathbb{R}$  fulfills

$$(\psi(t) = 0 \text{ iff } t = 0) \text{ and } \psi(1) = 1$$

and

$$a^t = \{i \in N | a_i = t\} .$$

The class of such fuzzy games is denoted by  $\Gamma_N^\psi$ . The so-called Shapley mapping function can be axiomatized on  $\Gamma_N^\psi$  [9.15, Axioms 1–3]: it turns out that there is only one Shapley mapping  $\Phi : \Gamma_N^\psi \rightarrow (\mathbb{R}^n)^{I^n}$  [9.15, Theorem 1].

### Theorem 9.8

There exists a unique Shapley mapping  $\Phi : \Gamma_N^\psi \rightarrow (\mathbb{R}^n)^{I^n}$  and it is given by the following formula:

$$\Phi_i(v)(a) = \begin{cases} \psi(r) \sum_{S \in \mathcal{P}_i(a^r)} \frac{(|S|-1)!(|a^r| - |S|)!}{|a^r|!} (v(S) - v(S \setminus \{i\})) , & \text{if } a_i = r > 0 , \\ 0, & \text{otherwise} , \end{cases}$$

where

$$\mathcal{P}_i(a^r) = \{R \subseteq N | i \in R \text{ and } R \subseteq a^r\} .$$

The expected total allocation of player  $i \in N$  is then obtained as

$$\hat{\Phi}_i(v) = \int_{I^n} \Phi_i(v)(a) da ,$$

provided that the above Lebesgue integral exists. The operator  $\hat{\Phi} = (\hat{\Phi}_1, \dots, \hat{\Phi}_n)$  is called the *cumulative value* of  $v$ . If the weight function  $\psi$  is bounded and Lebesgue integrable, then [9.15, Theorem 2] shows that the cumulative value is well-defined and its coordinates are

$$\hat{\Phi}_i(v) = v(\mathbb{1}_i) \int_0^1 \psi(t) dt$$

for each  $i \in N$ .

Owen's approach to classical Shapley value [9.22] cannot be, strictly speaking, classified as an attempt to define a Shapley-style value on some class of games with fuzzy coalitions, but we mention his construction for the sake of completeness. The idea is to extend a game  $v \in G_N$  with crisp coalitions from its domain  $\{\mathbb{1}_A | A \subseteq N\}$  to the whole unit cube  $I^n$  by way of the multilinear interpolation. The resulting *multilinear extension*  $\tilde{v}$  can be described explicitly as the function

$$\begin{aligned} \tilde{v}(a) &= \sum_{A \subseteq N} \left[ \prod_{i \in A} a_i \prod_{i \notin A} (1 - a_i) \right] v(A), \\ a &= (a_1, \dots, a_n) \in I^n. \end{aligned} \quad (9.13)$$

Function  $\tilde{v}$  is linear in each of its variables separately and  $v(A) = \tilde{v}(\mathbb{1}_A)$ , for each  $A \subseteq N$ . The usual formula (9.13) for the Shapley value  $\phi(v)$  of  $v$  now takes the following *diagonal form* [9.22]

$$\phi_i(v) = \int_0^1 \frac{\partial \tilde{v}}{\partial x_i}(t, \dots, t) dt. \quad (9.14)$$

Hence,  $\phi_i(v)$  is completely determined by the behavior of the function  $\tilde{v}$  in the neighborhood of the diagonal in  $I^n$ . The formula (9.14) is important from the computational point of view: its use in connection with statistical techniques can enhance computations with the Shapley value – see [9.23, Chap. XII.4] for further details.

Since the space of games with crisp coalitions is finite dimensional unlike the space of games with fuzzy coalitions, there is no general approach to the Shapley value of fuzzy games. Even a direct comparison of the cumulative value introduced above with the Shapley function on the space of games  $G_N^C$  of Tsurumi et al. [9.20] is hardly possible since the domains of Shapley operators are essentially different. The selection of the right space of games and an appropriate solution thus vary from one application to another.

## 9.3 Final Remarks

We presented results concerning basic concepts of solution for coalitional games with fuzzy coalitions and finitely many players in the case of transferable utility. We concentrated on those solutions which preoccupy the main part of cooperative game theory (the core and the Shapley value). A detailed discussion or just the comprehensive overview of the current trends in fuzzy games is beyond the reach of this chapter. Nevertheless, in this section we mention current developments and briefly discuss other solution concepts. The reader should always consult the relevant reference for the specification of the concepts used by the cited authors; for example, we can find at least two definitions of a convex fuzzy game:

1. Azrieli and Lehrer [9.13] and [9.16] use the definition (9.9) employed herein;
2. Tsurumi et al. [9.20] call a game with fuzzy coalitions  $v$  *convex* whenever

$$v(a \vee b) + v(a \wedge b) \geq v(a) + v(b)$$

holds true for every  $a, b \in I^n$ .

Sheellshear [9.24] employs the concavification of the fuzzy game – the strong supperadditive cover – in order to show [9.24, Theorem 4.4] that the strong supperadditive cover has a stable core if and only if the original game has a stable core. Further, he investigates important properties of the concavification and its superdifferential; new necessary and sufficient conditions for core stability are given in [9.23, Chap. XII.4].

Yang et al. [9.25] introduced the concept of bargaining sets for games with fuzzy coalitions; they prove that the bargaining set coincides with the Aubin core whenever a game is continuous and convex. Liu and Liu [9.26] extended the results from [9.25] in order to overcome some weakness of the previously used fuzzy bargaining sets. The concept of the classical Mas-Colell bargaining set was also generalized and the authors proved existence theorems for such fuzzy bargaining sets. Moreover, both Aumann and Maschler and Mas-Colell fuzzy bargaining sets of a continuous convex cooperative fuzzy game coincide with its Aubin core.

A fuzzy game is represented as a convex program in [9.27]. It is shown that the optimum of the program determines the optimal coalitions as well as the optimal rewards for the players. Further, this framework seems to unify a number of existing representations of solutions: the core, the least core, and the nucleolus.

Wu [9.28] investigates various types of cores based on the dominance among payoff vectors and the con-

cepts of the true payoff and quasi-payoff of a fuzzy coalition.

Interpretational difficulties related to fuzzy games are pointed out by Mareš and Vlach in [9.29]. The authors propose an alternative model for a fuzzy coalition – a collection of crisp coalitions – and discuss some of its consequences.

# Basics of Fuzzy Sets

János C. Fodor, Imre J. Rudas

In this chapter we summarize basic knowledge on fuzzy logics and fuzzy sets. After a short historical overview of ideas strongly connected to and preceding the notion of fuzzy logics and fuzzy sets, we outline links between many-valued and fuzzy logics. Then fuzzy subsets of a universe are introduced. Interpretations of unary and binary connectives in fuzzy logics as appropriate functions (operations) on the unit interval are central to the approach. Fundamental knowledge on these function classes is presented then, including results on triangular norms and conorms, as well as on impli-

cations. Our concluding remarks suggest further reading, beyond the basics.

In everyday life we use and process vague, imprecise linguistic terms like *young*, *hot*, or *around midnight*. Classical mathematics is unable and inadequate to provide models that can express the complex semantics of such terms. Fuzzy sets, introduced by Zadeh [10.1] on the basis of his observation that

*more often than not, the classes of objects encountered in the real physical world do not have precisely defined criteria or membership,*

are appropriate for modeling the semantics of vague linguistic terms. Fuzzy sets offer a framework to deal with predicates whose satisfaction is a matter of degree.

Some forerunners discussed ideas or formal definitions for describing vague predicates or classes with imprecise boundaries, very close to the basic notions introduced by Zadeh [10.1]. We should mention Peirce [10.2], Russel [10.3], Lukasiewicz [10.4], Black [10.5], Weyl [10.6], Kaplan and Schott [10.7]. The mathematician Karl Menger was the first (in 1951) who used the term *ensemble flou* (the French counterpart for fuzzy set) in the title of a paper in French [10.8]. In addition, Menger's work on probabilistic metric spaces also led to the introduction of so-called *triangular norms and conorms*, extensively studied by

Schweizer and Sklar [10.9], and which later have turned out to be basic operators for fuzzy sets [10.10]. For more historical facts we refer to [10.11].

We want to emphasize that Zadeh's motivations and background were quite different from those of the above-mentioned authors. He introduced the concept of a fuzzy set completely independently of their proposals in order to provide a tool for representing and reasoning with the available information in a manner similar to the way humans express knowledge and summarize data.

This Chapter is organized as follows. In the next section we briefly recall some notions from classical mathematics and its underlying two-valued (Boolean) logic. We extend this material, and in Sect. 10.3 we introduce key terms related to fuzzy sets. Sect. 10.4 contains the core knowledge on interpretations of connectives in fuzzy logic and fuzzy set-theoretic operations. This includes fundamentals of negations, triangular norms and conorms, together with the most important parametric families and particular operations. Fuzzy implications are also handled in a similar way. Concluding remarks are given at the end, including several suggested literature items for further reading.

## 10.1 Classical Mathematics and Logic

Classical mathematics is based on two-valued logic, in which the set of truth values consists of two elements:  $\{0, 1\}$ . There are two basic binary operations  $\wedge$  (AND),  $\vee$  (OR), and the unary complement  $\neg$  (NOT). All other logical operations, e.g. the *implication*  $\rightarrow$ , the *logical equivalence*  $\leftrightarrow$ , and the *exclusive or* XOR, can be constructed from the three basic operations  $\wedge, \vee, \neg$ .

A *proposition* is either an atomic propositional variable  $p_1, p_2, \dots$ , or a compound expression  $(p \wedge q)$ ,  $(p \vee q)$ , or  $\neg p$ , where  $p$  and  $q$  are propositions. A proposition is either *true* (with truth value 1) or *false* (with truth value 0), but not both.

A *set*  $A$  is a collection of objects in a given universe  $X$ , where, for each possible object  $x$  from  $X$ , it either belongs to the set  $A$  (in symbols:  $x \in A$ ) or not ( $x \notin A$ ). A set  $A$  is a *subset* of  $B$  if all objects in  $A$  are in  $B$  as well (in symbols:  $A \subseteq B$ ). We write  $A \subset B$  if  $A \subseteq B$  and there is at least one element in  $B$  which is not in  $A$ . The set of all subsets of  $X$  is denoted by  $\mathcal{P}(X)$ . The empty set, which does not contain any object, is denoted by  $\emptyset$ .

We consider three fundamental operations on sets. The *intersection* of two sets  $A$  and  $B$ , denoted by  $A \cap B$ , is the set of objects from  $X$  which belong both to  $A$  and  $B$ . The *union* of two sets  $A$  and  $B$ , denoted by  $A \cup B$ , is the set of objects from  $X$  which belong at least to one of the sets  $A$  and  $B$ . The *complement* of a set  $A$ , denoted by  $A^c$ , is the set of objects from  $X$  which do not belong to  $A$ .

A function  $\chi_A : X \rightarrow \{0, 1\}$  is called the *characteristic function* of the set  $A$  if

$$\chi_A(x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A \end{cases} .$$

The characteristic function discriminates between *members* and *nonmembers* of the set  $A$ . With the help of characteristic functions, set operations can be expressed as follows

$$\chi_{A \cap B}(x) = \chi_A(x) \wedge \chi_B(x) ,$$

$$\chi_{A \cup B}(x) = \chi_A(x) \vee \chi_B(x) ,$$

$$\chi_{A^c}(x) = \neg \chi_A(x) .$$

## 10.2 Fuzzy Logic, Membership Functions, and Fuzzy Sets

The idea behind *fuzzy logic* is to replace the set of truth values  $\{0, 1\}$  by the entire unit interval  $[0, 1]$ . Then a *fuzzy set* on a universe  $X$  is represented by a function which maps each element  $x \in X$  to a *degree of membership* from the unit interval  $[0, 1]$ . Larger values indicate higher degrees of membership.

For several decades, many-valued logic was considered as a pure mathematical topic. The introduction of fuzzy sets [10.1] produced a new impact to the investigation of many-valued logics. Informally speaking, fuzzy logic is understood as an extension of many-valued logics, with an ultimate goal of providing foundations for *approximate reasoning* with imprecise propositions using fuzzy set theory as the principal tool.

A many-valued propositional logic in which the class of truth values is modelled by the unit interval  $[0, 1]$ , and which forms an extension of the classical Boolean logic, i.e., the two-valued logic with truth values  $\{0, 1\}$ , is quite often called a *fuzzy logic* [10.10]. For sake of simplicity, it is assumed that all fuzzy logics have the same syntax, they may differ only by their semantics.

A *membership function*  $\mu_A$  is a mapping from the universal set  $X$  to the unit interval, i.e.,  $\mu_A : X \rightarrow [0, 1]$ . Membership functions are direct generalizations of characteristic functions. In a logical setting, the degree of membership  $\mu_A(x)$  can also be seen as the truth value of the statement  $x$  is *element of*  $A$ .

Notice that a membership grade can have three meanings:

- *Degree of similarity.* The membership grade  $\mu_A(x)$  represents the degree of proximity of  $x$  from prototype elements of  $A$ .
- *Degree of preference.*  $A$  represents a set of more or less preferred objects, and  $\mu_A(x)$  represents an intensity of preference in favor of object  $x$ .
- *Degree of uncertainty.* The degree  $\mu_A(x)$  can be viewed as the degree of plausibility that a parameter  $p$  has value  $x$ , given that all that is known about it is that  $p$  is  $A$ .

These three semantics of fuzzy sets appear in the works of Zadeh and he was the first to propose each of them.

A *fuzzy set* on  $X$  (or a *fuzzy subset* of  $X$ ) is defined as the collection of the ordered pairs of elements of  $X$  and their membership grades. Practically, a fuzzy set  $A$  on  $X$  is identified with the membership function  $\mu_A$ . The family of all fuzzy subsets of  $X$  is denoted by  $\mathcal{F}(X)$ . Classical subsets of  $X$  are special fuzzy subsets on  $X$ , and are called *crisp sets*. Note that one may represent membership grades not only by the unit interval but also by a (partially or completely) ordered set.

Given two fuzzy subsets  $A$  and  $B$  of  $X$ , we say that  $A$  is *equal* to  $B$  (in symbols  $A = B$ ) if  $\mu_A = \mu_B$ , and that  $A$  is a *subset* of  $B$  (in symbols  $A \subseteq B$ ) if  $\mu_A \leq \mu_B$ .

As it is emphasized in [10.11], membership functions express a *vertical view* of fuzzy sets. Another view is to consider a fuzzy set as a nested family of classical sets, by using the notion of  $\alpha$ -cuts. For any  $\alpha \in [0, 1]$  we can introduce the  $\alpha$ -cut  $A_\alpha$  of a fuzzy set  $A$ . By definition,  $A_\alpha$  is the crisp subset of  $X$  that contains all the elements of  $X$  that have a membership grade greater than or equal to the specified value  $\alpha$ . More formally,  $A_\alpha = \{x \in X | \mu_A(x) \geq \alpha\}, \alpha \in [0, 1]$ .

In the sequel, membership functions and fuzzy sets will be denoted by the same symbol: we write simply  $A(x)$  instead of  $\mu_A(x)$  for  $A \in \mathcal{F}(X)$  and  $x \in X$ .

## 10.3 Connectives in Fuzzy Logic

In order to generalize the classical set-theoretical operations like intersection, union and complement, it is quite natural to use interpretations of logic connectives  $\wedge$ ,  $\vee$  and  $\neg$ , respectively. Indeed, the values  $(A \cap B)(x)$ ,  $(A \cup B)(x)$  and  $A^c(x)$  describe the truth values of the statements  $x$  is element of  $A$  AND  $x$  is element of  $B$ ,  $x$  is element of  $A$  OR  $x$  is element of  $B$ , and  $x$  is NOT element of  $A$ , respectively.

We introduce appropriate classes of functions  $N : [0, 1] \rightarrow [0, 1]$ ,  $T : [0, 1]^2 \rightarrow [0, 1]$  and  $S : [0, 1]^2 \rightarrow [0, 1]$  in order to interpret logic operations  $\neg$ ,  $\wedge$  and  $\vee$ , respectively, on the evaluation set  $[0, 1]$ . In addition, fuzzy implications are also introduced later on.

Then, the *complement* of a fuzzy set  $A$ , the *intersection* and *union* of fuzzy sets  $A, B$  are specified by the functions  $N$ ,  $T$  and  $S$ , respectively, such that

$$\begin{aligned} A_N^c(x) &= N(A(x)), \\ (A \cap_T B)(x) &= T(A(x), B(x)), \\ (A \cup_S B)(x) &= S(A(x), B(x)), \end{aligned} \quad (10.1)$$

where  $x \in X$ ,  $A, B \in \mathcal{F}(X)$ . Therefore, desired properties of fuzzy set-theoretic (or equivalently, logic) operations can be obtained through the corresponding properties of the above functions  $N$ ,  $T$  and  $S$ .

### 10.3.1 Negations

Starting with the negation  $\neg$ , it is clear that its interpretation should map 1 to 0 and 0 to 1, in order to be an extension of the interpretation of the classical two-valued negation. Another natural property is that the interpretation of the negation  $\neg$  be a non-increasing function. To simplify notations, and since there is no

confusion possible, an interpretation of the negation  $\neg$  will also be called a negation.

#### Definition 10.1

A decreasing function  $N : [0, 1] \rightarrow [0, 1]$  with  $N(0) = 1$ ,  $N(1) = 0$  is called a *negation*. A strictly decreasing continuous negation is called a *strict negation*. A strict negation  $N$  is said to be a *strong negation* if  $N$  is also involutive:  $N(N(x)) = x$  holds for all  $x \in [0, 1]$ .

Since a strict negation  $N$  is a strictly increasing and continuous function, its inverse  $N^{-1}$  is also a strict negation, generally different from  $N$ . Obviously, we have  $N^{-1} = N$  if and only if  $N$  is involutive:  $N(N(x)) = x$  holds for all  $x \in [0, 1]$ . This means that the graph of the function  $N$  is symmetric with respect to the line  $\{(x, y) | x = y\}$ .

Another important property of a strict negation  $N$  is that there exists a unique value  $0 < v < 1$  such that  $N(v) = v$ . Then we also have  $N^{-1}(v) = v$ .

A negation which is neither strong nor strict is the *Gödel* (or intuitionistic) *negation* given by

$$N_G(x) = \begin{cases} 1 & \text{if } x = 0 \\ 0 & \text{if } x \in ]0, 1] \end{cases}.$$

By duality, we can define the *dual Gödel* negation as follows

$$N_{DG}(x) = \begin{cases} 1 & \text{if } x \in [0, 1[ \\ 0 & \text{if } x = 1 \end{cases}.$$

It is easy to see that for any negation  $N$  we have

$$N_G \leq N \leq N_{DG}.$$

A strict but not strong negation can be given by  $N(x) = 1 - x^3$ .

A parametric family of strong negations is defined as follows (see [10.12] under the name  $\lambda$ -complement)

$$N_\lambda(x) = \frac{1-x}{1+\lambda x}, \quad \lambda > -1.$$

The *standard negation*  $N_s$  is defined simply as  $N_s(x) = 1 - x$ ,  $x \in [0, 1]$ . This is the most frequently used negation, which is obviously a strong negation. It plays a key role in the representation of strong negations presented in the following theorem. In this chapter we call a continuous, strictly increasing function  $\varphi : [0, 1] \rightarrow [0, 1]$  with  $\varphi(0) = 0$ ,  $\varphi(1) = 1$  an *automorphism* of the unit interval.

### Theorem 10.1

A function  $N : [0, 1] \rightarrow [0, 1]$  is a strong negation if and only if there exists an automorphism  $\varphi$  of the unit interval such that [10.13]

$$N(x) = \varphi^{-1}(1 - \varphi(x)), \quad x \in [0, 1]. \quad (10.2)$$

In this case  $N_\varphi$  denotes  $N$  in (10.2) and is called a  $\varphi$ -transform of the standard negation. If the complement of fuzzy sets on  $X$  is defined by  $N_\varphi$ , we use the short notation  $A_\varphi^c$  for  $A \in \mathcal{F}(X)$ , instead of writing  $A_{N_\varphi}^c$ .

## 10.3.2 Triangular Norms and Conorms

It is assumed that the conjunction  $\wedge$ , which is always in the tuple of connectives, is interpreted by a t-norm, which, in a canonical way, is a generalization of the interpretation of the conjunction in Boolean logic. In a logical sense, a t-conorm is an ideal candidate for the interpretation of the disjunction  $\vee$ , since it is a canonical extension of the interpretation of the two-valued disjunction. This is clear from the following definition.

### Definition 10.2

A *triangular norm* (shortly: a *t-norm*) is a function  $T : [0, 1]^2 \rightarrow [0, 1]$  which is associative, commutative and increasing, and satisfies the boundary condition  $T(1, x) = x$  for all  $x \in [0, 1]$ .

A *triangular conorm* (shortly: a *t-conorm*) is a function  $S : [0, 1]^2 \rightarrow [0, 1]$  which is associative, commutative and increasing, with boundary condition  $S(0, x) = x$  for all  $x \in [0, 1]$ .

The class of t-norms (with slightly different axioms) was introduced in the theory of statistical (probabilistic) metric spaces as a tool for generalizing the classical triangular inequality by Menger [10.14] (see also Schweizer and Sklar [10.9], Alsina et al. [10.15], and Klement et al. [10.10]).

Notice that continuity of a t-norm and a t-conorm is not taken for granted. Even more: conditions in Definition 10.2 do not even imply that all t-norms, as two-place functions, are measurable (see [10.16] for a counter-example).

However, the definition implies the following properties

$$\begin{aligned} T(x, y) &\leq \min(x, y), \\ S(x, y) &\geq \max(x, y) \quad (x, y \in [0, 1]), \end{aligned}$$

and

$$T(0, y) = 0, \quad S(1, y) = 1 \quad \text{for all } y \in [0, 1].$$

The smallest t-norm is the *drastic product*  $T_D$  given by

$$T_D(x, y) = \begin{cases} 0 & \text{if } (x, y) \in [0, 1[ \\ \min(x, y) & \text{otherwise.} \end{cases}$$

The greatest (and the only idempotent) t-norm is obviously  $T_M = \min$ , the *minimum t-norm*. Thus, for any t-norm  $T$  we have

$$T_D \leq T \leq T_M.$$

The smallest and greatest t-norms ( $T_D$  and  $T_M$ ) together with the *product t-norm*  $T_P(x, y) = xy$ , and the *Lukasiewicz t-norm*  $T_L$  given by

$$T_L(x, y) = \max(0, x + y - 1)$$

are called *basic t-norms*.

The first known left-continuous and not continuous t-norm is the *nilpotent minimum* [10.17] defined by

$$T_{nM}(x, y) = \begin{cases} 0 & \text{if } x + y \leq 1 \\ \min(x, y) & \text{otherwise.} \end{cases}$$

A t-conorm  $S$  is called the dual to the t-norm  $T$  if  $S(x, y) = 1 - T(1 - x, 1 - y)$  holds for all  $x, y \in [0, 1]$ .

The t-conorm  $S_M = \max$  is the smallest t-conorm and it is dual to the greatest t-norm  $\min$ . The dual to the drastic product is the t-conorm  $S_D$  given by

$$S_D(x, y) = \begin{cases} 1 & \text{if } (x, y) \in ]0, 1[ \\ \max(x, y) & \text{otherwise.} \end{cases}$$

For each t-conorm  $S$ , we have  $S_M \leq S \leq S_D$ .

The dual t-conorm to the product  $T_P$  is called the *probabilistic sum* and it is denoted by  $S_P$ , with  $S_P(x, y) = x + y - xy$ .

The Łukasiewicz t-conorm  $S_L$ , called also the *bounded sum*, is given by  $S_L(x, y) = \min(1, x + y)$ .

From algebraic point of view, a function  $T : [0, 1]^2 \rightarrow [0, 1]$  is a t-norm if and only if  $([0, 1], T, \leq)$  is a fully ordered commutative semigroup with neutral element 1 and annihilator 0. Similarly, a function  $S : [0, 1]^2 \rightarrow [0, 1]$  is a t-conorm if and only if  $([0, 1], S, \leq)$  is a fully ordered commutative semigroup with neutral element 0 and annihilator 1.

Clearly, for every t-norm  $T$  and strict negation  $N$ , the operation  $S$  defined by

$$S(x, y) = N^{-1}(T(N(x), N(y))), \quad x, y \in [0, 1] \quad (10.3)$$

is a t-conorm. In addition, if  $N$  is a strong negation then  $N^{-1} = N$ , and we have for  $x, y \in [0, 1]$  that  $T(x, y) = N(S(N(x), N(y)))$ . In this case  $S$  and  $T$  are called *N-duals*. In case of the standard negation (i.e., when  $N = N_s$ ) we simply speak about *duals*. Obviously, equality (10.3) expresses the De Morgan's law.

#### Definition 10.3

A triplet  $(T, S, N)$  is called a *De Morgan triplet* if and only if  $T$  is a t-norm,  $S$  is a t-conorm,  $N$  is a strong negation and they satisfy (10.3).

It is worth noting that, given a De Morgan triplet  $(T, S, N)$ , the tuple  $([0, 1], T, S, N, 0, 1)$  can never be a Boolean algebra [10.18]: in order to satisfy distributivity we must have  $T = \min$  and  $S = \max$ , in which case it is impossible to have both  $T(x, N(x)) = 0$  and  $S(x, N(x)) = 1$  for all  $x \in [0, 1]$ . Depending on the operations used, one can, however, obtain rather general and useful structures such as, for instance, De Morgan algebras, residuated lattices, l-monoids, Girard algebras, MV-algebras, see [10.10].

There are several examples of De Morgan triplets. We list in Table 10.1 those ones that are related to the examples above. Let  $\varphi$  be an automorphism of the unit interval,  $N_\varphi$  the corresponding strong negation, and  $x, y \in [0, 1]$ .

A function  $K : [0, 1]^2 \rightarrow [0, 1]$  will often be called a *binary operation* on  $[0, 1]$ . For an automorphism  $\varphi$  of  $[0, 1]$ , the  $\varphi$ -transform  $K_\varphi$  of such a  $K$  is defined by  $K_\varphi(x, y) = \varphi^{-1}(K(\varphi(x), \varphi(y)))$ ,  $x, y \in [0, 1]$ . Thus, Ta-

ble 10.1 contains  $\varphi$ -transforms of some *fundamental* t-norms and t-conorms.

#### Continuous Archimedean t-Norms and t-Conorms

A broad class of problems consists of the representation of multi-place functions in general by composition of *simpler* functions and functions of fewer variables (see Ling [10.19] for a brief survey), such as

$$K(x, y) = g(f(x) + f(y)),$$

where  $K$  is a two-place function and  $f, g$  are real functions. In that general framework, the representation of (two-place) associative functions by appropriate one-place functions is a particular problem. It was Abel who first obtained such a representation in 1826 [10.20], by assuming also commutativity, strict monotonicity and differentiability. Since Abel's result, a lot of contributions have been made to representations of associative functions (and generally speaking, of abstract semi-groups).

For any  $x \in [0, 1]$ , any  $n \in \mathbb{N}$ , and for any associative binary operation  $K$  on  $[0, 1]$ , denote  $x_K^{(n)}$  the  $n$ -th power of  $x$  defined by

$$x_K^{(1)} = x,$$

and

$$x_K^{(n)} = \underbrace{K(x, \dots, x)}_{n\text{-times}} \text{ for } n \geq 2.$$

#### Definition 10.4

A t-norm  $T$  (resp. a t-conorm  $S$ ) is said to be:

- Continuous* if  $T$  (resp.  $S$ ) as a function is continuous on the unit interval;
- Archimedean* if for each  $(x, y) \in [0, 1]^2$  there is an  $n \in \mathbb{N}$  such that  $x_T^{(n)} < y$  (resp.  $x_S^{(n)} > y$ ).

Note that the definition of the Archimedean property is borrowed from the theory of semigroups.

**Table 10.1** Some  $N_\varphi$ -dual triangular norms and conorms

$T$	$S$
$\min(x, y)$	$\max(x, y)$
$\varphi^{-1}(\varphi(x)\varphi(y))$	$\varphi^{-1}(\varphi(x) + \varphi(y) - \varphi(x)\varphi(y))$
$\varphi^{-1}(\max(\varphi(x) + \varphi(y) - 1, 0))$	$\varphi^{-1}(\min(\varphi(x) + \varphi(y), 1))$
$\begin{cases} 0 & \text{if } \varphi(x) + \varphi(y) \leq 1 \\ \min(x, y) & \text{otherwise} \end{cases}$	$\begin{cases} \max(x, y) & \text{if } \varphi(x) + \varphi(y) < 1 \\ 1 & \text{otherwise} \end{cases}$

We state here the representation theorem of *continuous Archimedean t-norms and t-conorms* attributed very often to *Ling* [10.19]. In fact, her main theorem can be deduced from previously known results on topological semigroups, see [10.21–23]. Nevertheless, the advantage of Ling's approach is twofold: treating two different cases in a unified manner and establishing elementary proofs.

### Theorem 10.2

A t-norm  $T$  is continuous and Archimedean if and only if there exists a strictly decreasing and continuous function  $t : [0, 1] \rightarrow [0, \infty]$  with  $t(1) = 0$  such that

$$T(x, y) = t^{(-1)}(t(x) + t(y)) \quad (x, y \in [0, 1]), \quad (10.4)$$

where  $t^{(-1)}$  is the pseudoinverse of  $t$  defined by

$$t^{(-1)}(x) = \begin{cases} t^{-1}(x) & \text{if } x \leq t(0) \\ 0 & \text{otherwise.} \end{cases}$$

Moreover, representation (10.4) is unique up to a positive multiplicative constant. [10.19]

We say that  $T$  is *generated by*  $t$  if  $T$  has representation (10.4). In this case  $t$  is said to be an *additive generator* of  $T$ .

### Theorem 10.3

A t-conorm  $S$  is continuous and Archimedean if and only if there exists a strictly increasing and continuous function  $s : [0, 1] \rightarrow [0, \infty]$  with  $s(0) = 0$  such that

$$S(x, y) = s^{(-1)}(s(x) + s(y)) \quad (x, y \in [0, 1]), \quad (10.5)$$

where  $s^{(-1)}$  is the pseudoinverse of  $s$  defined by

$$s^{(-1)}(x) = \begin{cases} s^{-1}(x) & \text{if } x \leq s(1) \\ 1 & \text{otherwise.} \end{cases}$$

Moreover, representation (10.5) is unique up to a positive multiplicative constant. [10.19]

We say that a continuous Archimedean t-conorm  $S$  is *generated by*  $s$  if  $S$  has representation (10.5). In this case  $s$  is said to be an *additive generator* of  $S$ .

Remark that Aczél published the representation of strictly increasing, continuous and associative two-

place functions on open or half-open real intervals [10.24–26]. This was the starting point to be generalized by Ling [10.19].

### Definition 10.5

We say that a t-norm  $T$  has *zero divisors* if there exist  $x, y \in ]0, 1[$  such that  $T(x, y) = 0$ .  $T$  is said to be *positive* if  $x, y > 0$  imply  $T(x, y) > 0$ . A t-norm  $T$  or a t-conorm  $S$  is called *strict* if it is a continuous and strictly increasing function in each place on  $]0, 1[^2$ .  $T$  is called *nilpotent* if it is continuous and Archimedean with zero divisors. Triangular conorms which are duals of nilpotent t-norms are also called *nilpotent*.

The representation theorem of t-norms (resp. t-conorms) does not indicate any condition on the value of a generator function at 0 (resp. at 1). On the basis of this value, one can classify continuous Archimedean t-norms (resp. t-conorms) as it is stated in the following theorem.

### Theorem 10.4

Let  $T$  be a continuous Archimedean t-norm with additive generator  $t$ , and  $S$  be a continuous Archimedean t-conorm with additive generator  $s$ . Then:

- a)  $T$  is nilpotent if and only if  $t(0) < +\infty$ ;
- b)  $T$  is strict if and only if  $t(0) = \lim_{x \rightarrow 0} t(x) = +\infty$ ;
- c)  $S$  is nilpotent if and only if  $s(1) < +\infty$ ;
- d)  $S$  is strict if and only if  $s(1) = \lim_{x \rightarrow 1} s(x) = +\infty$ .

Using the general representation theorem of continuous Archimedean t-norms, we can give another form of representation for a class of continuous t-norms with zero divisors. More exactly, for continuous t-norms  $T$  such that  $T(x, N(x)) = 0$  holds with a *strict negation*  $N$  for all  $x \in [0, 1]$ . Such t-norms are Archimedean, as it was proved in [10.27]. The following theorem is established after [10.28].

### Theorem 10.5

A continuous t-norm  $T$  is such that  $T(x, N(x)) = 0$  holds for all  $x \in [0, 1]$  with a strict negation  $N$  if and only if there exists an automorphism  $\varphi$  of the unit interval such that for all  $x, y \in [0, 1]$  we have

$$T(x, y) = \varphi^{-1}(\max\{\varphi(x) + \varphi(y) - 1, 0\}) \quad (10.6)$$

and

$$N(x) \leq \varphi^{-1}(1 - \varphi(x)).$$

As a consequence, we obtain that any nilpotent t-norm is isomorphic to (i.e., is a  $\varphi$ -transform of) the Łukasiewicz t-norm  $T_L(x, y) = \max(x + y - 1, 0)$ . Similarly, any strict t-norm  $T$  is isomorphic to the algebraic product: there is an automorphism  $\varphi$  of  $[0, 1]$  such that  $T(x, y) = \varphi^{-1}(\varphi(x)\varphi(y))$ , for all  $x, y \in [0, 1]$ .

Similar statements can be proved for t-conorms, see [10.29] for more details. For instance, any strict t-conorm is isomorphic to the probabilistic sum  $S_P$ , and any nilpotent t-conorm is isomorphic to the bounded sum  $S_L$ .

### Continuous t-Norms and t-Conorms

Suppose that  $\{[\alpha_m, \beta_m]\}_{m \in M}$  is a countable family of non-overlapping, closed, proper subintervals of  $[0, 1]$ . With each  $[\alpha_m, \beta_m]$  associate a continuous Archimedean t-norm  $T_m$ . Let  $T$  be a function defined on  $[0, 1]^2$  by

$$T(x, y) = \begin{cases} \alpha_m + (\beta_m - \alpha_m) T_m \left( \frac{x - \alpha_m}{\beta_m - \alpha_m}, \frac{y - \alpha_m}{\beta_m - \alpha_m} \right) & \text{if } (x, y) \in [\alpha_m, \beta_m]^2 \\ \min(x, y) & \text{otherwise.} \end{cases} \quad (10.7)$$

Then  $T$  is a continuous t-norm. In this case  $T$  is called the *ordinal sum* of  $\{([\alpha_m, \beta_m], T_m)\}_{m \in M}$  and each  $T_m$  is called a *summand*.

Similar construction works for t-conorms  $S$ . Just replace  $T_m$  with a continuous Archimedean t-conorm  $S_m$ , and min with max in (10.7). Thus defined  $S$  is a continuous t-conorm, called the *ordinal sum* of  $\{([\alpha_m, \beta_m], S_m)\}_{m \in M}$ , where each  $S_m$  is called a *summand*.

Assume now that  $T$  is a continuous t-norm. Then,  $T$  is either the minimum, or  $T$  is Archimedean, or there exist a family  $\{([\alpha_m, \beta_m], T_m)\}_{m \in M}$  with continuous Archimedean summands  $T_m$  such that  $T$  is equal to the ordinal sum of this family, see [10.19, 22]. It has also been proved there that a continuous t-conorm  $S$  is either the maximum, or Archimedean, or there exist a family  $\{([\alpha_m, \beta_m], S_m)\}_{m \in M}$  with continuous Archimedean summands  $S_m$  such that  $S$  is the ordinal sum of this family.

### Parametric Families of Triangular Norms

We close this subsection by giving taste of the wide variety of parametric t-norm families. For a comprehensive list with detailed properties please look in [10.10].

**Frank t-norms**  $\{T_\lambda^F\}_{\lambda \in [0, \infty]}$ . Let  $\lambda > 0, \lambda \neq 1$  be a real number. Define a continuous Archimedean t-norm  $T_\lambda^F$  in the following way

$$T_\lambda^F(x, y) = \log_\lambda \left( 1 + \frac{(\lambda^x - 1)(\lambda^y - 1)}{\lambda - 1} \right) \times (x, y \in [0, 1]).$$

We can extend this definition for  $\lambda = 0, \lambda = 1$  and  $\lambda = \infty$  by taking the appropriate limits. Thus we get  $T_0^F$ ,  $T_1^F$  and  $T_\infty^F$  as follows

$$\begin{aligned} T_0^F(x, y) &= \lim_{\lambda \rightarrow 0} T_\lambda^F(x, y) = \min\{x, y\}, \\ T_1^F(x, y) &= \lim_{\lambda \rightarrow 1} T_\lambda^F(x, y) = xy, \\ T_\infty^F(x, y) &= \lim_{\lambda \rightarrow \infty} T_\lambda^F(x, y) = \max\{x + y - 1, 0\}. \end{aligned}$$

Each  $T_\lambda^F$  is a strict t-norm for  $\lambda \in ]0, \infty[$ . The corresponding additive generators  $t_\lambda^F$  are given by

$$t_\lambda^F(x) = \begin{cases} -\log x & \text{if } \lambda = 1 \\ -\log \frac{\lambda^x - 1}{\lambda - 1} & \text{if } \lambda \in ]0, \infty[, \lambda \neq 1 \end{cases}.$$

The family  $\{T_\lambda^F\}_{\lambda \in [0, \infty]}$  is called the *Frank family* of t-norms (see Frank [10.30]). Note that members of this family are decreasing functions of the parameter  $\lambda$  (see e.g. [10.31]).

The De Morgan law enables us to define the Frank family of t-conorms  $\{S_\lambda^F\}_{\lambda \in [0, \infty]}$  by

$$S_\lambda^F(x, y) = 1 - T_\lambda^F(1-x, 1-y)$$

for any  $\lambda \in [0, \infty]$ .

In [10.30] one can find the following interesting characterization of these parametric families.

### Theorem 10.6

A t-norm  $T$  and a t-conorm  $S$  satisfy the functional equation

$$T(x, y) + S(x, y) = x + y \quad (x, y \in [0, 1]) \quad (10.8)$$

if and only if

- there is a number  $\lambda \in [0, \infty]$  such that  $T = T_\lambda^F$  and  $S = S_\lambda^F$ , or
- $T$  is representable as an ordinal sum of t-norms, each of which is a member of the family  $\{T_\lambda^F\}$ ,  $0 < \lambda \leq \infty$ , and  $S$  is obtained from  $T$  via (10.8). [10.30]

**Hamacher t-norms**  $\{T_\lambda^H\}_{\lambda \in [0, \infty]}$ . Let us define three parameterized families of t-norms, t-conorms and strong negations, respectively, as follows.

$$\begin{aligned} T_\lambda^H(x, y) &= \frac{xy}{\lambda + (1-\lambda)(x+y-xy)}, \quad \lambda \geq 0, \\ S_\beta^F(x, y) &= \frac{x+y+(\beta-1)xy}{1+\beta xy}, \quad \beta \geq -1, \\ N_\gamma(x) &= \frac{1-x}{1+\gamma x}, \quad \gamma > -1. \end{aligned}$$

Hamacher proved the following characterization theorem [10.32].

### Theorem 10.7

$(T, S, N)$  is a De Morgan triplet such that

$$\begin{aligned} T(x, y) = T(x, z) &\implies y = z, \\ S(x, y) = S(x, z) &\implies y = z, \\ \forall z \leq x \quad \exists y, y' \text{ such that } T(x, y) = z, \\ S(z, y') &= x \end{aligned}$$

and  $T$  and  $S$  are rational functions if and only if there are numbers  $\lambda \geq 0$ ,  $\beta \geq -1$  and  $\gamma > -1$  such that  $\lambda = \frac{1+\beta}{1+\gamma}$  and  $T = T_\lambda^H$ ,  $S = S_\beta^F$  and  $N = N_\gamma$ .

Remark that another characterization of the Hamacher family of t-norms with positive parameter has been obtained in [10.33] as solutions of a functional equation.

**Dombi t-norms**  $\{T_\lambda^D\}_{\lambda \in [0, \infty]}$ . The formula for this t-norm family is given by

$$T_\lambda^D(x, y) = \begin{cases} T_D(x, y) & \text{if } \lambda = 0 \\ T_M(x, y) & \text{if } \lambda = \infty \\ \frac{1}{1 + \left( \left( \frac{1-x}{x} \right)^\lambda + \left( \frac{1-y}{y} \right)^\lambda \right)^{\frac{1}{\lambda}}} & \text{if } \lambda \in ]0, \infty[ \end{cases}$$

Essential properties of these t-norms and other well-known families can be found in [10.31].

### 10.3.3 Fuzzy Implications

Turning to the interpretation of the implication  $\rightarrow$  in fuzzy logics, it becomes apparent that there are several logical formulae which, in the Boolean two-valued logic, are equivalent to the implication, but give rise to different interpretations when replacing  $\{0, 1\}$  by

the unit interval  $[0, 1]$ . As in the case of the negation, we call an interpretation of the implication  $\rightarrow$  also an implication (or sometimes, a fuzzy implication). A comprehensive study of fuzzy implications can be found in the book [10.34].

In a very broad sense, any function  $I : [0, 1]^2 \rightarrow [0, 1]$  which is decreasing/increasing and preserves the values of the crisp implication on  $\{0, 1\}$  is considered as a fuzzy implication.

### Definition 10.6

A function  $I : [0, 1]^2 \rightarrow [0, 1]$  is called a *fuzzy implication* if and only if it satisfies the following conditions:

- I1.  $I(0, 0) = I(0, 1) = I(1, 1) = 1; I(1, 0) = 0.$
- I2. If  $x \leq z$  then  $I(x, y) \geq I(z, y)$  for all  $y \in [0, 1]$ .
- I3. If  $y \leq t$  then  $I(x, y) \leq I(x, t)$  for all  $x \in [0, 1]$ .

The reason behind I1 is obvious, while a fuzzy implication is required to be decreasing/increasing (i. e., I2 and I3 should be satisfied) because it measures that the consequent is more true than the antecedent [10.35].

Clearly, a fuzzy implication  $I$  has the following properties (as a consequence of the definition):

- I4.  $I(0, x) = 1$  for all  $x \in [0, 1]$ .
- I5.  $I(x, 1) = 1$  for all  $x \in [0, 1]$ .

Note that originally we defined a fuzzy implication in a slightly different form [10.29, Definition 1.15], which is equivalent to Definition 10.6.

Further properties may be required for a fuzzy implication that can be important also in some applications:

- I6.  $I(1, x) = x$  for all  $x \in [0, 1]$ . [10.36]
- I7.  $I(x, I(y, z)) = I(y, I(x, z))$  for all  $x, y, z \in [0, 1]$ . [10.36]
- I8.  $x \leq y$  if and only if  $I(x, y) = 1$  for all  $x, y \in [0, 1]$ . [10.37]
- I9.  $N(x) = I(x, 0)$  is a strong negation ( $x \in [0, 1]$ ).
- I10.  $I(x, y) \geq y$  for all  $x, y \in [0, 1]$ . [10.38]
- I11.  $I(x, x) = 1$  for all  $x \in [0, 1]$ . [10.39]
- I12.  $I(x, y) = I(N(y), N(x))$  with a strong negation  $N$ , for all  $x, y \in [0, 1]$ .
- I13.  $I$  is a continuous function.

Property I6 yields that tautology cannot justify anything. Condition I7 is called the exchange principle, and is based on the following equivalence:

$$\text{if } P_1 \text{ then } (\text{if } P_2 \text{ then } P_3) \iff \text{if } (P_1 \text{ AND } P_2) \text{ then } P_3 .$$

I8 expresses that implication defines an ordering, I9 reflects that  $P \rightarrow Q = \neg P$  if  $Q$  is false. I10 is the numerical counterpart of  $P \rightarrow (Q \rightarrow P)$ . I11 is called the identity principle and it yields that  $P \rightarrow P$  is always true. I12, the contraposition law (or in other words, the contrapositive symmetry), expresses a relationship between modus ponens and modus tollens, see [10.35]. In general, this is a strong condition, see [10.17]. I13 prevents implication from reacting in a chaotic way to a small change of the truth value of either the antecedent or the consequent. This is also a fairly restrictive condition.

### Fuzzy Implications Defined by t-Norms, t-Conorms and Negations

To be consistent, implications and conjunctions (or implications and disjunctions) cannot be studied independently. Thus, we introduce two particular classes of fuzzy implications based on t-norms, t-conorms and negations. These were identified in [10.36, 40–44].

For a left-continuous t-norm  $T$ , its  $T$ -residuum [10.10]  $I_T$  generalizes the Boolean implication, we prefer the name *R-implication* for  $I_T$  (see the next definition and the Remark after that).

Another way to introduce an implication (called *S-implication*) which is an extension of the Boolean implication is to exploit the fact that, in a two-valued logic, the formulae  $p \rightarrow q$  and  $\neg p \vee q$  are equivalent.

#### Definition 10.7

Suppose  $(T, S, N)$  is a De Morgan triplet.

An *R-implication*  $I_T$  associated with the t-norm  $T$  is defined by

$$I_T(x, y) = \sup\{z | T(x, z) \leq y\} \quad (x, y \in [0, 1]). \quad (10.9)$$

An *S-implication*  $I_{S,N}$  associated with the t-conorm  $S$  and the strong negation  $N$  is defined by

$$I_{S,N}(x, y) = S(N(x), y) \quad (x, y \in [0, 1]). \quad (10.10)$$

It is easy to see that both  $I_T$  and  $I_{S,N}$  satisfy properties I1–I3 for any t-norm  $T$ , t-conorm  $S$  and strong negation  $N$ , thus they are fuzzy implications. Note that if  $T$  is a continuous Archimedean t-norm with additive generator  $t$  then

$$I_T(x, y) = t^{-1}(\max\{t(y) - t(x), 0\}) \quad (x, y \in [0, 1]).$$

Let us emphasize an important link between R-implications defined by left-continuous t-norms, and residuums in lattice-ordered monoids.

Assume that  $L$  is a non-empty set,  $(L, \preceq)$  is a lattice and  $(L, *)$  is a semigroup with neutral element. We introduce some definitions, for more details see [10.45].

- i) The triplet  $(L, *, \preceq)$  is called a *lattice-ordered monoid* (or an *l-monoid*) if for all  $x, y, z \in L$  we have:
  - LM1)  $x * (y \vee z) = (x * y) \vee (x * z)$ ,
  - LM2)  $(x \vee y) * z = (x * z) \vee (y * z)$ .
- ii) An l-monoid  $(L, *, \preceq)$  is said to be *commutative* if the semigroup  $(L, *)$  is commutative.
- iii) A commutative l-monoid  $(L, *, \preceq)$  is called a *commutative, residuated l-monoid* if there exists a further binary operation  $\rightarrow *$  on  $L$ , i.e., a function  $\rightarrow * : L^2 \rightarrow L$  (the  $*$ -residuum), such that for all  $x, y, z \in L$  we have (R)  $x * y \preceq z$  if and only if  $x \preceq y \rightarrow * z$ .
- iv) An l-monoid  $(L, *, \preceq)$  is called *integral* if there is a greatest element in the lattice  $(L, \preceq)$  (often called the universal upper bound) which coincides with the neutral element of the semigroup  $(L, *)$ .

It is evident that  $([0, 1], T, \leq)$  is a commutative integral l-monoid if and only if the function  $T : [0, 1]^2 \rightarrow [0, 1]$  is a t-norm. It turns out that the left-continuity of a t-norm can be characterized by the fact that the corresponding l-monoid is residuated. In this case the  $T$ -residuum  $I_T$  is given by (10.9), see [10.10]. Because of its interpretation in  $[0, 1]$ -valued logics, the  $T$ -residuum is also called a *residual implication* (or briefly, an *R-implication*).

Given a left-continuous t-norm  $T$ , the R-implication  $I_T$  is left-continuous in its first and right-continuous in its second argument, and it is continuous if and only if the underlying t-norm is nilpotent [10.29, 46].

For the sake of completeness we mention a third type of connectives used in quantum logic and called *QL-implication* defined as follows

$$I_{T,S,N}(x, y) = S(N(x), T(x, y)) \quad (x, y \in [0, 1]). \quad (10.11)$$

For the idea behind QL-implications, see [10.47]. In general,  $I_T, S, N$  violates property I2, so it is not a fuzzy implication in the sense of Definition 10.6. Conditions under that I2 is satisfied can be found in [10.17].

### Negations Defined by Implications

As we have seen, several types of negations can be introduced in fuzzy logic. The link between fuzzy implications and negations can be expressed by requiring that the function  $N$  defined by

$$N(x) = I(x, 0) \quad \text{for all } x \in [0, 1],$$

be a negation, where  $I$  is a fuzzy implication. This is motivated by the corresponding classical rule.

Suppose that  $I : [0, 1]^2 \rightarrow [0, 1]$  is a function satisfying I3, I7, I8 and define  $N(x) = I(x, 0)$  ( $x \in [0, 1]$ ). Then (a)  $N$  is a negation; (b)  $x \leq N(N(x))$  for all  $x \in [0, 1]$ ;

(c)  $N(N(N(x))) = N(x)$  for all  $x \in [0, 1]$ . If, in addition,  $N$  is continuous then it is involutive [10.29]. Thus, under the above conditions,  $N$  cannot be a noninvolutive strict negation: it is either discontinuous or a strong negation. If  $N$  is continuous then  $I$  fulfils I12 with this  $N$ .

For a positive t-norm  $T$  (like min or the algebraic product), the negation obtained via its R-implication is not continuous at all. In fact, in this case we have that

$$I_T(x, 0) = \begin{cases} 1 & \text{if } x = 0 \\ 0 & \text{if } x > 0 \end{cases} \quad (x \in [0, 1]).$$

## 10.4 Concluding Remarks

The study of fuzzy implications, triangular norms and their extensions is a never ending story. During such research, fundamental new properties and classes have been discovered, essential results have been proved and applied to diverse problem classes. These are beyond the goal of the present chapter. Nevertheless, we name just a few directions.

Firstly, we mention *uninorms* [10.48, 49], a joint extension of both t-norms and t-conorms, with neutral element being an arbitrary number between 0 and 1. Their study includes the Frank functional equation [10.50], their residual operators [10.51], different extensions [10.52, 53], characterizing their mathematical properties [10.54] and important subclasses such as idempotent [10.55] and representable uninorms

[10.56]. It turns out that some special uninorms have already been hidden, without using the name uninorm, in the classical expert system MYCIN [10.57].

Secondly, some recent papers on fuzzy implications are briefly listed, in which the interested reader can find further references. After the book [10.34] was published, several important contributions have been made by the authors themselves, like [10.58]. Some *algebraic properties* of fuzzy implications such as distributivity [10.59] and contrapositive symmetry [10.60], the law of importation or the exchange principle [10.61], typically in the form of functional equations, have also been studied intensively. New construction methods have also been introduced and deeply studied [10.62–65].

# 11. Fuzzy Relations: Past, Present, and Future

# Fuzzy Relations

Susana Montes, Ignacio Montes, Tania Iglesias

Part B | 11

Relations are used in many branches of mathematics to model concepts like *is lower than*, *is equal to*, etc. Initially, only crisp relations were considered, but in the last years, fuzzy relations have been revealed as a very useful tool in psychology, engineering, medicine, economics or any mathematically based field. A first approach to the concept of fuzzy relations is given in this chapter. Thus, operations among fuzzy relations are defined in general. When considering the particular case of fuzzy binary relations, their main properties are studied. Also, some particular cases of fuzzy binary relations are considered and related among them. Of course, this chapter is just a starting point to study in detail more specialized literature.

The notion of relation plays a central role in various fields of mathematics. As a consequence of that, it is a very important concept in all engineering, science, and mathematically based fields.

Crisp or classical relations show a problem; they do not allow to express partial levels of relationship among two elements. This is a problem in many practical situations since not always an element is *clearly* related to another one. The valued theory arises with the aim of allowing to assign degrees to the relations between alternatives. As it is well known, according to fuzzy set theory [11.1], the connection established among two alternatives admits different degrees of intensity and that intensity is represented by a value in the interval  $[0, 1]$ . The idea of working with values different from 0 and 1 to express the relationship between two elements was already considered by Łukasiewicz in the 1920s

when he introduced his three-valued logic, and later by Luce [11.2] or Menger [11.3], but it was Zadeh [11.4] who formally defined the concept of a fuzzy (or multi-valued) relation.

In the history of fuzzy mathematics, fuzzy relations were early considered to be useful in various applications: fuzzy modeling, fuzzy diagnosis, and fuzzy control. They also have applications in fields such as psychology, medicine, economics, and sociology. For this reason, they have been extensively investigated. For a contemporary general approach to fuzzy relations one should look at Bělohlávek's book [11.5], and also to other general publications, as for instance the books by Klir and Yuan [11.6] and Turunen [11.7].

Since this chapter is entirely devoted to fuzzy relations, our aim is to give a detailed introduction to them for a nonexpert reader.

## 11.1 Fuzzy Relations

Assume that  $X$  and  $Y$  are two given sets. A *fuzzy relation*  $R$  is a mapping from the Cartesian product  $X \times Y$  to the interval  $[0, 1]$ . Therefore,  $R$  is basically a fuzzy set in the universe  $X \times Y$ . This means that, for any  $x \in X$  and any  $y \in Y$ , the value  $R(x, y)$  measures the strength with which  $R$  connects  $x$  with  $y$ . If  $R(x, y)$  is close to 1,  $x$  is related to  $y$  by  $R$ . If  $R(x, y)$  is a value close to 0, then it hardly connects  $x$  with  $y$  and so on.

This definition can be extended to the Cartesian products of more than two sets and then they are called *n-ary fuzzy relations*. Note that fuzzy sets may be viewed as degenerate, 1-ary fuzzy relations.

### Example 11.1

If we consider the case  $X = Y = [0, 3]$ , we could define the fuzzy relation *approximately equal to* as follows

$$R(x, y) = e^{-|x-y|}, \quad \forall (x, y) \in [0, 3] \times [0, 3]$$

which is represented in Fig. 11.1.

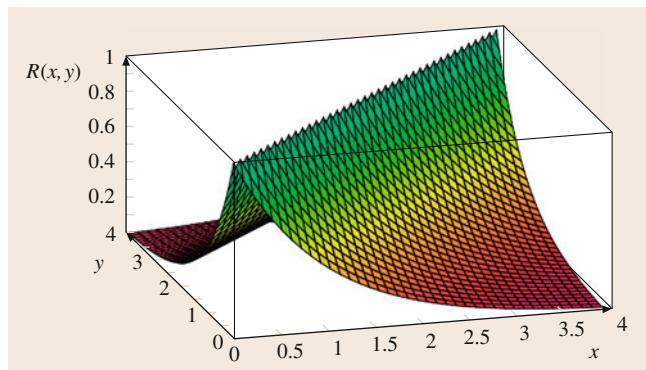

The *domain* of a fuzzy relation  $R$  is a fuzzy set on  $X$ , whose membership function is given by

$$\text{dom } R(x) = \sup_{y \in Y} R(x, y)$$

and the *range* is given by

$$\text{ran } R(x) = \sup_{x \in X} R(x, y).$$

When  $X$  and  $Y$  are finite sets, we can consider a matrix representation for any fuzzy relation. The entry on the line  $x$  and column  $y$  of the associated matrix is the value  $R(x, y)$ .

### Example 11.2

Let us consider the set  $X$  formed by three papers,  $X = \{p_1, p_2, p_3\}$ , and let  $Y$  be a set formed by five different topics  $Y = \{t_1, t_2, t_3, t_4, t_5\}$ . The fuzzy relation  $R$  measuring the degree of relationship of any paper with any topic is defined by

$R$	$t_1$	$t_2$	$t_3$	$t_4$	$t_5$
$p_1$	1.0	0.7	0.9	0.4	0.2
$p_2$	0.5	0.8	1.0	0.3	0.9
$p_3$	0.7	0.5	0.8	0.3	0.8

and its domain is given by the fuzzy subset of  $X$

$$\text{dom } R = \{(p_1, 1), (p_2, 1), (p_3, 0.8)\},$$

and its range by

$$\text{ran } R = \{(t_1, 1), (t_2, 0.8), (t_3, 1), (t_4, 0.4), (t_5, 0.9)\}.$$

### 11.1.1 Operations on Fuzzy Relations

All concepts and operations applicable to fuzzy sets are applicable to fuzzy relations as well. Thus, for any fuzzy relations  $R$  and  $Q$  on the Cartesian product  $X \times Y$ , we have

- Given a *t-norm*  $T$  (for a complete study about *t-norms* and *t-conorms*, we refer to [11.8]), the *T-intersection* (or just intersection if there is no ambiguity) of  $R$  and  $Q$  is the fuzzy relation on  $X \times Y$  defined by

$$R \cap_T Q(x, y) = T(R(x, y), Q(x, y)), \\ \forall (x, y) \in X \times Y.$$

**Fig. 11.1** Membership function of the fuzzy relation *(approximately equal to)* introduced in Example 11.1

Initially,  $T$  was considered to be the minimum operator.

- Given a  $t$ -conorm  $S$ , the  $S$ -union of  $R$  and  $Q$  is the fuzzy relation on  $X \times Y$  defined by

$$\begin{aligned} R \cup_S Q(x, y) &= S(R(x, y), Q(x, y)), \\ &\forall (x, y) \in X \times Y. \end{aligned}$$

At the initial proposal, the maximum  $t$ -conorm was considered.

- The transpose or inverse of the fuzzy relation  $R$ , denoted as in the classical case by  $R^{-1}$ , is the fuzzy relation that satisfies

$$R^{-1}(x, y) = R(y, x), \quad \forall (x, y) \in X \times Y.$$

- The complement of a fuzzy relation is not unique. It depends on the negator  $n$  we choose. The  $n$ -complement of the fuzzy relation  $R$ , denoted by  $R^c$ , is the fuzzy relation defined by

$$R^c(x, y) = n(R(x, y)), \quad \forall (x, y) \in X \times Y.$$

Although the definition is given for any negator, the most widely used one is the standard negator ( $n(x) = 1 - x$ ). In this case, it is called the *standard complement* and is defined by  $R^c(x, y) = 1 - R(x, y)$ .

- The dual of the fuzzy relation  $R$  is defined and denoted as in the classical case. The fuzzy relation  $R^d$  is the complement of the transpose of  $R$

$$R^d(x, y) = n(R(y, x)), \quad \forall (x, y) \in X \times Y.$$

That is,  $R^d = (R^{-1})^c$ .

- We say that  $R$  is contained in  $Q$ , and we denote it by  $R \subseteq Q$ , if and only if for all  $(x, y) \in X \times Y$  the inequality  $R(x, y) \leq Q(x, y)$  holds.
- $R$  and  $Q$  are said to be equal if and only if for all  $(x, y) \in X \times Y$  we have the inequality  $R(x, y) = Q(x, y)$ , that is,  $R \subseteq Q$  and  $Q \subseteq R$ .

## 11.1.2 Specific Operations on Fuzzy Relations

In the previous items, we are only considering that fuzzy relations can be seen as fuzzy sets on  $X \times Y$  and we have adapted the corresponding definitions. However, fuzzy relations involve additional concepts and operations. The most important are: compositions, projections and cylindrical extensions, among others.

- Let  $R$  and  $Q$  two fuzzy relations on  $X \times Y$  and  $Y \times Z$ , respectively. The  $T$ -composition of  $R$  and  $Q$  is the

fuzzy relation defined by

$$\begin{aligned} R \circ_T Q(x, z) &= \sup_{y \in Y} T(R(x, y), Q(y, z)), \\ &\forall (x, z) \in X \times Z. \end{aligned}$$

Due to associativity and nondecreasingness of the  $t$ -norms, the following result can be easily proven.

### Proposition 11.1

Let  $R$ ,  $Q$ , and  $P$  be the three fuzzy relations on  $X \times Y$ ,  $Y \times Z$ ,  $Z \times U$ , respectively. Then:

- $R \circ_T (Q \circ_T P) = (R \circ_T Q) \circ_T P$ ,
- If  $R'$  is another fuzzy relation on  $X \times Y$  such that  $R \subseteq R'$ , then  $R \circ_T Q \subseteq R' \circ_T Q$ .

- Let  $R$  be a fuzzy relation on  $X \times Y$ . We can project  $R$  with respect  $X$  and  $Y$  as follows:

$$R_X(x) = \sup_{y \in Y} R(x, y), \quad \forall x \in X, \text{ and}$$

$$R_Y(y) = \sup_{x \in X} R(x, y), \quad \forall y \in Y$$

where  $R_X$  and  $R_Y$  denote the projected relation of  $R$  to  $X$  and  $Y$ , respectively.

It is clear that the projection to  $X$  coincides with the domain of  $R$  and the projection to  $Y$  with the range. The definition given for 2-ary fuzzy relations can be generalized to  $n$ -ary relations. Thus, if  $R$  is a fuzzy relation on  $X_1 \times X_2 \times \dots \times X_n$ , the projected relation of  $R$  to the subspace  $X_{i_1} \times X_{i_2} \times \dots \times X_{i_k}$  is defined by

$$\begin{aligned} R_{X_{i_1} \times X_{i_2} \times \dots \times X_{i_k}}(x_{i_1}, x_{i_2}, \dots, x_{i_k}) \\ = \sup_{x_{j_1}, x_{j_2}, \dots, x_{j_m}} R(x_1, x_2, \dots, x_n), \end{aligned}$$

where  $X_{j_1}, X_{j_2}, \dots, X_{j_m}$  represent the omitted dimensions and  $X_{i_1}, X_{i_2}, \dots, X_{i_k}$  the remained ones. That is

$$\{i_1, i_2, \dots, i_k\} \cup \{j_1, j_2, \dots, j_m\} = \{1, 2, \dots, n\}$$

and

$$\{i_1, i_2, \dots, i_k\} \cap \{j_1, j_2, \dots, j_m\} = \emptyset.$$

- Another operation on relations, which is in some sense an inverse to the projection, is called a cylindrical extension. If  $A$  is a fuzzy subset of  $X$ , then its cylindrical extension to  $Y$  is the fuzzy relation defined by

$$\text{cyl } A(x, y) = A(x), \quad \forall (x, y) \in X \times Y.$$

## 11.2 Cut Relations

Any fuzzy relation  $R$  has an associated family of crisp relations  $\{R_\alpha | \alpha \in [0, 1]\}$ , called cut relations, which are defined by

$$R_\alpha = \{(x, y) \in X \times Y | R(x, y) \geq \alpha\}.$$

It is clear that they are just the  $\alpha$ -cuts of  $R$ , considered as a fuzzy set. Thus, it is immediate that they form a chain (nested family) of relations, that is,

$$\emptyset \subseteq R_{\alpha_m} \subseteq R_{\alpha_{m-1}} \subseteq \cdots \subseteq R_{\alpha_1} \subseteq X \times Y$$

if  $0 \leq \alpha_1 \leq \dots \alpha_{m-1} \leq \alpha_m \leq 1$ .

Moreover, it is possible to represent a fuzzy relation by means of its cuts relations, since

$$R(x, y) = \sup_{\alpha \in [0, 1]} \min(\alpha, R(x, y)),$$

$$\forall (x, y) \in X \times Y,$$

which is denoted by

$$R = \sup_{\alpha \in [0, 1]} \alpha R_\alpha.$$

## 11.3 Fuzzy Binary Relations

In the particular case  $X = Y$ , fuzzy relations are called *fuzzy binary relations* or *valued binary relations* and they have specific and interesting properties. A detailed proof of the results presented here can be found in [11.9].

The first specific characteristic of fuzzy binary relations is that, apart from the matrix representation, they admit a graph representation if  $X$  is finite. In this *directed graph*,  $X$  is the set of nodes (vertices) and  $R$  is the set of arcs (edges). The arc from  $x$  to  $y$  exists if and only if  $x$  and  $y$  are related in some sense ( $R(x, y) > 0$ ). A number on each arc represents the membership degree of this elements to  $R$ .

### Example 11.3

If we consider  $X = \{x, y, z, t\}$ , the fuzzy binary relation

$R$	$x$	$y$	$z$	$t$
$x$	1.0	0.4	0.2	0.0
$y$	0.6	0.9	0.0	0.0
$z$	0.0	0.0	0.0	0.0
$t$	0.0	0.0	0.8	0.0

can also be represented by the graph in Fig. 11.2.

In the following, we will list some basic properties of fuzzy binary relations. Usually, these properties are translations of the equivalent for the particular case of (crisp) binary relations.

### 11.3.1 Reflexivity

The most used definition of reflexivity for fuzzy binary relations was given by Zadeh in 1971 [11.4]. Thus,

a fuzzy binary relation  $R$  on  $X$  is said to be *reflexive* iff

$$R(x, x) = 1, \quad \forall x \in X.$$

This means that every vertex in the graph originates a simple loop.

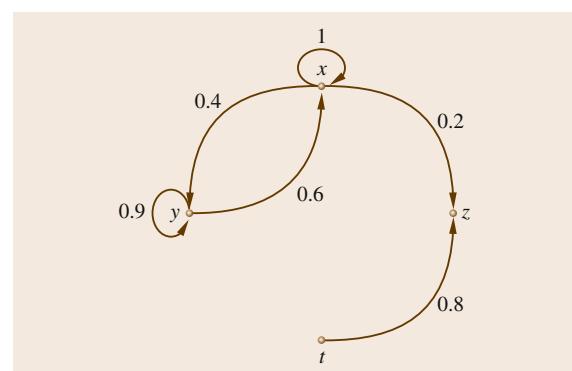

Other less restrictive definitions have also been considered in the literature. Thus, we say that  $R$  is  $\epsilon$ -reflexive [11.10], with  $\epsilon \in (0, 1]$ , iff

$$R(x, x) \geq \epsilon, \quad \forall x \in X$$

and *weakly reflexive* [11.10] iff

$$R(x, x) \geq R(x, y), \quad \forall x, y \in X.$$

Of course, in the particular case of crisp binary relations, all of them are the usual definition of reflexivity. Moreover, if  $R$  is reflexive, it is  $\epsilon$ -reflexive for any

**Fig. 11.2** Directed graph associated to a fuzzy binary relation

$\epsilon \in (0, 1]$  and weakly reflexive. The remaining implications are not true in general.

A cutworthy study of this property is given in the following proposition.

### Proposition 11.2

Let  $R$  be a fuzzy binary relation on  $X$ . If  $R$  is reflexive, then its associated cut relations  $R_\alpha$ , with  $\alpha \in (0, 1]$ , are reflexive.

The cutworthy property is not fulfilled, in general, by  $\epsilon$ -reflexive or weakly reflexive fuzzy binary relations.

### 11.3.2 Irreflexivity

A fuzzy binary relation that is *irreflexive*, or *antireflexive*, is a fuzzy binary relation where no element is related in any degree to itself. Formally

$$R(x, x) = 0, \quad \forall x \in X.$$

This means that there is not any vertex in the graph originating a simple loop.

Analogous to the case of reflexivity, we can consider some generalizations of this concept:

- $\epsilon$ -Irreflexive, with  $\epsilon \in [0, 1)$ :  $R(x, x) \leq \epsilon, \forall x \in X$
- Weakly irreflexive:  $R(x, x) \leq R(x, y), \forall x, y \in X$ .

The behavior of cut relations is similar to the previous case.

### Proposition 11.3

Let  $R$  be a fuzzy binary relation on  $X$ . If  $R$  is irreflexive, then its associated cut relations  $R_\alpha$ , with  $\alpha \in (0, 1]$ , are irreflexive.

Again this condition is not fulfilled for  $\epsilon$ -reflexivity or weak reflexivity.

### 11.3.3 Symmetry

For symmetry, there is not any change with the classical definition for crisp relations. Thus, a fuzzy binary relation  $R$  on  $X$  is said to be *symmetric* if

$$R(x, y) = R(y, x), \quad \forall x, y \in X.$$

This is equivalent to require that  $R$  and its inverse are equal

$$R = R^{-1}.$$

Of course, if  $R$  is symmetric, so are their associated cut relations for any  $\alpha \in (0, 1]$ .

### 11.3.4 Antisymmetry

In the crisp case, a binary relation  $R$  is antisymmetric iff  $xRy$  and  $yRx$  which implies that  $x = y$ . This is equivalent to require that  $x \neq y$  implies that  $(x, y) \notin R \cap R^{-1}$ . Thus, the intersection can be used in order to define antisymmetry. In the fuzzy case, the intersection will be defined, as usual, by means of a  $t$ -norm  $T$ . The definition will be directly related to the  $t$ -norm, and therefore the used  $t$ -norm should appear in the name of the property. Thus, a fuzzy binary relation  $R$  on  $X$  is said to be  $T$ -antisymmetric if

$$x \neq y \implies T(R(x, y), R(y, x)) = 0$$

or, equivalently

$$R \cap_T R^{-1}(x, y) = 0, \quad \forall x \neq y.$$

It is immediate that if  $T$  and  $T'$  are  $t$ -norms such that  $T' \leq T$ , then the  $T$ -antisymmetry of a fuzzy relation implies its  $T'$ -antisymmetry.

In 1971, Zadeh [11.4] proposed to use the minimum  $t$ -norm for this aim, and he called it *perfect antisymmetry* or just antisymmetry. In that case, its cut relations are antisymmetric, for any  $\alpha \in (0, 1]$ . This is also true for  $T$ -antisymmetry for a positive  $t$ -norm ( $x, y > 0 \Rightarrow T(x, y) > 0$ ), since in this case,  $T$ -antisymmetry and perfect antisymmetry are equivalent. However, the cutworthy property is not fulfilled, in general, for any other  $T$ -norm.

Clearly, perfect antisymmetry implies the  $T$ -antisymmetry for any  $t$ -norm  $T$ . However, perfect antisymmetry can be too restrictive in many cases, since it excludes relations where  $R(x, y)$  and  $R(y, x)$  are almost zero. If we consider  $t$ -norms with zero divisors, this problem is solved. In this way, the case when  $R(x, y)$  and  $R(y, x)$  are high is avoided, but the equality to zero is not required. For instance, if we consider the Łukasiewicz  $t$ -norm ( $T(x, y) = \max(x + y - 1, 0)$ ),  $T$ -antisymmetry is equivalent to require that

$$R(x, y) + R(y, x) \leq 1, \quad \forall x, y \in X \text{ such that } x \neq y.$$

### 11.3.5 Asymmetry

Asymmetry is a stronger condition, since it is not only required for pairs of elements  $(x, y)$  such that  $x \neq y$ , but

also for any pair of elements in  $X \times X$ . Thus, the  $T$ -asymmetry of a fuzzy binary relation  $R$  on  $X$  is defined by

$$T(R(x, y), R(y, x)) = 0, \quad \forall x, y \in X$$

or, equivalently,

$$R \cap_T R^{-1} = \emptyset.$$

Clearly,  $T$ -asymmetry implies  $T'$ -asymmetry if  $T' \leq T$  and then, classic asymmetry ( $T = \min$ ) implies  $T$ -asymmetry for any  $t$ -norm  $T$ . Usually it is called just asymmetry. In particular, asymmetry is equivalent to the  $T$ -asymmetry if  $T$  is positive. In that case, its associated cut relations are crisp asymmetric relations for any  $\alpha \in (0, 1]$ .

It is possible to relate asymmetry and irreflexivity as follows:

#### **Proposition 11.4**

Let  $R$  be a  $T$ -asymmetric fuzzy binary relation on  $X$ . The following statements hold:

- i)  $R$  is irreflexive if and only if  $T$  is a positive  $t$ -norm;
- ii)  $R$  is  $\epsilon$ -irreflexive for  $\epsilon < 1$  if and only if  $T$  has zero divisors and  $\epsilon$  belongs to the interval  $(0, \sup\{x \in [0, 1] | T(x, x) = 0\})$ .

### 11.3.6 Transitivity

The pairwise comparison of possible alternatives is a first step in many approaches to decision making. If this first step lacks coherence, the whole decision process might become meaningless. A popular criterion for coherence is the transitivity of the involved relations, expressing that the strength of the link between two alternatives cannot be weaker than the strength of any chain involving another alternative [11.11].

The usual definition of transitivity for fuzzy relations is related to a  $t$ -norm and it is a generalization of the proposal given by Zadeh in 1971 [11.4]. Thus, a fuzzy binary relation  $R$  on  $X$  is said to be  $T$ -transitive if

$$T(R(x, y), R(y, z)) \leq R(x, z)$$

for all  $x, y, z \in X$ .

As it happened for the concepts of  $T$ -asymmetry and  $T$ -antisymmetry,  $T$ -transitivity is not unique as it

happened for classical relations. When  $T$  is the minimum  $t$ -norm that definition can also be expressed as

$$R(x, z) \geq \max_{y \in X} (\min(R(x, y), R(y, z))), \quad \forall x, z \in X.$$

Then, it is sometimes called *max-min-transitivity*. This coincides with the initial definition proposed by Zadeh.

The  $T$ -transitivity is a natural way of extending the original definition by Zadeh, specially after  $t$ -norms and  $t$ -conorms began to be used in the 1970s by different authors to generalize the intersection and the union. However, many other types of transitivity were defined. From the least restrictive ones as the *minimal transitivity* [11.12] defined by

$$R(x, y) = 1 \text{ and } R(y, z) = 1 \implies R(x, z) = 1$$

or the *preference sensitive transitivity* [11.13], also called *quasitransitivity* [11.12], defined by

$$R(x, y) > 0 \quad \text{and} \quad R(y, z) > 0 \implies R(x, z) > 0.$$

The *weak and parametric transitivities* [11.14] defined, respectively, by

$$\begin{aligned} R(x, y) &> R(y, x) \text{ and } R(y, z) > R(z, y) \\ &\implies R(x, z) > R(z, x) \end{aligned}$$

and by

$$\begin{aligned} R(x, y) &> \theta > R(y, x) \text{ and } R(y, z) > \theta > R(z, y) \\ &\implies R(x, z) > \theta > R(z, x) \end{aligned}$$

where  $\theta$  is a fixed value in the interval  $[0, 1]$ .

Or the *weighted mean transitivity* [11.15] stating that the inequalities  $R(x, y) > 0$  and  $R(y, z) > 0$  require the existence of some  $\theta \in (0, 1)$  such that

$$\begin{aligned} R(x, z) &\geq \theta \cdot \max(R(x, y), R(y, z)) \\ &\quad + (1 - \theta) \cdot \min(R(x, y), R(y, z)) \end{aligned}$$

among others.

$T$ -norms offer a way of defining transitivity for fuzzy relations, but it is known that these operators are too restrictive in some cases. If we have a look at the properties an operator defining transitivity must satisfy, associativity is only necessary if we try to extend the definition to more than three elements. Concerning the commutativity and the boundary condition, a much weaker condition is sufficient to generalize the classical

definition: commutativity and boundary condition on  $\{0, 1\}^2$ . Thus, recent studies about transitivity for fuzzy binary relations are not restricted to  $t$ -norms, but a much more general definition of transitivity is considered, the one obtained by considering only the necessary conditions [11.16]. Thus, we consider a *conjunction*, that is an increasing binary operator  $f : [0, 1]^2 \rightarrow [0, 1]$  which coincides with the Boolean conjunction on  $\{0, 1\}^2$ . Recall that this definition preserves the concept of conjunction for classical relations. It is also clear that the notion of conjunction is much more general than the one of  $t$ -norm. Neither associativity nor commutativity are required. Note that conjunctions are even not required to have neutral element 1.

Given a conjunction  $f$ , we can define the  *$f$ -transitivity* of a fuzzy relation  $R$  in the same way as it is defined for  $t$ -norms

$$f(R(x, y), R(y, z)) \leq R(x, z), \quad \forall x, y, z \in X.$$

Since conjunctions are a much wider family of operators, this definition includes more types of transitivity than the definition given just for  $t$ -norms. It is trivial that if we restrict this definition to  $t$ -norms, we get the classical definition of  $T$ -transitivity.

The definition for conjunctions is a too general notion in a particular case: if we consider a reflexive relation  $Rf$ -transitive, where  $f$  is a conjunction, that conjunction must be bounded by the minimum. That is, only conjunctions smaller than or equal to minimum can define the transitivity of reflexive fuzzy relations.

### 11.3.7 Negative Transitivity

Another important property is negative transitivity, which is a dual property of transitivity. Thus, given a  $t$ -conorm  $S$ , a fuzzy binary relation  $R$  on  $X$  is said to be *negatively  $S$ -transitive* if

$$R(x, z) \leq S(R(x, y), R(y, z))$$

for all  $x, y, z \in X$ .

If  $T$  is a  $t$ -norm and  $S$  is its dual  $t$ -conorm,  $R$  is  $T$ -transitive if and only if its dual  $R^d$  is negatively  $S$ -transitive.

Clearly, if  $R$  is negatively  $S$ -transitive, then it is negatively  $S'$ -transitive for any other  $t$ -conorm  $S'$  such that  $S \leq S'$ . In particular, the negative transitivity of the maximum implies the negatively  $S$ -transitivity for any  $t$ -conorm  $S$ .

### 11.3.8 Semitransitivity

In the classical case, a crisp relation  $R$  is semitransitive if  $xRy$  and  $yRz$  implies that there exists  $t \in X$  such that  $xRt$  or  $tRz$ .

If we consider  $t$ -norms and  $t$ -conorms to generalize AND and OR, respectively, we obtain that a fuzzy binary relation  $R$  on  $X$  is  *$T$ - $S$ -semitransitive* if

$$T(R(x, y), R(y, z)) \leq S(R(x, t), R(t, z))$$

for every  $x, y, z, t \in X$ .

It is clear that  $T$ - $S$ -semitransitivity implies  $T'$ - $S'$ -semitransitivity of any  $t$ -norm  $T'$  such that  $T' \leq T$  and any  $t$ -conorm  $S'$  such that  $S \leq S'$ . Thus, the classical semitransitivity with the minimum  $t$ -norm and the maximum  $t$ -conorm implies the  $T$ - $S$ -transitivity for any  $t$ -norm  $T$  and any  $t$ -conorm  $S$ .

As a consequence of the definition, for any  $T$ - $S$ -semitransitive fuzzy relation  $R$  we have that:

- If  $R$  is reflexive, then it is negatively  $S$ -transitive
- If  $R$  is irreflexive, then it is  $T$ -transitive.

Moreover, we can easily prove the following propositions [11.9].

#### Proposition 11.5

If  $R$  is  $T$ -transitive and negatively  $S$ -transitive, then  $R$  is  $T$ - $S$ -semitransitive.

#### Proposition 11.6

Suppose that  $T$  is a continuous  $t$ -norm in the De Morgan triple  $(T, S, n)$ . If  $R$  is  $T$ -asymmetric and negatively  $S$ -transitive then  $R$  is  $T$ - $S$ -semitransitive.

### 11.3.9 Completeness

In the crisp set theory, the concept of completeness is clear, the relation  $R$  defined on  $X$  is complete if every two elements are related by  $R$ , that is, if at least  $xRy$  or  $yRx$  for any pair of values  $x$  different from  $y$  in  $X$ . And it is still equivalent, for reflexive relations, to the concept of strong completeness ( $xRy$  or  $yRx$ ,  $\forall x, y \in X$ ). It is logical that in the setting of classical relations, the completeness is equivalent to the absence of incomparability. There is no pair of elements that cannot be compared since they are related at least by  $R$  or  $R^{-1}$ .

When we try to generalize this concept to fuzzy relations, the problem arises when trying to fuzzify the

notion *related at least by R or  $R^{-1}$* . In the classical case, it is clear that  $x$  and  $y$  are related by  $R$  if and only if  $R(x, y) = 1$  or  $R(y, x) = 1$ . This could be a first way to define the concept of completeness for fuzzy relations.

Thus, a fuzzy binary relation  $R$  defined on  $X$  is *strongly complete* if

$$\max(R(x, y), R(y, x)) = 1, \quad \forall x, y \in X.$$

Perny and Roy [11.17] call it just complete.

But this condition could be considered too restrictive for fuzzy relations. Consider, for example, the case in which both  $R(x, y) = 0.95$  and  $R(y, x) = 0.95$ . By the definition given above (strong completeness),  $R$  is not complete but it is clear that  $x$  and  $y$  are related by  $R$ . Taking into account this type of situations, other less restrictive completeness conditions were proposed.

Among the most employed in the literature, we find the one known as weak completeness. A fuzzy relation  $R$  defined on  $X$  is *weakly complete* if

$$R(x, y) + R(y, x) \geq 1, \quad \forall x, y \in X.$$

This condition is called *connectedness* in [11.13, 18] while in other works [11.14] this name makes reference to the strong completeness.

It is clear that this definition is much less restrictive than the one called strong completeness. Strongly complete relations are a particular type of weakly complete relations.

If we take a careful look at these two definitions, we can express them by means of a  $t$ -conorm. On the one hand, we can quickly identify the maximum  $t$ -conorm as the operator that relates  $R$  and its transpose in the first definition. On the other hand, since  $R(x, y) + R(y, x) \geq 1$  is equivalent to  $\min(R(x, y) + R(y, x), 1) = 1$ , then the weakly completeness relates  $R$  and  $R^{-1}$  by means of the Łukasiewicz  $t$ -conorm.

These two conditions are special cases of what is called  $S$ -completeness. A fuzzy relation  $R$  defined on  $X$  is called  *$S$ -complete* [11.19], where  $S$  is a  $t$ -conorm, if

$$S(R(x, y), R(y, x)) = 1, \quad \forall x, y \in X.$$

It is immediate that this is equivalent to require that

$$R \cup_S R^{-1} = X \times X.$$

Remark that the previous definition corresponds, according to [11.19], to *strong  $S$ -completeness*, while the concept of  $S$ -completeness only requires the equality

$S(R(x, y), R(y, x)) = 1$  for pairs of different elements,  $x \neq y$ .

A direct consequence of the definition is that for any two  $t$ -conorms  $S$  and  $S'$ , such that  $S \leq S'$ ,  $S$ -completeness (respectively, strong  $S$ -completeness) implies  $S'$ -completeness (respectively, strong  $S'$ -completeness). It is easy to check that strong completeness can be identified not only with the  $S$ -completeness defined by the maximum  $t$ -conorm, but also with any  $t$ -conorm of which the dual  $t$ -norm has no zero divisors. The  $S$ -completeness of a fuzzy relation  $R$  is equivalent to the  $T$ -antisymmetry of its dual  $R^d$  [11.19], where  $T$  is the dual  $t$ -norm of  $S$  by means of a strong negation  $n$ .

The behavior of cut relations are the same as in the previous properties. Thus, if  $R$  is a max-complete (resp. strongly max-complete) fuzzy binary relation, then its associated cut relations  $R_\alpha$  are complete (resp. strongly complete) crisp binary relations, for any  $\alpha \in (0, 1]$ .

As it happens in the crisp case, we can relate completeness and reflexivity. In this case, we obtain different results depending on the chosen  $t$ -norm.

### Proposition 11.7

Let  $R$  be a strongly  $S$ -complete fuzzy binary relation on  $X$ :

1.  $R$  is reflexive if and only if the dual  $t$ -norm associated to  $S$  is a positive  $t$ -norm.
2.  $R$  is  $\epsilon$ -reflexive with  $\epsilon < 1$  if, and only if,  $S$  is a nilpotent  $t$ -conorm and  $\epsilon$  belongs to the interval  $[\inf\{x \in [0, 1] | S(x, x) = 1\}, 1)$ .

**Table 11.1** Some properties of fuzzy binary relations

Property	Definition
Reflexivity	$R(x, x) = 1, \quad \forall x \in X$
Irreflexivity	$R(x, x) = 0, \quad \forall x \in X$
Symmetry	$R(x, y) = R(y, x), \quad \forall x, y \in X$
$T$ -antisymmetry	$T(R(x, y), R(y, x)) = 0, \quad \forall x, y \in X, x \neq y$
$T$ -asymmetry	$T(R(x, y), R(y, x)) = 0, \quad \forall x, y \in X$
$T$ -transitivity	$T(R(x, y), R(y, z)) \leq R(x, z), \quad \forall x, y, z \in X$
Negative	$R(x, z) \leq S(R(x, y), R(y, z)), \quad \forall x, y, z \in X$
$S$ -transitivity	
$T$ - $S$ -semitransitivity	$T(R(x, y), R(y, z)) \leq S(R(x, t), R(t, z)), \quad \forall x, y, z, t \in X$
$S$ -completeness	$S(R(x, y), R(y, x)) = 1, \quad \forall x, y \in X$
Strong completeness	$\max(R(x, y), R(y, x)) = 1, \quad \forall x, y \in X$
Weak completeness	$R(x, y) + R(y, x) \geq 1, \quad \forall x, y \in X$
$T$ -linearity	$n_T(R(x, y)) \leq R(y, x), \quad \forall x, y \in X$

Completeness also plays an important role in order to relate transitivity and negative transitivity [11.9]. Thus, given a De Morgan triple  $(T, S, n)$ , with  $T$  a continuous  $t$ -norm, and a strongly  $S$ -complete fuzzy binary relation  $R$ , the  $T$ -transitivity of  $R$  implies:

- Its negatively  $S$ -transitivity
- The  $T$ -transitivity of  $R^d$ .

### 11.3.10 Linearity

$S$ -completeness is also very related to the concept of  $T$ -linearity. Given a  $t$ -norm  $T$ , a fuzzy relation  $R$  defined

on  $X$  is called  $T$ -linear [11.20] if

$$n_T(R(x, y)) \leq R(y, x), \quad \forall x, y \in X,$$

where  $n_T$  stands for the negator  $n_T(x) = \sup\{z \in [0, 1] | T(x, z) = 0\}$ .

$S$ -completeness is equivalent to  $T$ -linearity whenever  $T$  is nilpotent and  $S$  is the dual  $t$ -conorm of  $T$  by using  $n_T$ , that is,  $S(x, y) = n_T(T(n_T(x), n_T(y)))$ .

As the Łukasiewicz  $t$ -norm  $T_L$  is in particular a nilpotent  $t$ -norm, the weak completeness, that is  $S_{T_L}$ -completeness, is equivalent to  $T_L$ -linearity.

We summarize the properties and definitions we have introduced in this section in Table 11.1.

## 11.4 Particular Cases of Fuzzy Binary Relations

In this section, we deal with some particular cases of fuzzy binary relations, which are very important in several fields and they generalize classic concepts.

### 11.4.1 Similarity Relation

The notion of *similarity* is essentially a generalization of the notion of equivalence.

More concretely, a  $T$ -indistinguishability relation  $R$  is a fuzzy binary relation which is reflexive, symmetric, and  $T$ -transitive. Sometimes it is also called *fuzzy equivalence relation* or *equality relation*.  $R(x, y)$  is interpreted as the degree of indistinguishability (or similarity) between  $x$  and  $y$ .

In this definition, reflexivity expresses the fact that every object is completely indistinguishable from itself. Symmetry says that the degree in which  $x$  and  $y$  are indistinguishable is the same as the degree in which  $y$  and  $x$  are indistinguishable. For transitivity, as it depends on a  $t$ -norm, we have a more flexible property. In particular, when we use the product  $t$ -norm, we obtain the so-called *possibility relations* introduced by *Menger* in [11.3]; if we choose the Łukasiewicz  $t$ -norm, we obtain the relations called *likeness* introduced by *Rusconi* [11.21]; while for the minimum  $t$ -norm we obtain *similarity relations* [11.22].

When the transitivity is not required, the relation  $R$  is said to be a *proximity relation*.

### 11.4.2 Fuzzy Order

Next, we make a quick overview on some different fuzzy ordering relations, focusing on the properties they shall satisfy. Consider a fuzzy binary relation  $R$  on the set  $X$ .  $R$  is called:

- *Partial T-preorder* or *T-quasiorder* if  $R$  is reflexive and  $T$ -transitive;
- *Total T-preorder* or *linear T-quasiorder* if  $R$  is strongly complete and  $T$ -transitive;
- *Partial T-order* if  $R$  is antisymmetric and  $T$ -transitive;
- *Strict partial T-order* if  $R$  is asymmetric and  $T$ -transitive;
- *Total T-order* or *linear T-order* if  $R$  is a complete partial  $T$ -order, that is,  $R$  is antisymmetric,  $T$ -transitive and complete;
- *Strict total T-order* if  $R$  is a complete strict partial  $T$ -order, that is,  $R$  is asymmetric,  $T$ -transitive and complete.

As in the previous concepts, when  $T$  is the  $t$ -norm of the minimum, we call  $R$  simply total preorder, total order, etc.

The previous definitions are summarized in Table 11.2.

**Table 11.2** Fuzzy binary relations by properties

	Reflexivity	Symmetry	Antisymmetry	Asymmetry	Transitivity
Preorder	Yes				Yes
Order	Yes	No	Yes		Yes
Strict order	Yes	No	Yes	Yes	Yes
Proximity	Yes	Yes	No	No	
<i>T</i> -indistinguishability	Yes	Yes	No	No	Yes

## 11.5 Present and Future of Fuzzy Relations

In this chapter, we have tried to give to the reader a first approach to the concept of fuzzy relations. Of course this is just a starting point. Due to the current development of the topics related to fuzzy relations, a researcher interested in this notion should study in detail more specialized materials.

Here we have presented the definition of classic fuzzy relations, which take values in the interval  $[0, 1]$ .

However, lattice-valued fuzzy relations are considered as a interesting tool in some areas. In that case, the relation  $R$  is a map from  $X \times Y$  in a complete lattice  $L$ . Some approaches and interesting references for this lattice-valued relations are in [11.23].

A particular interesting case is when the lattice is a chain of linguistic labels. Some approaches in this direction can be found, for instance, in [11.24–26].

# 12. Fuzzy Implications: Past, Present, and Future

Michał Baczyński, Balasubramaniam Jayaram, Sebastia Massanet, Joan Torrens

Fuzzy implications are a generalization of the classical two-valued implication to the multi-valued setting. They play a very important role both in the theory and applications, as can be seen from their use in, among others, multivalued mathematical logic, approximate reasoning, fuzzy control, image processing, and data analysis. The goal of this chapter is to present the evolution of fuzzy implications from their beginnings to the current days. From the theoretical point of view, we present the basic facts, as well as the main topics and lines of research around fuzzy implications. We also devote a specific section to state and recall a list of main application fields where fuzzy implications are employed, as well as another one to the main open problems on the topic.

Fuzzy logic connectives play a fundamental role in the theory of fuzzy sets and fuzzy logic. The basic fuzzy connectives that perform the role of generalized *And*, *Or*, and *Not* are *t*-norms, *t*-conorms, and negations, respectively, whereas fuzzy conditionals are usually managed through fuzzy implications. Fuzzy implications play a very important role both in theory and applications, as can be seen from their use in, among others, multivalued mathematical logic, approximate reasoning, fuzzy control, image processing, and data analysis. Thus, it is hardly surprising that many researchers have devoted their efforts to the study of implication functions. This interest has become more evident in the last decade when many works have appeared and have led to some surveys [12.1, 2] and even some research monographs entirely devoted to this topic [12.3, 4]. Thus, most of the known results and applications of fuzzy implications until the publication date were collected in [12.3], and very recently the edited volume [12.4] has been published complimenting the earlier monograph

with the most recent lines of investigation on fuzzy implications.

In this regard, we have decided to devote this chapter, as the title suggests, to present the evolution of fuzzy implications from their beginnings to the present time. The idea is not to focus on a list of results already collected in other works, but unraveling the relations and highlighting the importance in the development and progress that fuzzy implications have experienced along the time. From the theoretical point of view we present the basic facts, as well as the main topics and lines of research around fuzzy implications, recalling in most of the cases where the corresponding results can be found, instead of listing them. Of course, we also devote a specific section to state and recall a list of the main application fields where fuzzy implications are employed. A final section looks ahead to the future by listing some of the main open-problem-solutions of which are certain to enrich the existing literature on the topic.

## 12.1 Fuzzy Implications: Examples, Properties, and Classes

Fuzzy implications are a generalization of the classical implication to fuzzy logic. It is a well-established fact that fuzzy concepts have to generalize the corresponding crisp one, and consequently fuzzy implications restricted to  $\{0, 1\}^2$  must coincide with the classical implication. Currently, the most accepted definition of a fuzzy implication is the following one.

### Definition 12.1 [12.3, Definition 1.1.1]

A function  $I: [0, 1]^2 \rightarrow [0, 1]$  is called a *fuzzy implication* if it satisfies the following conditions:

- (I1)  $I(x, z) \geq I(y, z)$  when  $x \leq y$ , for all  $z \in [0, 1]$
- (I2)  $I(x, y) \leq I(x, z)$  when  $y \leq z$ , for all  $x \in [0, 1]$
- (I3)  $I(0, 0) = I(1, 1) = 1$  and  $I(1, 0) = 0$ .

This definition is flexible enough to allow uncountably many fuzzy implications. This great repertoire of fuzzy implications allows a researcher to pick out, depending on the context, that fuzzy implication which satisfies some desired additional properties. Many additional properties, all of them arising from tautologies in classical logic, have been postulated in many works. The most important of them are collected below:

- (NP): The *left neutrality principle*,

$$I(1, y) = y, \quad y \in [0, 1].$$

- (EP): The *exchange principle*,

$$I(x, I(y, z)) = I(y, I(x, z)), \quad x, y, z \in [0, 1].$$

- (OP): The *ordering property*,

$$x \leq y \iff I(x, y) = 1, \quad x, y \in [0, 1].$$

- (IP): The *identity principle*,

$$I(x, x) = 1, \quad x \in [0, 1].$$

- (CP(N)): The *contrapositive symmetry* with respect to a fuzzy negation  $N$ ,

$$I(x, y) = I(N(y), N(x)), \quad x, y \in [0, 1].$$

Given a fuzzy implication  $I$ , its *natural negation* is defined as  $N_I(x) = I(x, 0)$  for all  $x \in [0, 1]$ . This function is always a fuzzy negation. For the definitions of basic fuzzy logic connectives like fuzzy negations, t-norms and t-conorms please see [12.5]. Moreover,  $N_I$  can be continuous, strict, or strong and these are also additional properties usually required of a fuzzy implication  $I$ .

Table 12.1 lists the most well-known fuzzy implications along with the additional properties they satisfy [12.3, Chap.1]. In addition, the following

**Table 12.1** Basic fuzzy implications and the additional properties they satisfy where  $N_C$ ,  $N_{D_1}$ , and  $N_{D_2}$  stand for the classical, the least and the greatest fuzzy negations, respectively

Name	Formula	(NP)	(EP)	(IP)	(OP)	(CP(N))	$N_I$
Łukasiewicz	$I_{LK}(x, y) = \min\{1, 1 - x + y\}$	✓	✓	✓	✓	$N_C$	$N_C$
Gödel	$I_{GD}(x, y) = \begin{cases} 1 & \text{if } x \leq y \\ y & \text{if } x > y \end{cases}$	✓	✓	✓	✓	X	$N_{D_1}$
Reichenbach	$I_{RC}(x, y) = 1 - x + xy$	✓	✓	X	X	$N_C$	$N_C$
Kleene–Dienes	$I_{KD}(x, y) = \max\{1 - x, y\}$	✓	✓	X	X	$N_C$	$N_C$
Goguen	$I_{GG}(x, y) = \begin{cases} 1 & \text{if } x \leq y \\ \frac{y}{x} & \text{if } x > y \end{cases}$	✓	✓	✓	✓	X	$N_{D_1}$
Rescher	$I_{RS}(x, y) = \begin{cases} 1 & \text{if } x \leq y \\ 0 & \text{if } x > y \end{cases}$	X	X	✓	✓	$N_C$	$N_{D_1}$
Yager	$I_{YG}(x, y) = \begin{cases} 1 & \text{if } (x, y) = (0, 0) \\ y^x & \text{if } (x, y) \neq (0, 0) \end{cases}$	✓	✓	X	X	X	$N_{D_1}$
Weber	$I_{WB}(x, y) = \begin{cases} 1 & \text{if } x < 1 \\ y & \text{if } x = 1 \end{cases}$	✓	✓	✓	X	X	$N_{D_2}$
Fodor	$I_{FD}(x, y) = \begin{cases} 1 & \text{if } x \leq y \\ \max\{1 - x, y\} & \text{if } x > y \end{cases}$	✓	✓	✓	✓	$N_C$	$N_C$

two implications

$$I_0(x, y) = \begin{cases} 1, & \text{if } x = 0 \text{ or } y = 1, \\ 0, & \text{if } x > 0 \text{ and } y < 1, \end{cases}$$

$$I_1(x, y) = \begin{cases} 1, & \text{if } x < 1 \text{ or } y > 0, \\ 0, & \text{if } x = 1 \text{ and } y = 0, \end{cases}$$

are the least and the greatest fuzzy implications, respectively, of the family of all fuzzy implications.

Beyond these examples of fuzzy implications, several families of these operations have been proposed and deeply studied. There exist basically two strategies in order to define classes of fuzzy implications. The most usual strategy is based on some combinations of aggregation functions. In this way,  $t$ -norms and  $t$ -conorms [12.5] were the first classes of aggregation functions used to generate fuzzy implications. Thus, the following are the three most important classes of fuzzy implications of this type:

1)  $(S, N)$ -implications defined as

$$I_{S,N}(x, y) = S(N(x), y), \quad x, y \in [0, 1],$$

where  $S$  is a  $t$ -conorm and  $N$  a fuzzy negation. They are the immediate generalization of the classical boolean material implication  $p \rightarrow q \equiv \neg p \vee q$ . If  $N$  is involutive, they are called strong or  $S$ -implications.

2) Residual or  $R$ -implications defined by

$$I_T(x, y) = \sup\{z \in [0, 1] \mid T(x, z) \leq y\}, \quad x, y \in [0, 1],$$

where  $T$  is a  $t$ -norm. When they are obtained from left-continuous  $t$ -norms, they come from residuated lattices based on the residuation property

$$T(x, y) \leq z \Leftrightarrow I(x, z) \geq y, \quad \text{for all } x, y, z \in [0, 1].$$

3)  $QL$ -operations defined by

$$I_{T,S,N}(x, y) = S(N(x), T(x, y)), \quad x, y \in [0, 1],$$

where  $S$  is a  $t$ -conorm,  $T$  is a  $t$ -norm and  $N$  is a fuzzy negation. Their origin is the quantum mechanic logic.

Note that  $R$ - and  $(S, N)$ -implications are always implications in the sense of Definition 12.1, whereas  $QL$ -operations are not implications in general (they are called  $QL$ -implications when they actually are).

A characterization of those  $QL$ -operations which are also implications is still open (Sect. 12.4), but a common necessary condition is  $S(N(x), x) = 1$  for all  $x \in [0, 1]$ . Yet another class of fuzzy implications is that of Dishkant or  $D$ -operations [12.6] which are the contraposition of  $QL$ -operations with respect to a strong fuzzy negation.

These initial classes were successfully generalized considering more general classes of aggregation functions, mainly uninorms, generating new classes of fuzzy implications with interesting properties. In this way,  $(U, N)$ ,  $RU$ -implications and  $QLU$ -operations have been deeply analyzed [12.3, Chap. 5], [12.6].

A second approach to obtain fuzzy implications is based on the direct use of unary monotonic functions. In this way, the most important families are Yager's  $f$ - and  $g$ -generated fuzzy implications which can be seen as implications generated from additive generators of continuous Archimedean  $t$ -norms and  $t$ -conorms, respectively [12.3, Chap. 3]:

1) Yager's  $f$ -generated implications are defined as

$$I_f(x, y) = f^{-1}(x \cdot f(y)), \quad x, y \in [0, 1],$$

with the understanding  $0 \cdot \infty = 0$ , where  $f: [0, 1] \rightarrow [0, \infty]$  is a strictly decreasing and continuous function with  $f(1) = 0$ .

2) Yager's  $g$ -generated implications are defined as

$$I_g(x, y) = g^{-1}\left(\min\left\{\frac{1}{x} \cdot g(y), g(1)\right\}\right), \\ x, y \in [0, 1],$$

with the understanding  $\frac{1}{0} = \infty$  and  $\infty \cdot 0 = \infty$  where  $g: [0, 1] \rightarrow [0, \infty]$ , is a strictly increasing and continuous function with  $g(0) = 0$ .

The above classes give rise to fuzzy implications with different additional properties which are collected in Table 12.2. All the results referred in Table 12.2 are from [12.3, Chaps. 2 and 3].

One of the main topics in this field is the characterization of each of these families of fuzzy implications through algebraic properties. This is an essential step in order to understand the behavior of these families. The available characterization results of the above families of implications are collected below.

### Theorem 12.1 [12.3, Theorem 2.4.10]

For a function  $I: [0, 1]^2 \rightarrow [0, 1]$  the following statements are equivalent:

**Table 12.2** Classes of fuzzy implications and the additional properties they satisfy

Class / Properties	(NP)	(EP)	(IP)	(OP)	(CP(N))	$N_I$
$(S, N)$ -imp.	✓	✓	Thm. 2.4.17	Thm. 2.4.19	Prop. 2.4.3	$N$
$R$ -imp. with l-c. $T$	✓	✓	✓	✓	Prop. 2.5.28	$N_T$
QL-imp.	✓		Thm. 2.6.19	Sect. 2.6.3	Sect. 2.6.4	Sect. 2.6.5
$f$ -gen.	✓	✓	✗	✗	Thm. 3.1.7	Prop. 3.1.6
$g$ -gen.	✓	✓	Thm. 3.2.8	Thm. 3.2.9	✗	$N_{D_1}$

- i)  $I$  is an  $(S, N)$ -implication with a continuous (strict, strong) fuzzy negation  $N$ .  
ii)  $I$  satisfies (I1), (EP), and  $N_I$  is a continuous (strict, strong) fuzzy negation.

Moreover, in this case the representation  $I(x, y) = S(N(x), y)$  is unique with  $N = N_I$  and  $S(x, y) = I(\mathfrak{N}_N(x), y)$  (for the definition of  $\mathfrak{N}_N$  see [12.3, Lemma 1.4.10]).

### Theorem 12.2 [12.3, Theorem 2.5.17]

For a function  $I: [0, 1]^2 \rightarrow [0, 1]$  the following statements are equivalent:

- i)  $I$  is an  $R$ -implication generated from a left-continuous  $t$ -norm.  
ii)  $I$  satisfies (I2), (EP), (OP) and it is right continuous with respect to the second variable.

Moreover, the representation

$$I(x, y) = \max\{t \in [0, 1] | T(x, t) \leq y\}$$

is unique with

$$T(x, y) = \min\{t \in [0, 1] | I(x, t) \geq y\}.$$

As already said, it is still an open question when QL-operations are fuzzy implications. However, in the continuous case, when  $S$  and  $N$  are the  $\varphi$ -conjugates of the Łukasiewicz  $t$ -conorm  $S_{LK}$  and the classical negation  $N_C$ , respectively, for some order automorphism  $\varphi$  on the unit interval, the QL-operation has the following expression

$$\begin{aligned} I_{T,S,N}(x, y) &= I_{\varphi,T}(x, y) \\ &= \varphi^{-1}(1 - \varphi(x) + \varphi(T(x, y))), \\ x, y &\in [0, 1], \end{aligned}$$

and we have the following characterization result.

### Theorem 12.3 [12.3, Theorem 2.6.12]

For a QL-operation  $I_{\varphi,T}$ , where  $T$  is a  $t$ -norm and  $\varphi$  is an automorphism on the unit interval, the following statements are equivalent:

- i)  $I_{\varphi,T}$  is a QL-implication.  
ii)  $T_{\varphi^{-1}}$  satisfies the Lipschitz condition, i.e.,

$$\begin{aligned} &|T_{\varphi^{-1}}(x_1, y_1) - T_{\varphi^{-1}}(x_2, y_2)| \\ &\leq |x_1 - x_2| + |y_1 - y_2|, \quad x_1, x_2, y_1, y_2 \in [0, 1]. \end{aligned}$$

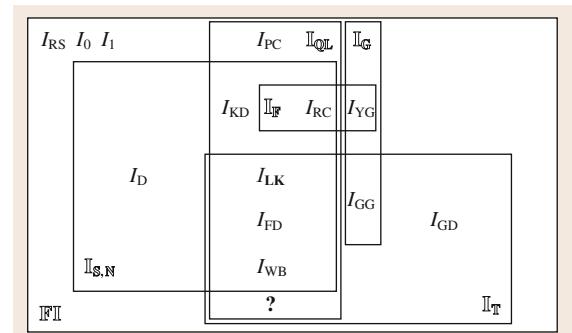

In addition,  $(U, N)$ -implications are characterized in [12.3, Theorem 5.3.12] and more recently, Yager's  $f$  and  $g$ -generated [12.7] and  $RU$ -implications [12.8] have been also characterized. Finally, due to its importance in many results, we recall the characterization of the family of the conjugates of the Łukasiewicz implication.

### Theorem 12.4 [12.3, Theorem 7.5.1]

For a function  $I: [0, 1]^2 \rightarrow [0, 1]$  the following statements are equivalent:

- i)  $I$  is continuous and satisfies both (EP) and (OP).  
ii)  $I$  is a  $\varphi$ -conjugate with the Łukasiewicz implication  $I_{LK}$ , i.e., there exists an automorphism  $\varphi$  on the unit interval, which is uniquely determined, such that  $I$  has the form

$$\begin{aligned} I(x, y) &= (I_{LK})_{\varphi}(x, y) \\ &= \varphi^{-1}(\min\{1 - \varphi(x) + \varphi(y), 1\}), \\ x, y &\in [0, 1]. \end{aligned}$$

**Fig. 12.1** Intersections between the main classes of fuzzy implications

For the conjugates of the other basic implications in Table 12.1, see the characterization results in [12.3, Sect. 7.5].

The great number of classes of fuzzy implications induces the study of the intersection between the different classes which brings out both the unity that exists among this diversity of classes and where the basic implications from Table 12.1 are located. The intersections among the main classes of fuzzy implications were studied in [12.3, Chap. 4] and are graphically displayed in Fig. 12.1 (note that  $\mathbb{FI}$ ,  $\mathbb{I}_{S,N}$ ,  $\mathbb{I}_T$ ,  $\mathbb{I}_{QL}$ ,  $\mathbb{I}_F$  and  $\mathbb{I}_G$  denote the families of all fuzzy implications,  $(S,N)$ -implications,  $R$ -implications,  $QL$ -implications, Yager's  $f$ -generated implications and Yager's  $g$ -generated implica-

cations, respectively). In this figure, we have included the fuzzy implications of Table 12.1 and the following fuzzy implications which are examples of implications lying in some intersection between some families

$$I_{g^\lambda}(x, y) = \min \left\{ 1, \frac{y}{x^{\frac{1}{\lambda}}} \right\},$$

$$I_D(x, y) = \begin{cases} 1, & \text{if } x = 0, \\ y, & \text{if } x > 0, \end{cases}$$

$$I_{PC}(x, y) = 1 - (\max\{x(x + xy^2 - 2y), 0\})^{\frac{1}{2}}.$$

Also note that it is still an open problem to prove if  $(\mathbb{I}_{QL} \cap \mathbb{I}_T) \setminus \mathbb{I}_{S,N} = \emptyset$ .

## 12.2 Current Research on Fuzzy Implications

In the previous sections, we have seen some functional equations, namely, the exchange property (EP), the contrapositive symmetry (CP(N)) and the like. In this section, we deal with a few functional equations (or inequalities) involving fuzzy implications. These equations, once again, arise as the generalizations of the corresponding tautologies in classical logic involving boolean implications.

### 12.2.1 Functional Equations and Properties

A study of such equations stems from their applicability. The need for a plethora of fuzzy implications possessing various properties is quite obvious. On the one hand, they allow us to clearly classify and characterize different fuzzy implications, while on the other hand, they make themselves appealing to different applications. Thus, the functional equations presented in this section are chosen to reflect this dichotomy.

#### Distributivity over other Fuzzy Logic Operations

The distributivity of fuzzy implications over different fuzzy logic connectives, like  $t$ -norms,  $t$ -conorms, and uninorms is reduced to four equations

$$I(x, C_1(y, z)) = C_2(I(x, y), I(x, z)), \quad (12.1)$$

$$I(x, D_1(y, z)) = D_2(I(x, y), I(x, z)), \quad (12.2)$$

$$I(C(x, y), z) = D(I(x, z), I(y, z)), \quad (12.3)$$

$$I(D(x, y), z) = C(I(x, z), I(y, z)), \quad (12.4)$$

satisfied for all  $x, y, z \in [0, 1]$ , where  $I$  is some generalization of classical implication,  $C, C_1, C_2$  are some

generalizations of classical conjunction and  $D, D_1, D_2$  are some generalizations of classical disjunction.

All the above equations can be investigated in two different ways. On the one hand, one can assume that function  $I$  belongs to some known class of fuzzy implications and investigate the connectives  $C_i, D_i$  that satisfy (12.1)–(12.4), as is done in the following works, for e.g., Trillas and Alsina [12.9], Balasubramaniam and Rao [12.10], Ruiz-Aguilera and Torrens [12.11, 12] and Massanet and Torrens [12.13]. On the other hand, one can assume that the connectives  $C_i, D_i$  come from the known classes of functions and investigate the fuzzy implications  $I$  that satisfy (12.1)–(12.4). See the works of Baczyński [12.14, 15], Baczyński and Jayaram [12.16], Baczyński and Qin [12.17, 18] for such an approach.

The above distributive equations play an important role in reducing the complexity of fuzzy systems, since the number of rules directly affects the computational duration of the overall application (we will discuss this problem again in Sect. 12.3.2).

#### Law of Importation

One of the desirable properties of a fuzzy implication is the law of importation as given below

$$I(x, I(y, z)) = I(T(x, y), z), \quad x, y, z \in [0, 1], \quad (12.5)$$

where  $T$  is a  $t$ -norm (or, in general, some conjunction). It generalizes the classical tautology  $(p \wedge q) \rightarrow r \equiv (p \rightarrow (q \rightarrow r))$  into fuzzy logic context. This equation has been investigated for many different families

of fuzzy implications (for results connected with main classes see [12.3, Sect. 7.3]). Fuzzy implications satisfying (12.5) have been found extremely useful in fuzzy relational inference mechanisms, since one can obtain an equivalent hierarchical scheme which significantly decreases the computational complexity of the system without compromising on the approximation capability of the inference scheme. For more on this, we refer the readers to the following works [12.19, 20]. Related with (12.5) is its equivalence with (EP) that has been an open problem till the recent paper [12.21], where it is proved that (12.5) is stronger than (EP) and equivalent when  $N_I$  is continuous.

### T-Conditionality or Modus Ponens

Another property investigated in the scientific literature, which is of great practical importance (see also Sect. 12.3.1), is the so-called *T*-conditionality, defined in the following way. If  $I$  is a fuzzy implication and  $T$  is a  $t$ -norm, then  $I$  is called an *MP-fuzzy implication* for  $T$ , if

$$T(x, I(x, y)) \leq y, \quad x, y \in [0, 1]. \quad (12.6)$$

Investigations of (12.6) have been done for the three main families of fuzzy implications, namely, (*S, N*)-, *R*-, and *QL*-implications [12.3, Sect. 7.4].

### Nonsaturating Fuzzy Implications

Investigations connected with subsethood measures (see Sect. 12.3.3) and constructing strong equality functions by aggregation of implication functions by the formula  $\Psi(x, y) = M(I(x, y), I(y, x))$ , where  $M$  is some symmetric function, have led researchers to consider under which properties a fuzzy implication  $I$  satisfies the following conditions:

- (P1)  $I(x, y) = 1$  if and only if  $x = 0$  or  $y = 1$ ;
- (P2)  $I(x, y) = 0$  if and only if  $x = 1$  and  $y = 0$ .

In [12.22], the authors considered the possible relationships between these two properties and the properties usually required of implication operations. Moreover, they developed different construction methods of strong equality indexes using fuzzy implications that satisfy these two additional properties.

### Special Fuzzy Implications

Special implications were introduced by Hájek and Koutný [12.23] in their investigations on some statistics on marginals. The authors further have shown that they are related to special GUHA-implicative quantifiers (see, for instance, [12.24–26]). Thus, special fuzzy impli-

cations are related to data mining. In their quest to obtain some many-valued connectives as extremal values of some statistics on contingency tables with fixed marginals, they especially focussed on special homogenous implicative quantifiers and showed that:

*Each special implicative quantifier determines a special implication. Conversely, each special implication is given by a special implicative quantifier.*

### Definition 12.2

A fuzzy implication  $I$  is said to be special, if for any  $\varepsilon > 0$  and for all  $x, y \in [0, 1]$  such that  $x + \varepsilon, y + \varepsilon \in [0, 1]$  the following condition is satisfied

$$I(x, y) \leq I(x + \varepsilon, y + \varepsilon). \quad (12.7)$$

Recently, Jayaram and Mesiar [12.27] have investigated the above functional equation. Their study shows that among the main classes of fuzzy implications, no *f*-implication is a special implication, while the Goguen implication  $I_{GG}$  is the only special *g*-implication. Based on the available results, they have conjectured that the (*S, N*)-implications that are special also turn out to be *R*-implications. However, in the case of *R*-implications (generated from any  $t$ -norm) they have obtained the following result.

### Theorem 12.5 [12.27, Theorem 4.6]

Let  $T$  be any  $t$ -norm and  $I_T$  be the *R*-implication obtained from  $T$ . Then the following statements are equivalent:

- i)  $I_T$  satisfies (12.7).
- ii)  $T$  satisfies the 1-Lipschitz condition.
- iii)  $T$  has an ordinal sum representation  $(\langle e_\alpha, a_\alpha, T_\alpha \rangle)_{\alpha \in A}$  where each  $t$ -norm  $T_\alpha$ ,  $\alpha \in A$  is generated by a convex additive generator (for the definition of ordinal sum, see [12.5]).

Having shown that the families of (*S, N*)-, *f*-, and *g*-implications do not lead to any new special implications, Jayaram and Mesiar [12.27] turned to the most natural question: *Are there any other special implications, than those that could be obtained as residuals of t-norms?* This led them to propose some interesting constructions of fuzzy implications which were also special – one such construction is given in Definition 12.4 in Sect. 12.2.

## 12.2.2 New Classes and Generalizations

Another current research line on fuzzy implications is devoted to the study of new classes and generalizations of the already known families. The research in this direction has been extensively developed in recent years. Among many generalizations of already known classes of implications that have been dealt with in the literature, we highlight the following ones.

### Generalizations of *R*-implications

The family of residual implications is one of the most commonly selected families for generalization. As already mentioned in Sect. 12.1, the *RU*-implications were the first generalization obtained via residuation from uninorms instead of from *t*-norms. In the same line, many other families of aggregation functions have been used to derive residual implications:

1. Copulas, quasi-copulas, and semicopulas were used in [12.28]. The main results in this work relate to the axiomatic characterizations of those functions  $I$  that are the residual implications of left-continuous commutative semicopulas, the residuals of quasi-copulas, and the residuals of associative copulas. For details on these characterizations, that involve up to ten different axioms, see [12.28].
2. Representable aggregation functions (**RAFs**) were used in [12.29]. These are aggregation functions constructed from additive generators of continuous Archimedean *t*-conorms and strong negations. The interest in the residual implications obtained from them lies in the fact that they are always continuous and in many cases they also satisfy the modus ponens with a nilpotent *t*-conorm. In particular, residual implications that depend only on a strong negation  $N$  are deduced from the general method just by considering specific generators of continuous Archimedean *t*-conorms.
3. A more general situation is studied in [12.30] where residual implications derived from binary functions  $F: [0, 1]^2 \rightarrow [0, 1]$  are studied. In this case, the paper deals with the minimal conditions that  $F$  must satisfy in order to obtain an implication by residuation. The same is done in order to obtain residual implications satisfying each one of the most usual properties.
4. It is well known that residual implications derived from continuous Archimedean *t*-norms can be expressed directly from the additive generator of the *t*-norm. A generalization of this idea is

presented in [12.31], where strictly decreasing functions  $f: [0, 1] \rightarrow [0, +\infty]$  with  $f(1) = 0$  are used to derive implications as follows

$$I(x, y) = \begin{cases} 1, & \text{if } x \leq y, \\ f^{(-1)}(f(y^+) - f(x)), & \text{if } x > y, \end{cases}$$

where  $f(y^+) = \lim_{y \rightarrow y^+} f(y)$  and  $f(1^+) = f(1)$ . Properties of these implications are studied and many new examples are also derived in [12.31].

### Generalizations of $(S, N)$ -Implications

Once again a first generalization of this class of implications has been done using uninorms leading to the  $(U, N)$ -implications mentioned in Sect. 12.1, but recently many other aggregation functions were also employed.

This is the case for instance in [12.32], where the authors make use of *TS*-functions obtained from a *t*-norm  $T$ , a *t*-conorm  $S$  and a continuous, strictly monotone function  $f: [0, 1] \rightarrow [-\infty, +\infty]$  through the expression

$$TS_{\lambda, f}(x, y) = f^{-1}((1 - \lambda)f(T(x, y)) + \lambda f(S(x, y)))$$

for  $x, y \in [0, 1]$ , where  $\lambda \in (0, 1)$ . Operators defined by  $I(x, y) = TS_{\lambda, f}(N(x), y)$  are studied in [12.32] giving the conditions under which they are fuzzy implications.

Another approach is based on the use of dual representable aggregation functions  $G$ , that are simply the *N*-dual of **RAFs**, introduced earlier. In this case, the corresponding  $(G, N)$ -operator is always a fuzzy implication and several examples and properties of this class can be found in [12.33]. See also [12.34] where it is proven that they satisfy (EP) (or (12.5)) if and only if  $G$  is in fact a nilpotent *t*-conorm.

### Generalizations of Yager's Implications

In this case, the generalizations usually deal with the possibility of varying the generator used in the definition of the implication. A first step in this line was taken in [12.35] by considering multiplicative generators of *t*-conorms, but it was proven in [12.36] that this new class is included in the family of all  $(S, N)$ -implications obtained from *t*-conorms and continuous fuzzy negations.

Another approach was given in [12.37] introducing  $(f, g)$ -implications. In this case, the idea is to generalize  $f$ -generated Yager's implications by substituting the factor  $x$  by  $g(x)$  where  $g: [0, 1] \rightarrow [0, 1]$  is an increasing function satisfying  $g(0) = 0$  and  $g(1) = 1$ .

In the same direction, a generalization of  $f$ - and  $g$ -generated Yager's implications based on aggregation operators is presented and studied in [12.38], where the implications are constructed by replacing the product  $t$ -norm in Yager's implications by any aggregation function.

Finally,  $h$ -implications were introduced in [12.39] and are constructed from additive generators of representable uninorms as follows.

### Definition 12.3 ([12.39])

Let  $h: [0, 1] \rightarrow [-\infty, \infty]$  be a strictly increasing and continuous function with  $h(0) = -\infty$ ,  $h(e) = 0$  for an  $e \in (0, 1)$  and  $h(1) = +\infty$ . The function  $I^h: [0, 1]^2 \rightarrow [0, 1]$  defined by

$$I^h(x, y) = \begin{cases} 1, & \text{if } x = 0, \\ h^{-1}(x \cdot h(y)), & \text{if } x > 0 \text{ and } y \leq e, \\ h^{-1}\left(\frac{1}{x} \cdot h(y)\right), & \text{if } x > 0 \text{ and } y > e, \end{cases}$$

is called an  $h$ -implication.

This kind of implications maintains several properties of those satisfied by Yager's implications, like (EP) and (12.5) with the product  $t$ -norm, but at the same time they satisfy other interesting ones. For more details on this kind of implications, as well as some generalizations of them, see [12.39].

### 12.2.3 New Construction Methods

In this section, we recall some construction methods of fuzzy implications. The relevance of these methods is based on their capability of preserving the additional properties satisfied by the initial implication(s). First, note that some of them were already collected in [12.3, Chaps. 6 and 7], like:

- The  $\varphi$ -conjugation of a fuzzy implication  $I$

$$I_\varphi(x, y) = \varphi^{-1}(I(\varphi(x), \varphi(y))), \quad x, y \in [0, 1],$$

where  $\varphi$  is an order automorphism on  $[0, 1]$ .

- The min and max operations from two given fuzzy implications

$$(I \vee J)(x, y) = \max\{I(x, y), J(x, y)\}, \quad x, y \in [0, 1],$$

$$(I \wedge J)(x, y) = \min\{I(x, y), J(x, y)\}, \quad x, y \in [0, 1].$$

- The convex combinations of two fuzzy implications, where  $\lambda \in [0, 1]$

$$I_{I,J}^\lambda(x, y) = \lambda \cdot I(x, y) + (1 - \lambda) \cdot J(x, y), \quad x, y \in [0, 1].$$

- The  $N$ -reciprocal of a fuzzy implication  $I$

$$I_N(x, y) = I(N(y), N(x)), \quad x, y \in [0, 1],$$

where  $N$  is a fuzzy negation.

- The upper, lower, and medium contrapositivization of a fuzzy implication  $I$  defined, respectively, as

$$\begin{aligned} I_N^u(x, y) &= \max\{I(x, y), I_N(x, y)\} \\ &= (I \vee I_N)(x, y), \end{aligned}$$

$$\begin{aligned} I_N^l(x, y) &= \min\{I(x, y), I_N(x, y)\} \\ &= (I \wedge I_N)(x, y), \end{aligned}$$

$$I_N^m(x, y) = \min\{I(x, y) \vee N(x), I_N(x, y) \vee y\},$$

where  $N$  is a fuzzy negation and  $x, y \in [0, 1]$ . Please note that the lower (upper) contrapositivization is based on applying the min (max) method to a fuzzy implication  $I$  and its  $N$ -reciprocal.

It should be emphasized that the first major work to explore contrapositivization in detail, in its own right, was that of Fodor [12.40], where he discusses the contrapositive symmetry of fuzzy implications for the three main families, namely,  $S$ -,  $R$ -, and  $QL$ -implications. In fact, during this study Fodor discovered the nilpotent minimum  $t$ -norm  $T_{nM}$ , which is by far the first left-continuous but noncontinuous  $t$ -norm known in the literature. This study had a major impact on the development of left-continuous  $t$ -norms with strong natural negation, for instance, see the early works of Jenei [12.41], and references therein].

The above fact clearly illustrates how the study of functional equations involving fuzzy implications have also had interesting spin-offs and have immensely benefited other areas and topics in fuzzy logic connectives.

Among the new construction methods proposed in the recent literature, we can roughly divide them into the following categories.

#### Implications Generated from Negations

The first method was introduced by Jayaram and Mesiar in [12.42], while they were studying special implications (see Definition 12.2). From this study, they introduced the neutral special implications with a given negation and they studied the main properties of this new class.

**Definition 12.4 [12.42]**

Let  $N$  be a fuzzy negation such that  $N \leq N_C$ . Then the function  $I_{[N]}: [0, 1]^2 \rightarrow [0, 1]$  given by

$$I_{[N]}(x, y) = \begin{cases} 1, & \text{if } x \leq y, \\ y + \frac{N(x-y)(1-x)}{1-x+y}, & \text{if } x > y, \end{cases}$$

with the understanding  $\frac{0}{0} = 0$ , is called the neutral special implication generated from  $N$ .

The second method of generation of fuzzy implications from fuzzy negations was introduced in [12.43].

**Definition 12.5 [12.43]**

Let  $N$  be a fuzzy negation. The function  $I^{[N]}: [0, 1]^2 \rightarrow [0, 1]$  is defined by

$$I^{[N]}(x, y) = \begin{cases} 1, & \text{if } x \leq y, \\ \frac{(1-N(x))y}{x} + N(x), & \text{if } x > y. \end{cases}$$

Again, several properties of these new implications can be derived, specially when the following classes of fuzzy negations are considered

$$\begin{aligned} N_A(x) &= \begin{cases} 1, & \text{if } x \in A, \\ 0, & \text{if } x \notin A, \end{cases} \\ N_{A,\beta}(x) &= \begin{cases} 1, & \text{if } x \in A, \\ \frac{1-x}{1+\beta x}, & \text{if } x \notin A, \end{cases} \end{aligned}$$

where  $A = [0, \alpha]$  with  $\alpha \in (0, 1)$  or  $A = [0, \alpha]$  with  $\alpha \in [0, 1]$ . Note that  $N_{\{0\}} = N_{D_1}$  and  $N_{\{0\},\beta}$  is the Sugeno class of negations. Note also that  $I^{[N]}$  can be expressed as  $I^{[N]}(x, y) = S_P(N(x), I_{GG}(x, y))$  for all  $x, y \in [0, 1]$ . From this observation, replacing  $S_P$  for any  $t$ -conorm  $S$  and  $I_{GG}$  for any implication  $I$ , the function

$$I^{[N,S,I]}(x, y) = S(N(x), I(x, y)), \quad x, y \in [0, 1],$$

is always a fuzzy implication.

**Implications Constructed from Two Given Implications**

In this section, we present methods that generate a fuzzy implication from two given ones.

The first method is based on an adequate scaling of the second variable of the two initial implications and it is called the *threshold generation method* [12.44].

**Definition 12.6 [12.44]**

Let  $I_1$  and  $I_2$  be two fuzzy implications and  $e \in (0, 1)$ . The function  $I_{I_1-I_2}: [0, 1]^2 \rightarrow [0, 1]$  defined by

$$I_{I_1-I_2}(x, y) = \begin{cases} 1, & \text{if } x = 0, \\ e \cdot I_1\left(x, \frac{y}{e}\right), & \text{if } x > 0 \text{ and } y \leq e, \\ e + (1-e) \cdot I_2\left(x, \frac{y-e}{1-e}\right), & \text{if } x > 0 \text{ and } y > e, \end{cases}$$

is called the  $e$ -threshold generated implication from  $I_1$  and  $I_2$ .

This method allows for a certain degree of control over the rate of increase in the second variable of the generated implication. Furthermore, the importance of this method derives from the fact that it allows us to characterize  $h$ -implications as the threshold generated implications of an  $f$ -generated and a  $g$ -generated implication [12.13, Theorem 2 and Remark 30]. Further, in contrast to many other generation methods of fuzzy implications from two given ones, it preserves (EP) and (12.5) if the initial implications possess them. Moreover, for an  $e \in (0, 1)$ , the  $e$ -threshold generated implications can be characterized as those implications that satisfy  $I(x, e) = e$  for all  $x > 0$ .

The threshold generation method given above is based on splitting the domain of the implication with a horizontal line and then scaling the two initial implications in order to be well defined in those two regions. An alternate but analogous method can be proposed by using a vertical line instead of a horizontal line. This is the idea behind the *vertical threshold generation* method of fuzzy implications. This method does not preserve as many properties as the horizontal threshold method, but some results can still be proven. In particular, they are characterized as those fuzzy implications such that  $I(e, y) = e$  for all  $y < 1$  [12.45].

The following two construction methods were presented in [12.46]. Given two implications  $I, J$ , the following operations are introduced

$$\begin{aligned} (I \nabla J)(x, y) &= I(J(y, x), J(x, y)), \\ (I \otimes J)(x, y) &= I(x, J(x, y)), \end{aligned}$$

for all  $x, y \in [0, 1]$ . The properties of these new operations as well as the structure of the set of all implications  $\mathbb{FI}$  equipped with each one of these operations is studied in [12.46].

### Other Construction Methods

In addition to the above methods, we would like to recall the following interesting method based on conditional probability and conditional distribution functions presented by Grzegorzewski in [12.47].

#### **Definition 12.7** [12.47, 48]

The function  $I_C: [0, 1]^2 \rightarrow [0, 1]$  given by

$$I_C(x, y) = \begin{cases} 1, & \text{if } x = 0, \\ \frac{C(x, y)}{x}, & \text{if } x > 0, \end{cases}$$

where  $C$  is a copula, is called a *probabilistic implication* based on copula  $C$ .

Conditions on copula  $C$  ensuring that the corresponding  $I_C$  is an implication, as well as properties of these implications are detailed in [12.48]. The main interest on this kind of implications lies in the fact that they are a powerful link between probability theory and fuzzy implications theory that can be useful in approximate reasoning. Moreover, results on these probabilistic implications can also be useful for examining and interpreting the behavior of some stochastic events. Some early results in this direction have appeared in [12.49, 50], where some generalizations of the previous idea are considered. In particular in [12.51], *survival implications* based on the probability that a given object will survive a fixed time into a population are studied. In this case, the survival implications are defined by

$$I_C^*(x, y) = \begin{cases} 1, & \text{if } x = 0, \\ \frac{x + y - 1 + C(1-x, 1-y)}{x}, & \text{if } x > 0, \end{cases}$$

where  $C$  is again a copula.

Finally, we only briefly mention that there exist other construction methods. For instance, Massanet and Torrens [12.13, 44, 45] have proposed methods of constructing implications derived from a given implication  $I$  and a fuzzy negation  $N$  as part of their study on some properties of horizontal and vertical threshold generated implications.

### 12.2.4 Fuzzy Implications in Nonclassical Settings

When we deal with uncertainty through fuzzy sets and fuzzy logic the natural framework is the unit interval  $[0, 1]$  and hence the logical connectives to be used

are interpreted as operators on this interval. However, there are many different tools that have been proposed for managing uncertainty. In this context, some extensions of fuzzy logic and fuzzy sets have also been developed. One can list at least the following extensions: interval-valued fuzzy sets, Atanassov intuitionistic fuzzy sets (that are equivalent to the interval-valued approach, [12.52]), interval-valued intuitionistic fuzzy sets, type-2 fuzzy sets, fuzzy multisets,  $n$ -dimensional fuzzy sets, and hesitant fuzzy sets.

For all these extensions, the usual logical connectives like fuzzy conjunctions and fuzzy disjunctions need to be studied to develop a comprehensive theory, and especially fuzzy implications in order to make inferences in each one of these extensions. Due to space constraints, we only recall some aspects of interval-valued (or intuitionistic) fuzzy implications and the references where they can be found.

### Interval-Valued Approach

A good compilation of the known results related to fuzzy implications (and other operations) in the interval-valued framework, can be found in [12.53] or [12.54] wherein, interval-valued or intuitionistic ( $S, N$ )- and  $R$ -implications are developed and some of their properties are presented. Works that deal with the construction of these classes of interval-valued implications can also be found in the literature. For instance, in [12.55] a construction method for the residual implication associated with a representable  $t$ -norm (constructed from two standard  $t$ -norms  $T_1$  and  $T_2$  with  $T_1 \leq T_2$ ) is presented. Similarly, ( $S, N$ )- and  $R$ -implications generated from:

- i) Aggregation functions and a standard fuzzy negation are presented in [12.56].
- ii) Some classes of interval-valued aggregation functions based on  $t$ -norms and  $t$ -conorms are dealt with in [12.57].
- iii) The so-called  $K_\alpha$ -operators have been proposed in [12.58].

### Discrete Approach

Note that all the above mentioned tools are mainly used in the management of imprecise quantitative information. However, experts deal with many problems where qualitative information is usually expressed through linguistic terms. Qualitative information is often interpreted to take values in a totally ordered finite scale like

$$\{Extremely\ Bad, Very\ Bad, Bad, Fair, Good, Very\ Good, Extremely\ Good\}. \quad (12.8)$$

In these cases, the representative finite chain  $L_n = \{0, 1, \dots, n\}$  is usually considered to model these linguistic hedges and several researchers have developed an extensive study of operations on  $L_n$ , usually called *discrete operations*. This approach allows avoiding numerical interpretations and consequently, the fuzzification and defuzzification steps become unnecessary. In this framework, the smoothness condition is usually considered as the discrete counterpart of continuity. In fact, in the discrete framework this property is equivalent to the divisibility property as well as to the Lipschitz condition. In this way, smooth discrete  $t$ -norms and  $t$ -conorms were studied and characterized in [12.59] and also discrete fuzzy implications derived from them have been introduced.

As in the case of  $[0, 1]$ , the four most usual ways to construct discrete implications from  $t$ -norms and  $t$ -conorms on  $L_n$  are  $(S, N)$ -,  $R$ -,  $QL$ -, and  $D$ -implications. The first two classes derived from smooth  $t$ -norms and  $t$ -conorms and the only strong negation on  $L_n$  (given by  $N_0(x) = n - x$ ) were studied in [12.60]. In the smooth case, it is proven that the intersection between  $(S, N)$ - and  $R$ -implications contains only the Łukasiewicz implication [12.60, Proposition 10]. Further, the nonsmooth case has also been investigated showing a parameterized family of nonsmooth  $t$ -norms  $T$  for which the corresponding  $R$ -implication coincides with the  $(S, N)$ -implication derived from the  $N_0$ -dual of  $T$ . The case of discrete  $QL$ - and  $D$ -operators is studied in [12.61], where characterization results on when such operators are in fact implications are given and, moreover, it is proven that both these classes coincide in the smooth case.

However, the modeling of linguistic information is limited because the information provided by experts for each variable must be expressed by a simple linguistic term. In most cases, this is a problem for experts because their opinion does not agree with a concrete term. On the contrary, experts' values are usually expressions like *better than Good*, *between Fair and Very Good*, or other even more complex expressions.

To avoid the limitation above, an approach has recently appeared trying to increase the flexibility of the elicitation of linguistic information. This approach deals with the possibility of extending monotonic operations on  $L_n$  to operations on the set of *discrete fuzzy numbers* whose support is a subinterval of  $L_n$ , usually denoted by  $\mathcal{A}_1^{L_n}$ . The idea lies in the fact that any discrete fuzzy number  $A \in \mathcal{A}_1^{L_n}$  can be considered (identifying the scale  $\mathcal{L}$  given in (12.8) with the chain  $L_6$ ) as an assignment of a  $[0, 1]$ -value to each term in our linguistic scale. As an example, the above mentioned expression *between Fair and Very Good* can be performed, for instance, by a discrete fuzzy number  $A \in \mathcal{A}_1^{L_6}$ , with support given by the subinterval

$$[\text{Fair, Very Good}] = \{\text{Fair, Good, Very Good}\},$$

(that corresponds to the subinterval  $[3, 5]$  in  $L_6$ ). The values of  $A$  in its support should be described by experts, allowing in this way a complete flexibility of the qualitative valuation. Usual operations like  $t$ -norms,  $t$ -conorms, strong negations, aggregation functions, and also fuzzy implications have been introduced in this framework. The case of  $(S, N)$ -,  $QL$ - and  $D$ -implications can be found in [12.62, 63] and the case of  $R$ -implications in [12.64].

## 12.3 Fuzzy Implications in Applications

So far, we have discussed the theoretical aspects of fuzzy implications, namely, analytical and algebraic. In this section, we discuss their applicational value which shows a wide spectrum of areas wherein they are employed and how the gamut of properties that a fuzzy implication possesses plays an important role in its employability.

### 12.3.1 $FL_n$ -Fuzzy Logic in the Narrow Sense

Boolean implications are employed in inference schemas like *modus ponens*, *modus tollens*, etc., where

the reasoning is done with statements or propositions whose truth-values are two valued. Fuzzy implications play a similar role in the generalizations of the above inference schemas, where reasoning is done with fuzzy statements whose truth-value lies in  $[0, 1]$  instead of  $\{0, 1\}$ .

#### Fuzzy Propositions

An expression of the form  $x$  is  $A$  where  $A$  is a fuzzy set on an appropriate domain  $U$ , with reference to the context, is termed as a *Fuzzy Statement* or a *Fuzzy Proposition*. (The above two interpretations bear a close

resemblance to the *Adjunctive* and *Connective* interpretations as given in [12.65, pp. 331], though they are originally given for a binary operator. For other views and interpretation of the above statement, see, for instance, *Bezdek et al.*, [12.66].)

Let it be given that  $x$  is  $A$  and also that  $x$  assumes the precise value, let us say,  $x = u$ , where  $u \in U$ , the domain of  $A$ . Then the truth value of the above fuzzy statement is obtained as follows

$$t(x \text{ is } A) = A(u),$$

i.e., the truth value of the above fuzzy statement, given that  $x$  is precisely known, is equal to the degree to which  $u$  – the value  $x$  assumes – is itself compatible with the fuzzy set  $A$ . Thus greater the membership degree of  $u$  in the concept  $A$ , higher is the truth value of the fuzzy statement.

Consider the statement *John is Tall* and that  $x$  – the height of John – is precisely given to be  $5'10'' \in U$ . Now,  $A(5'10'')$  gives the membership degree of  $5'10''$  in the concept  $A = \text{Tall}$ , which can be interpreted as how much *John* belongs to the set of all *Tall* men, or equivalently, how much *John is Tall* is true, which is nothing but the truth-value  $t(\text{John is Tall})$ .

### Fuzzy Conditionals or Fuzzy IF–THEN Rules

A fuzzy statement of the type discussed above  $\tilde{x}$  is  $A$  can be interpreted in yet another way, namely, as a linguistic statement, i.e., as an assignment of a fuzzy set to a variable.

Let  $A: U \rightarrow [0, 1]$  be a fuzzy set on a suitable domain  $U$ . Then  $A$  can be taken to represent a concept. A *linguistic variable* of  $U$  is a symbol  $\tilde{x}$  that can assume or be assigned any fuzzy subset of  $U$ . Then a linguistic statement  $\tilde{x}$  is  $A$  is interpreted as the linguistic variable  $\tilde{x}$  taking the *linguistic value*  $A$ .

For example, let  $U$  denote the set of all values in degrees centigrade. If the linguistic variable  $\tilde{x}$  denotes *Temperature*, then it can assume the following linguistic values  $A$ , namely, *high*, *more or less high*, *medium*, *cool*, *very cold*, etc. Each of the linguistic values (say  $A = \text{cool}$ ) is represented by a fuzzy set on the domain  $U$  of the linguistic variable  $\tilde{x}$ , i.e.,  $A: U \rightarrow [0, 1]$ .

The shape of the graph of the function represents the concept (say high temperature). The concept of high temperature is itself again context dependent. For example, high temperature (fever) for a human being is different from the high temperature in a blast furnace, and accordingly the domain of the linguistic variable is selected.

A fuzzy *IF–THEN* rule is of the form

$$\text{IF } \tilde{x} \text{ is } A \text{ THEN } \tilde{y} \text{ is } B, \quad (12.9)$$

where  $A, B$  are linguistic expressions/values assumed by the linguistic variables  $\tilde{x}, \tilde{y}$ . For example,

$$\begin{aligned} &\text{IF } \tilde{x} \text{ (temperature) is } A \text{ (high)} \\ &\text{THEN } \tilde{y} \text{ (pressure) is } B \text{ (low).} \end{aligned}$$

### Generalized Modus Ponens

Let  $\alpha, \beta$  be two fuzzy propositions as given above and let  $\alpha \rightarrow \beta$  be the fuzzy conditional which is a fuzzy IF–THEN rule as above. In classical logic, one uses rules of deduction, like modus ponens and modus tollens to deduce new knowledge from a given set of propositions. For instance, modus ponens states that  $\alpha \wedge (\alpha \rightarrow \beta) \vdash \beta$ .

In fuzzy logic, since we deal with fuzzy propositions whose truth values vary over the entire  $[0, 1]$  interval we employ fuzzy logic operations. Typically  $\wedge$  is interpreted as a  $t$ -norm  $T$  and for the  $\rightarrow$  a fuzzy implication is used.

Unlike with classical propositions, when we deal with fuzzy propositions it is not always given that from  $\alpha \wedge (\alpha \rightarrow \beta)$  one obtains  $\beta$ . This type of deduction is known as *generalized modus ponens* (**GMP**) and the study of pairs of operators  $(\wedge, \rightarrow)$ , or alternately, a  $t$ -norm and fuzzy implication  $(T, I)$ , that can be employed in **GMP** becomes important. It can be shown that this property translates to studying pairs  $(T, I)$  that satisfy the functional equation  $T(x, I(x, y)) \leq y$  for  $x, y \in [0, 1]$ , which is nothing but  $T$ -conditionality as dealt with in Sect. 12.2.1.

### Proof by Contradiction

In classical logic, many a time one proves a statement of the form  $\alpha \rightarrow \beta$  by proving its contrapositive, i.e.,  $\neg\beta \rightarrow \neg\alpha$ . However, in the setting of fuzzy logic, often the negation  $\neg$  used is noninvolutive, i.e.,  $\neg\neg\alpha \neq \alpha$ .

For instance, when the underlying fuzzy logic operations come from the Gödel residuated lattice  $([0, 1], T_M, I_{GD}, \wedge, \vee)$ , the natural negation of the fuzzy implication  $I_{GD}$  is not involutive and  $I_{GD}$  is not contrapositive w.r.t. any fuzzy negation. This led to the study of contrapositionalization of fuzzy implications which was begun by *Fodor* [12.40] and is dealt with in Sect. 12.2.3 above.

### 12.3.2 Approximate Reasoning

One of the best known application areas of fuzzy logic is *approximate reasoning* (AR), wherein from imprecise inputs and fuzzy premises or rules we obtain, often, imprecise conclusions [12.67]. AR with fuzzy sets encompasses a wide variety of inference schemes and have been readily embraced in many fields, especially among others: decision making, expert systems, and control. Fuzzy implications play a vital role in many of these inference mechanisms, a brief discussion of which is presented below.

#### Inference Mechanisms in AR

Let us be given a set of  $n$  fuzzy IF–THEN rules of the form given in (12.10)

$$\text{If } \tilde{x} \text{ is } A_i \text{ Then } \tilde{y} \text{ is } B_i, \quad i = 1, 2, \dots, n, \quad (12.10)$$

where  $A_i, B_i$  are fuzzy sets on input and output domains. Now, given a fuzzy input, i.e., a fuzzy proposition or a statement of the form  $\tilde{x}$  is  $A'$ , the role of an inference mechanism is to obtain a fuzzy output  $B'$  that satisfies some desirable properties [12.68, 69].

Note that, if we denote the fuzzy rules as  $A_i \rightarrow B_i$ ,  $i = 1, 2, \dots, n$ , as is typically done, then these are exactly the fuzzy conditionals discussed above in Sect. 12.3.1. Further, if we denote the input as  $A'$  then an inference mechanism implements the generalized modus ponens by *composing* the fuzzy input  $A'$  with all the rules  $A_i \rightarrow B_i$  to obtain the fuzzy output  $B'$ .

There are two established ways to accomplish the above, namely, *fuzzy relational inference* (FRI) and *similarity based reasoning* (SBR). Fuzzy implications play a major role in both the types of inference mechanisms as detailed below.

#### Fuzzy Relational Inference (FRI)

In a fuzzy relational inference, all the rules  $A_i \rightarrow B_i$  are combined into a single fuzzy relation  $R$  and the output  $B'$  is obtained as an image of the input  $A'$  composed with  $R$ .

A fuzzy IF–THEN rule base of the form (12.10) is modeled as a fuzzy relation  $\hat{R}(x, y): X \times Y \rightarrow [0, 1]$  as follows

$$\begin{aligned} \hat{R}(x, y) &= \wedge_{i=1}^n (A_i(x) \rightarrow B_i(y)) \\ &= \wedge_{i=1}^n (I(A_i(x), B_i(y))), \end{aligned} \quad (12.11)$$

which reflects the conditional nature of the rules and where  $I$  is usually a fuzzy implication. Then given a fact  $\tilde{x}$  is  $A'$ , the inferred output  $B'$  is obtained either as:

- i) sup- $T$  composition, as in the compositional rule of inference (**CRI**) of Zadeh [12.70], or
- ii) An inf- $I$  composition, as in the Bandler–Kohout subproduct (**BKS**) [12.71],

of  $A'(x)$  and  $\hat{R}(x, y)$ , i.e.,

$$B'(y) = A'(x) \circ T \hat{R}(x, y) = \sup_{x \in X} T(A'(x), \hat{R}(x, y)), \quad (12.12)$$

$$B'(y) = A'(x) \triangleleft I \hat{R}(x, y) = \inf_{x \in X} I(A'(x), \hat{R}(x, y)), \quad (12.13)$$

where  $T$  can be any  $t$ -norm and  $I$  is any fuzzy implication.

It is clear from (12.12) and (12.13) that the important role fuzzy implications and their properties play in the goodness of an inference scheme. In the following subsection, we present a few issues where this role is highlighted.

#### Issues in FRI

While the rule base is an example of a single input single output (**SISO**) case, in practice we need multi-input single-output (**MISO**) rules of the form given below, with  $m$  input domains  $X_j, j = 1, 2, \dots, m$ ,

$$\begin{aligned} R_i : \text{IF } \tilde{x}_1 \text{ is } A_{i1} \text{ AND } \tilde{x}_2 \text{ is } A_{i2} \text{ AND} \\ \dots \text{ AND } \tilde{x}_n \text{ is } A_{in} \text{ THEN } \tilde{y} \text{ is } B_i. \end{aligned}$$

While **MISO** rule bases are of great practical necessity, they spring up some new issues when they are employed in **FRI**s.

#### Combinatorial Explosion of Rules and Distributivity of Fuzzy Implications

Let there be  $k_j$  fuzzy sets defined on each of the domains  $X_j, j = 1, 2, \dots, m$ . Then in a complete **MISO** rule base, we will have  $n = k_1 \times k_2 \times \dots \times k_m$  number of rules. Clearly, as  $m$  or  $k_j$  increases  $n$  increases and we have a combinatorial explosion of rules.

In a seminal work on studying this issue, Combs and Andrews [12.72] proposed an equivalent transformation of the **CRI** to mitigate the computational cost. The authors showed that the distributivity of fuzzy implications over  $t$ -norms play a major role in this transformation. This was further studied by Balasubramaniam and Rao [12.10] and its use in **SBR** was also demonstrated later by Jayaram [12.73].

### Computational Complexity, Hierarchical Systems, and the Law of Importation

Let us consider an **MISO** rule base. From (12.11), it is clear that the relation  $\hat{R}$  obtained is a multidimensional matrix, with  $\hat{R} : X_1 \times X_2 \times \dots \times X_m \times Y \rightarrow [0, 1]$ . In fact, when one uses the First-Infer-Then-Aggregate mechanism in an **FRI**, either **CRI** or **BKS**, one needs to store  $n$  such  $m$ -dimensional matrices. Further, the input  $A'$  is also an  $m$ -dimensional matrix and the computation of the output gets costlier.

To overcome this, *Jayaram* [12.19] proposed an alternate hierarchical inference scheme which can be shown to be equivalent both in the **CRI** [12.19] and **BKS** [12.20] setting, when the underlying operators are such that the  $t$ -norm  $T$  and the fuzzy implication  $I$  satisfy the law of importation (12.5).

### 12.3.3 Fuzzy Subsethood Measures

Inclusion or subsethood of sets is an important concept. The first such definition of inclusion of a fuzzy set  $A$  over  $X$  in another fuzzy set  $B$ , was given by *Zadeh* [12.74] as follows

$$A \subset_Z B \iff A(x) \leq B(x), \quad \text{for all } x \in X.$$

Note that this definition was more or less *crisp*, since an  $A$  was either contained in  $B$  or not. A more general notion of degree of inclusion was missing in the above definition. Subsequently many fuzzy subsethood measures, denoted (usually) *Inc*, were proposed.

#### Axiomatic Studies on Fuzzy Subsethood Measures

From the isomorphism that exists between classical set theory and classical logic, we know that  $A \subseteq B$  is equivalent to  $\chi_A \implies \chi_B$ , where  $\chi_X$  is the characteristic function of the set  $X$ . Thus, early fuzzy subsethood measures also mimicked this equivalence by defining them based on fuzzy implications. Many researchers, in particular, *Sinha* and *Dougherty* [12.75], *Kitainik* [12.76], *Bandler* and *Kohout* [12.77] proposed sets of axioms for an *Inc* to satisfy.

It is easy to see that all of the above axiomatic approaches, eventually lead to employing implications as the underlying operators to define the corresponding *Inc*

measure, as given below

$$\text{Inc}_{\text{SD}}(A, B) = \inf_{x \in X} \min(1, \lambda(A(x)) + \lambda(1 - B(x))) ,$$

$$\text{Inc}_{\text{K}}(A, B) = \inf_{x \in X} \varphi(I_{\text{KD}}(B(x), A(x)),$$

$$1 - I_{\text{KD}}(A(x), B(x))) ,$$

$$\text{Inc}_{\text{BK}}(A, B) = \inf_{x \in X} (I(A(x), B(x))) ,$$

where  $\lambda : [0, 1] \rightarrow [0, 1]$  is a decreasing function with some additional properties,  $\varphi : \mathcal{A} \rightarrow [0, 1]$  a function with additional properties where  $\mathcal{A} = \{(x, y) \in [0, 1]^2 | x \geq y\}$  and  $I$  is any fuzzy implication.

From the above formulae the important position a fuzzy implication  $I$  holds in measuring fuzzy subsethood is apparent. Note that the *Inc* measure is used extensively in similarity based reasoning (**SBR**) and in fuzzy mathematical morphology (**FMM**) which are discussed below.

### 12.3.4 Fuzzy Control

While Sect. 12.3.2 dealt with **FRI**s which are largely used in the context of decision making and expert systems, in this section we deal with another type of fuzzy inference mechanism (**FIM**) that is used in fuzzy control, where the approximation properties of the **FIM** are important.

#### Similarity-Based Reasoning (**SBR**)

Let us once again consider a fuzzy IF–THEN rule base of the form (12.10) and a fuzzy input  $A'$ . In an **SBR** inference scheme, the following steps are employed to produce the output:

- **Matching:** The input  $A'$  is matched against each of the antecedents  $A_i$  of the rules (12.10) using a matching function  $M$  to obtain the corresponding similarity values  $s_i = M(A', A_i) \in [0, 1]$  for  $i = 1, 2, \dots, n$ .
- **Modification:** Each of the similarity values  $s_i$  is used to modify the corresponding consequent  $B_i$  of the rule (12.10) using a modification  $J$  to obtain the modified output  $B'_i = J(s_i, B_i)$ .
- **Aggregation:** Finally all the modified outputs  $B'_i$  are aggregated to obtain an overall output  $B = G(B'_1, \dots, B'_n)$ .

In notations, we can write the above as

$$B'(y) = G_{i=1}^n (J(M(A', A_i), B_i(y))) , \quad y \in Y . \quad (12.14)$$

### Fuzzy Implications and Matching Functions

Clearly, since  $A, A' \in \mathcal{F}(X)$ , we see that the matching function  $M : \mathcal{F}(X) \times \mathcal{F}(X) \rightarrow [0, 1]$ . Typically, a fuzzy subsethood measure  $Inc$  is employed as an  $M$ . While there exist  $M$  that are not based on fuzzy implications, it is seen that those that are based on fuzzy implications often satisfy many of the desirable properties required on the matching function  $M$  in different contexts, for instance, when the **SBR** is required to be interpolative, monotonic or for the **SBR** to possess good approximation properties. For more on this topic, see the works of Jayaram [12.73] or *Mandal and Jayaram* [12.78].

### Fuzzy Implications and Modification Functions

From (12.14), it is clear that the modification function  $J$  can be seen simply as a binary function on  $[0, 1]$ . While any fuzzy logic operation could be used for  $J$ , fuzzy implications are preferred either due to their properties or due to the conditional nature of the underlying rules. For instance, when  $J = I$  a fuzzy implication, if the original output  $B_i$  is normal then the modified output  $B'_i$  is also normal, which is usually not the case when one uses, say, a  $t$ -norm. In fact, different properties of  $I$  like (**OP**), (**IP**) and the nature of its natural negation  $N_I$  all play a role in the reasonableness of the final output of an **SBR**.

In real-life systems, the input and output domains  $X, Y$  are subsets of  $\mathbb{R}$ . Now, let the consequents  $B_i$  be of bounded support, i.e.,  $\{y \in Y \subset \mathbb{R} | B_i(y) > 0\} = [a, b] \subsetneq Y$  for some finite  $a, b \in \mathbb{R}$ . When an  $I$  whose  $N_I$  is not the Gödel least negation  $N_{D1}$  is employed, the support of  $B'_i$  becomes larger and in the case  $N_I$  is involutive then the support of the modified output sets  $B'_i$  become the whole of the set  $Y$ . This often makes the modified output sets  $B'_i$  to be nonconvex (and of larger support) and makes it difficult to apply standard defuzzification methods. For more on these see the works of Štěpnička and De Baets [12.79]. The above discussion brings out an interesting aspect of fuzzy implications. While fuzzy implications  $I$  whose  $N_I$  are strong are to be preferred in the setting of fuzzy logic  $FL_n$  for inferencing as noted in Sect. 12.3.1 above, an  $I$  with an  $N_I$  that is not even continuous is to be preferred in inference mechanisms used in fuzzy control.

By the *core* of a fuzzy set  $B$  on  $Y$ , we mean the set  $\{y \in Y | B(y) = 1\}$ . Now, an  $I$  which possesses (**OP**) or (**IP**) is preferred in an **SBR** to ensure there is an overlap between the cores of the modified outputs  $B'_i$  – a property that is so important to ensure *coherence* in the system [12.80] and that, once again, standard defuzzification methods can be applied.

### 12.3.5 Fuzzy Mathematical Morphology

Consider a 2D binary image  $\mathcal{P}$ , i.e., the value at a pixel is either 0 or 1.  $\mathcal{P}$  can be seen as a function from  $X \subset \mathbb{R}^2 \rightarrow \{0, 1\}$  or just a classical subset  $X \subset \mathbb{R}^2$ . Mathematical morphology (**MM**) is a set-theoretic method for the extraction of shape information from a scene. Here, a  $Y \subset \mathbb{R}^2$  – which can be seen as another image  $\mathcal{Q}$  and often referred to as the structuring element – is used to transform the original image  $\mathcal{P}$  by some well-defined local operators termed *Dilation* and *Erosion* as defined below

$$D(\mathcal{P}, \mathcal{Q}) = \{v \in \mathbb{R}^2 | \mathcal{A}_v(\mathcal{Q}) \cap \mathcal{P} \neq \emptyset\}, \quad (12.15)$$

$$E(\mathcal{P}, \mathcal{Q}) = \{v \in \mathbb{R}^2 | \mathcal{A}_v(\mathcal{Q}) \subseteq \mathcal{P}\}, \quad (12.16)$$

where  $\mathcal{A}_v(\mathcal{Q}) = \{u \in \mathbb{R}^2 | u - v \in \mathcal{Q}\}$  is the translation of  $\mathcal{Q}$  by  $v \in \mathbb{R}^2$ .

**FMM** is the extension of **MM** to gray-level images by using fuzzy sets and possibility theory. Note that a gray-level image  $\mathcal{P}$  can be interpreted as a fuzzy set  $X \subset \mathbb{R}^2 \rightarrow [0, 1]$  where the pixel value is interpreted as its membership degree to the original data set. This fuzzified image is then processed via morphological operators that are extensions of the boolean ones.

In the literature, one finds two approaches to this extension:

- i) As a formal translation of crisp equations using  $t$ -norms and negations, by employing a fuzzy intersection for  $\cap$  in (12.15) and a fuzzy subsethood measure  $Inc$  for  $\subseteq$  in (12.16), and
- ii) Using adjunction and residual implications.

While the first approach is based on the duality between dilation and erosion, the second approach stems more from an algebraic setting.

De Baets [12.81, 82] took the second approach, and defined the fuzzy *dilation* and *erosion* as follows

$$\tilde{D}(\mathcal{P}, \mathcal{Q})(y) = \sup_{x \in \mathcal{A}_v(Y) \cap X} [C(\mathcal{P}(x - y), \mathcal{Q}(x))],$$

$$\tilde{E}(\mathcal{P}, \mathcal{Q})(y) = \inf_{x \in \mathcal{A}_v(Y)} [I(\mathcal{P}(x - y), \mathcal{Q}(x))],$$

where  $C$  is any fuzzy conjunction and  $I$  is a fuzzy implication.

When the pair of operations  $(C, I)$  satisfy the adjunction property, or equivalently,  $I$  is a residual implication obtained from  $C$ , then many interesting aspects emerge. Firstly, it can be shown that *opening* and *closing* operations, which are some morphological operations obtained from the defined  $\tilde{D}, \tilde{E}$  turn out to

be idempotent, which is highly desirable [12.83]. Secondly, it can be shown, as was done by *Nachtegaeel* and *Kerre* [12.84], that this approach is more general and many other approaches become a specific case of it. Thirdly, recently, *Bloch* [12.85] showed that both the above approaches based on duality and adjunction are equivalent under some rather general and mild conditions,

## 12.4 Future of Fuzzy Implications

Since the publication of [12.2, 3], the peak of interest in fuzzy implications has led to a rapid progress in attempts to solve open problems in this topic. Specially, in [12.3], many open problems were presented covering all the subtopics of this field: characterizations, intersections, additional properties, etc. Many of these problems have been already solved and the solutions have been collected in [12.88]. However, there still remain many open problems involving fuzzy implications. Thus, in this section, we will list some of them whose choice has been dictated either based on the importance of the problem or the significance of the solution.

The first subset corresponds to open problems dealing with the satisfaction of particular additional properties of fuzzy implications. The first one deals with the law of importation (**LI**). Recently, some works have dealt with this property and its equivalence to the exchange principle and from them, some new characterizations of  $(S, N)$ - and  $R$ -implications based on (12.5) have been proposed, see [12.21]. However, some questions are still open. Firstly, (12.5) with a  $t$ -norm (or a more general conjunction) and (**EP**) are equivalent when  $N_I$  is a continuous negation, but the equivalence in general is not fully determined.

### Problem 12.1

Characterize all the cases when (**LI**) and (**EP**) are equivalent.

Secondly, it is not yet known which fuzzy implications satisfy (**LI**) when the conjunction operation is fixed.

### Problem 12.2

Given a conjunction  $C$  (usually a  $t$ -norm or a conjunctive uninorm), characterize all fuzzy implications  $I$  that satisfy (**LI**) with this conjunction  $C$ . For instance, which implications  $I$  satisfy the following functional equation

$$I(xy, z) = I(x, I(y, z))$$

that comes from (**LI**) with  $T = T_P$ ?

ditions, but those that often lead to highly desirable settings.

Recently, the approach initiated by De Baets has been enlarged by considering uninorms instead of  $t$ -norms and their residual implications with good results in edge detection, as well as in noise reduction [12.86, 87].

Another problem now concerning only the exchange principle follows.

### Problem 12.3

Give a necessary condition on a nonborder continuous  $t$ -norm  $T$  for the corresponding  $I_T$  to satisfy (**EP**).

It should be mentioned that some related work on the above problem appeared in [12.89].

Some other open problems with respect to the satisfaction of particular additional properties are based on the preservation of these properties from some initial fuzzy implications to the generated one using some construction methods like max, min, or the convex combination method.

### Problem 12.4

Characterize all fuzzy implications  $I, J$  such that  $I \vee J$ ,  $I \wedge J$  and  $K^\lambda$  satisfy (**EP**) or (**LI**), where  $\lambda \in [0, 1]$ .

The above problem is also related to the following one:

### Problem 12.5

Characterize the convex closures of the following families of fuzzy implications:  $(S, N)$ -,  $R$ - and Yager's  $f$ - and  $g$ -generated implications.

Another open problem which has immense applicational value is the satisfaction of the  $T$ -conditionality by the Yager's families of fuzzy implications.

### Problem 12.6

Characterize Yager's  $f$ -generated and  $g$ -generated implications satisfying the  $T$ -conditionality property with some  $t$ -norm  $T$ .

The following two open problems are related to the characterization of some particular classes of fuzzy implications.

**Problem 12.7**

What is the characterization of  $(S, N)$ -implications generated from noncontinuous negations?

**Problem 12.8**

Characterize triples  $(T, S, N)$  such that the corresponding QL-operation  $I_{T,S,N}$  satisfies (I1).

Finally, a fruitful topic where many open problems are still to be solved is the study of the intersections among the classes of fuzzy implications (Fig. 12.1).

**Problem 12.9**

- i) Is there a fuzzy implication  $I$ , other than the Weber implication  $I_{WB}$ , which is both an  $(S, N)$ -implication and an R-implication which is obtained from a nonborder continuous  $t$ -norm and cannot be obtained as the residual of any other left-continuous  $t$ -norm?

- ii) If the answer to the above question is affirmative, characterize the above nonempty intersection.

**Problem 12.10**

- i) Characterize the nonempty intersection between  $(S, N)$ -implications and QL-implications, i.e.,  $\mathbb{I}_{S,N} \cap \mathbb{I}_{QL}$ .
- ii) Is the Weber implication  $I_{WB}$  the only QL-implication that is also an R-implication obtained from a nonleft continuous  $t$ -norm? If not, give other examples from the above intersection and hence, characterize the nonempty intersection between R-implications and QL-implications.
- iii) Prove or disprove by giving an example: that there is no fuzzy implication which is both a QL- and an R-implication, but it is not an  $(S, N)$ -implication, i.e.,  $(\mathbb{I}_{QL} \cap \mathbb{I}_T) \setminus \mathbb{I}_{S,N} = \emptyset$ .

# Fuzzy Rule-Based Systems

Luis Magdalena

Fuzzy rule-based systems are one of the most important areas of application of fuzzy sets and fuzzy logic. Constituting an extension of classical rule-based systems, these have been successfully applied to a wide range of problems in different domains for which uncertainty and vagueness emerge in multiple ways. In a broad sense, fuzzy rule-based systems are rule-based systems, where fuzzy sets and fuzzy logic are used as tools for representing different forms of knowledge about the problem at hand, as well as for modeling the interactions and relationships existing between its variables. The use of fuzzy statements as one of the main constituents of the rules allows capturing and handling the potential uncertainty of the represented knowledge. On the other hand, thanks to the use of fuzzy logic, inference methods have become more robust and flexible. This chapter will mainly analyze what is a fuzzy rule-based system (from both conceptual and structural points of view), how is it built, and how can be used. The analysis will start by considering the two main conceptual components of these systems, knowledge, and reasoning, and how they are represented. Then, a review of the main structural approaches to fuzzy rule-based systems will be considered. Hierarchical fuzzy systems will also be analyzed. Once defined the components, struc-

ture and approaches to those systems, the question of design will be considered. Finally, some conclusions will be presented.

From the point of view of applications, one of the most important areas of fuzzy sets theory is that of fuzzy rule-based systems (**FRBSs**). These kind of systems constitute an extension of classical rule-based systems, considering *IF–THEN* rules whose antecedents and consequents are composed of fuzzy logic (**FL**) statements, instead of classical logic ones.

Conventional approaches to knowledge representation are based on bivalent logic, which has associated a serious shortcoming: the inability to reason in situa-

tions of uncertainty and imprecision. As a consequence, conventional approaches do not provide an adequate framework for this mode of reasoning familiar to humans, and most commonsense reasoning falls into this category.

In a broad sense, an **FRBS** is a rule-based system where fuzzy sets and **FL** are used as tools for representing different forms of knowledge about the problem at hand, as well as for modeling the interactions and relationships existing between its variables.

The use of fuzzy statements as one of the main constituents of the rules, allows capturing and handling the potential uncertainty of the represented knowledge. On the other hand, thanks to the use of fuzzy logic, inference methods have become more robust and flexible.

Due to these properties, **FRBSs** have been successfully applied to a wide range of problems in different domains for which uncertainty and vagueness emerge in multiple ways [13.1–5].

The analysis of **FRBSs** will start by considering the two main conceptual components of these systems, knowledge and reasoning, and how they are repre-

sented. Then, a review of the main structural approaches to **FRBSs** will be considered. Hierarchical fuzzy systems would probably match in this previous section, but being possible to combine the hierarchical approach with any of the structural models defined there, it seems better to consider it independently. Once defined the components, structure, and approaches to those systems, the question of design will be considered. Finally, some conclusions will be presented. It is important to notice that this chapter will concentrate on the general aspects related to **FRBSs** without deepening in the foundations of **FL** which are widely considered in previous chapters.

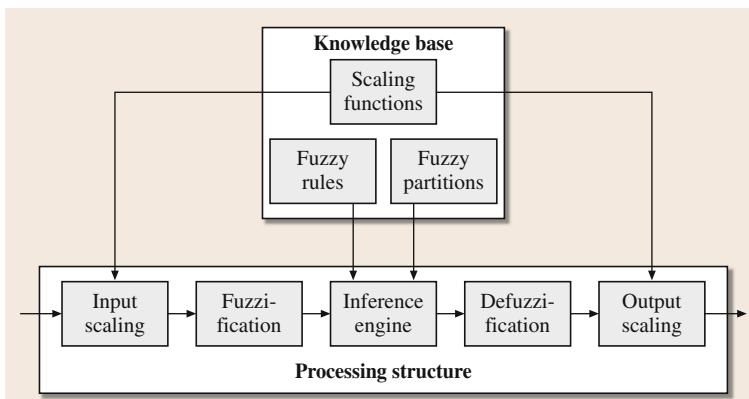

## 13.1 Components of a Fuzzy Rule-Based System

Knowledge representation in **FRBSs** is enhanced with the use of linguistic variables and their linguistic values, that are defined by context-dependent fuzzy sets whose meanings are specified by gradual membership functions [13.6–8]. On the other hand, **FL** inference methods such as generalized Modus Ponens, generalized Modus Tollens, etc., form the basis for approximate reasoning [13.9]. Hence, **FL** provides a unique computational framework for inference in rule-based systems. This idea implies the presence of two clearly different concepts in **FRBSs**: knowledge and reasoning. This clear separation between knowledge and reasoning (the *knowledge base (KB)*) and processing structure shown in Fig. 13.1) is the key aspect of knowledge-based systems, so that from this point of view, **FRBSs** can be considered as a type of knowledge-based system.

The first implementation of an **FRBS** dealing with real inputs and outputs was proposed by *Mam-*

*dani* [13.10], who considering the ideas published just a few months before by *Zadeh* [13.9] was able to augment his initial formulation allowing the application of fuzzy systems (**FSSs**) to a control problem, so creating the first fuzzy control application. These kinds of **FSSs** are also referred to as **FRBSs** with fuzzifier and defuzzifier or, more commonly, as *fuzzy logic controllers (FLCs)*, as proposed by the author in his pioneering paper [13.11], or *Mamdani FRBSs*. From the beginning, the term **FLC** became popular since control systems design constituted the main application of *Mamdani FRBSs*. At present, control is only one more of the many application areas of **FRBSs**.

The generic structure of a *Mamdani FRBS* is shown in Fig. 13.1. The **KB** stores the available knowledge about the problem in the form of fuzzy *IF–THEN* rules. The processing structure, by means of these rules, puts into effect the inference process on the system inputs.

**Fig. 13.1** General structure of a Mamdani **FRBS**

The fulfillment of rule antecedent gives rise to the execution of its consequent, i.e., one output is produced. The overall process includes several steps. The input and output scalings produce domain adaptations. Fuzzification interface establishes a mapping between crisp values in the input domain  $U$ , and fuzzy sets defined on the same universe of discourse. On the other hand, the defuzzification interface performs the opposite operation by defining a mapping between fuzzy sets defined in the output domain  $V$  and crisp values defined in the same universe. The central step of the process is inference.

The next two subsections analyze in depth the two main components of an **FRBS**, the **KB** and the processing structure, considering the case of a Mamdani **FRBS**.

### 13.1.1 Knowledge Base

The **KB** of an **FRBS** serves as the repository of the problem-specific knowledge – that models the relationship between input and output of the underlying system – upon which the inference process reasons to obtain from an observed input, an associated output.

This knowledge is represented in the form of rules, and the most common rule structure in Mamdani **FRBSs** involves the use of linguistic variables [13.6–8]. Hence, when dealing with multiple inputs-single output (**MISO**) systems, these *linguistic* rules possess the following form

$$\begin{aligned} \text{IF } X_1 \text{ is } LT_1 \text{ and } \dots \text{ and } X_n \text{ is } LT_n \\ \text{THEN } Y \text{ is } LT_o, \end{aligned} \quad (13.1)$$

with  $X_i$  and  $Y$  being, respectively, the input and output linguistic variables, and with  $LT_i$  being linguistic terms associated with these variables.

Note that the **KB** contains two different information levels, i.e., the linguistic variables (providing fuzzy rule semantics in the form of fuzzy partitions) and the linguistic rules representing the expert knowledge. Apart from that, a third component, scaling functions, is added in many **FRBSs** to act as an interfacing component for domain adaptation between the external world and the universes of discourse used at the level of the fuzzy partitions. This conceptual distinction drives to the three separate entities that constitute the **KB**:

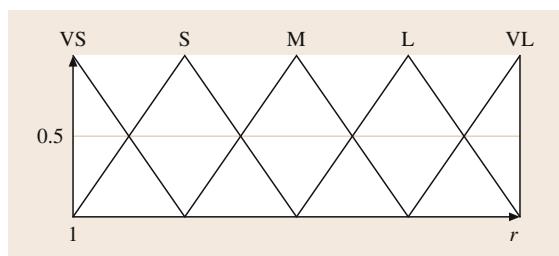

- The *fuzzy partitions* (also called Frames of Cognition) describe the sets of linguistic terms associated

with each variable and considered in the linguistic rules, and the membership functions defining the semantics of these linguistic terms. Each linguistic variable involved in the problem will have associated a fuzzy partition of its domain. Figure 13.2 shows a fuzzy partition using triangular membership functions. This structure provides a natural framework to include expert knowledge in the form of fuzzy rules. The fuzzy partition shown in the figure uses five linguistic terms *{very small, small, medium, large, and very large}*, (represented as VS, S, M, L, and VL, respectively) with the interval  $[l, r]$  being its domain (Universe of discourse). The figure also shows the membership function associated to each of these five terms.

- A *rule base (RB)* is comprised of a collection of linguistic rules (as the one shown in (13.1)) that are joined by the *also* operator. In other words, multiple rules can fire simultaneously for the same input.
- Moreover, the **KB** also comprises the *scaling functions* or scaling factors that are used to transform between the universe of discourse in which the fuzzy sets are defined from/to the domain of the system input and output variables.

It is important to note that the **RB** can present several structures. The usual one is the list of rules, although a decision table (also called rule matrix) becomes an equivalent and more compact representation for the same set of linguistic rules when only a few input variables (usually one or two) are considered by the **FRBS**.

Let us consider an **FRBS** where two input variables ( $x_1$  and  $x_2$ ) and a single output variable ( $y$ ) are involved, with the following term sets associated: *{small, medium, large}*, *{short, medium, long}* and *{bad, medium, good}*, respectively. The following **RB**

**Fig. 13.2** Example of a fuzzy partition

composed of five linguistic rules

- $R_1: \text{IF } X_1 \text{ is small and } X_2 \text{ is short THEN } Y \text{ is bad, also}$
  - $R_2: \text{IF } X_1 \text{ is small and } X_2 \text{ is medium THEN } Y \text{ is bad, also}$
  - $R_3: \text{IF } X_1 \text{ is medium and } X_2 \text{ is short THEN } Y \text{ is medium, also}$
  - $R_4: \text{IF } X_1 \text{ is large and } X_2 \text{ is medium THEN } Y \text{ is medium, also}$
  - $R_5: \text{IF } X_1 \text{ is large and } X_2 \text{ is long THEN } Y \text{ is good,}$
- (13.2)

can be represented by the decision table shown in Table 13.1.

Before concluding this section, we should notice two aspects. On one hand, the structure of a linguistic rule may be more generic if a connective other than the *and* operator is used to aggregate the terms in the rule antecedent. However, it has been demonstrated that the above rule structure is generic enough to subsume other possible rule representations [13.12]. The above rules are therefore commonly used throughout the literature due to their simplicity and generality. On the other hand, linguistic rules are not the only option and rules with a different structure can be considered, as we shall see in Sect. 13.2.

### 13.1.2 Processing Structure

The functioning of FRBSs has been described as the interaction of knowledge and reasoning. Once briefly considered the knowledge component, this section will analyze the reasoning (processing) structure. The processing structure of a Mamdani FRBS is composed of the following five components:

- The *input scaling* that transforms the values of the input variables from its domain to the one where the input fuzzy partitions are defined.

**Table 13.1** Example of a decision table

$x_2$	$x_1$	$x_1$	$x_1$
	<i>small</i>	<i>medium</i>	<i>large</i>
<i>short</i>	bad	medium	
<i>medium</i>	bad		medium
<i>long</i>			good

- A *fuzzification interface* that transforms the crisp input data into fuzzy values that serve as the input to the fuzzy reasoning process.
- An *inference engine* that infers from the fuzzy inputs to several resulting output fuzzy sets according to the information stored in the KB.
- A *defuzzification interface* that converts the fuzzy sets obtained from the inference process into a crisp value.
- The *output scaling* that transforms the defuzzified value from the domain of the output fuzzy partitions to that of the output variables, constituting the global output of the FRBS.

In the following, the five elements will be briefly described.

#### The Input/Output Scaling

Input/output scaling maps (applying the corresponding scaling functions or factors contained in the KB) the input/output variables to/from the universes of discourse over which the corresponding linguistic variables were defined.

This mapping can be performed with different functions ranging from a simple scaling factor to linear and nonlinear functions.

The initial idea for scaling was the use of *scaling factors* with a tuning purpose [13.13], giving a certain adaptation capability to the fuzzy system.

Additional degrees of freedom could be obtained by using a more complex scaling function. A second option is the use of *linear scaling* with a function of the form

$$f(x) = \lambda \cdot x + v, \quad (13.3)$$

where the scaling factor  $\lambda$  enlarges or reduces the operating range, which in turn decreases or increases the sensitivity of the system in respect to that input variable, or the corresponding gain in the case of an output variable. The parameter  $v$  shifts the operating range and plays the role of an offset for the corresponding variable.

Finally, it is possible to use more complex mappings generating *nonlinear scaling*. A common nonlinear scaling function is

$$f(x) = \text{sign}(x) \cdot |x|^\alpha. \quad (13.4)$$

This nonlinear scaling increases ( $\alpha > 1$ ) or decreases ( $\alpha < 1$ ) the relative sensitivity in the region closer to the

central point of the interval and has the opposite effect when moving far from the central point [13.14].

### The Fuzzification Interface

The fuzzification interface enables Mamdani FRBSs to handle crisp input values. Fuzzification establishes a mapping from crisp input values to fuzzy sets defined in the universe of discourse of those inputs. The membership function of the fuzzy set  $A'$  defined over the universe of discourse  $U$  associated to a crisp input value  $x_0$  is computed as

$$\mu_{A'} = F(x_0) , \quad (13.5)$$

in which  $F$  is a fuzzification operator.

The most common choice for the fuzzification operator  $F$  is the *point wise* or *singleton fuzzification*, where  $A'$  is built as a singleton with support  $x_0$ , i. e., it presents the following membership function:

$$\mu_{A'}(x) = \begin{cases} 1, & \text{if } x = x_0 \\ 0, & \text{otherwise.} \end{cases} \quad (13.6)$$

Nonsingleton options [13.15] are also possible and have been considered in some cases as a tool to represent the imprecision of measurements.

### The Inference System

The inference system is the component that derives the fuzzy outputs from the input fuzzy sets according to the relation defined through the fuzzy rules. The usual fuzzy inference scheme employs the generalized Modus Ponens, an extension to the classical Modus Ponens [13.9]

$$\begin{aligned} \text{IF } X \text{ is } A \text{ THEN } Y \text{ is } B \\ X \text{ is } A' \\ Y \text{ is } B'. \end{aligned} \quad (13.7)$$

In this expression, *IF X is A THEN Y is B* describes a conditional statement that in this case is a fuzzy conditional statement, since  $A$  and  $B$  are fuzzy sets, and  $X$  and  $Y$  are linguistic variables. A fuzzy conditional statement like this one represents a fuzzy relation between  $A$  and  $B$  defined in  $U \times V$ . This fuzzy relation is expressed again by a fuzzy set ( $R$ ) whose membership function  $\mu_R(x, y)$  is given by

$$\mu_R(x, y) = I(\mu_A(x), \mu_B(y)), \quad \forall x \in U, y \in V , \quad (13.8)$$

in which  $\mu_A(x)$  and  $\mu_B(y)$  are the membership functions of the fuzzy sets  $A$  and  $B$ , and  $I$  is a fuzzy implication operator that models the existing fuzzy relation.

Going back to (13.7), the result of applying generalized Modus Ponens is obtaining the fuzzy set  $B'$  (through its membership function) by means of the *compositional rule of inference* [13.9]:

*If  $R$  is a fuzzy relation defined in  $U$  and  $V$ , and  $A'$  is a fuzzy set defined in  $U$ , then the fuzzy set  $B'$ , induced by  $A'$ , is obtained from the composition of  $R$  and  $A'$ ,*

that is

$$B' = A' \circ R . \quad (13.9)$$

Now it is needed to compute the fuzzy set  $B'$  from  $A'$  and  $R$ . According to the definition of composition (*T-composition*) given in the chapter devoted to fuzzy relations, the result will be

$$\mu_{B'}(y) = \sup_{x \in U} T(\mu_{A'}(x), \mu_R(x, y)) , \quad (13.10)$$

where  $T$  is a triangular norm (t-norm). The concept and properties of t-norms have been previously introduced in the chapter devoted to fuzzy sets.

Given now an input value  $X = x_0$ , obtaining  $A'$  in accordance with (13.6) (where  $\mu_{A'}(x) = 0 \quad \forall x \neq x_0$ ), and considering the properties of t-norms ( $T(1, a) = a$ ,  $T(0, a) = 0$ ), the previous expression is reduced to

$$\begin{aligned} \mu_{B'}(y) &= T(\mu_{A'}(x_0), \mu_R(x_0, y)) \\ &= T(1, \mu_R(x_0, y)) = \mu_R(x_0, y) . \end{aligned} \quad (13.11)$$

The only additional point to arrive to the final value of  $\mu_{B'}(y)$  is the definition of  $R$ , the fuzzy relation representing the Implication. This is a somehow controversial question. Since the very first applications of FRBSs [13.10, 11] this relation has been implemented with the minimum (product has been also a common choice). If we analyze the definition of fuzzy implication given in the corresponding chapter, it is clear that the minimum does not satisfy all the conditions to be a fuzzy implication, so, why is it used? It can be said that initially it was a short of heuristic decision, which demonstrated really good results being accepted and reproduced in all subsequent applications. Further analysis can offer different explanations to this choice [13.16–18].

In any case, assuming the minimum as the representation for  $R$ , (13.11) produces the following final result:

$$\mu_{B'}(y) = \min(\mu_A(x_0), \mu_B(y)) . \quad (13.12)$$

Considering now an  $n$ -dimensional input space, the inference will establish a mapping between fuzzy sets defined in the Cartesian product ( $U = U_1 \times U_2 \times \dots \times U_n$ ) of the universes of discourse of the input variables  $X_1, \dots, X_n$ , and fuzzy sets defined in  $V$ , being the universe of discourse of the output variable  $Y$ . Therefore, when applied to the  $i$ th rule of the **RB**, defined as

$$R_i : \text{IF } X_1 \text{ is } A_{i1} \text{ and } \dots \text{ and } X_n \text{ is } A_{in} \text{ THEN } Y \text{ is } B_i , \quad (13.13)$$

considering an input value  $x_0 = (x_1, \dots, x_n)$ , the output fuzzy set  $B'$  will be obtained by replacing  $\mu_A(x_0)$  in (13.12) with,

$$\mu_{A_i}(x_0) = T(\mu_{A_{i1}}(x_1), \dots, \mu_{A_{in}}(x_n)) ,$$

where  $T$  is a fuzzy conjunctive operator (a t-norm).

### The Defuzzification Interface

The inference process in Mamdani-type **FRBSs** operates at the level of individual rules. Thus, the application of the compositional rule of inference to the current input, using the  $m$  rules in the **KB**, generates  $m$  output fuzzy sets  $B'_i$ . The defuzzification interface has to aggregate the information provided by the  $m$  individual outputs and obtain a crisp output value from the aggregated set. This task can be done in two different ways [13.1, 12, 19]: *Mode A-FATI* (first aggregate, then infer) and *Mode B-FITA* (first infer, then aggregate).

Mamdani originally suggested the mode A-FATI in his first conception of **FLCs** [13.10]. In the last few years, the Mode B-FITA is becoming more popular [13.19–21], in particular, in real-time applications which demand a fast response time.

**Mode A-FATI: First Aggregate, then Infer.** In this case, the defuzzification interface operates as follows:

- Aggregate the individual fuzzy sets  $B'_i$  into an overall fuzzy set  $B'$  by means of a fuzzy aggregation operator  $G$  (usually named as the *also* operator):

$$\mu_{B'}(y) = G \left\{ \mu_{B'_1}(y), \mu_{B'_2}(y), \dots, \mu_{B'_m}(y) \right\} . \quad (13.14)$$

- Employ a defuzzification method,  $D$ , transforming the fuzzy set  $B'$  into a crisp output value  $y_0$ :

$$y_0 = D(\mu_{B'}(y)) . \quad (13.15)$$

Usually, the aggregation operator  $G$  is implemented by the maximum (a t-conorm), and the defuzzifier  $D$  is the *center of gravity* (**CG**) or the *mean of maxima* (**MOM**), whose expressions are as follows:

- **CG:**

$$y_0 = \frac{\int_Y y \cdot \mu_{B'}(y) dy}{\int_Y \mu_{B'}(y) dy} . \quad (13.16)$$

- **MOM:**

$$y_{\inf} = \inf \{z | \mu_{B'}(z) = \max_y \mu_{B'}(y)\}$$

$$y_{\sup} = \sup \{z | \mu_{B'}(z) = \max_y \mu_{B'}(y)\}$$

$$y_0 = \frac{y_{\inf} + y_{\sup}}{2} . \quad (13.17)$$

**Mode B-FITA: First Infer, then Aggregate.** In this second approach, the contribution of each fuzzy set is considered separately and the final crisp value is obtained by means of an averaging or selection operation applied to the set of crisp values derived from each of the individual fuzzy sets  $B'_i$ .

The most common choice is either the **CG** or the **maximum value** (**MV**), then weighted by the matching degree. Its expression is shown as follows:

$$y_0 = \frac{\sum_{i=1}^m h_i \cdot y_i}{\sum_{i=1}^m h_i} , \quad (13.18)$$

with  $y_i$  being the **CG** or the **MV** of the fuzzy set  $B'_i$ , inferred from rule  $R_i$ , and  $h_i = \mu_{A_i}(x_0)$  being the matching between the system input  $x_0$  and the antecedent (premise) of rule  $i$ .

Hence, this approach avoids aggregating the rule outputs to generate the final fuzzy set  $B'$ , reducing the computational burden compared to mode A-FATI defuzzification.

This defuzzification mode constitutes a different approach to the notion of the *also* operator, and it is directly related to the idea of interpolation and the approach of Takagi–Sugeno–Kang (**TSK**) fuzzy systems, as can be seen by comparing (13.18) and (13.25).

## 13.2 Types of Fuzzy Rule-Based Systems

As discussed earlier, the first proposal of an **FRBS** was that of Mamdani, and this kind of system has been considered as the basis for the general description of previous section. This section will focus on the different structures that can be considered when building an **FRBS**.

### 13.2.1 Linguistic Fuzzy Rule-Based Systems

This approach corresponds to the original *Mamdani FRBS* [13.10, 11], being the main tool to develop Linguistic models, and is the approach that has been mainly considered to this point in the chapter.

A Mamdani **FRBS** provides a natural framework to include expert knowledge in the form of linguistic rules. This knowledge can be easily combined with rules which are automatically generated from data sets that describe the relation between system input and output. In addition, this knowledge is highly interpretable. The fuzzy rules are composed of input and output variables, which take values from their term sets having a meaning (a semantics) associated with each linguistic term. Therefore, each rule is a description of a condition-action statement that exhibits a clear interpretation to a human – for this reason, these kinds of systems are usually called *linguistic* or *descriptive Mamdani FRBSs*. This property makes Mamdani **FRBSs** appropriate for applications in which the emphasis lies on model interpretability, such as fuzzy control [13.20, 22, 23] and linguistic modeling [13.4, 21].

### 13.2.2 Variants of Mamdani Fuzzy Rule-Based Systems

Although Mamdani **FRBSs** possess several advantages, they also come with some drawbacks. One of the problems, especially in linguistic modeling applications, is their limited accuracy in some complex problems, which is due to the structure of the linguistic rules. [13.24] and [13.25] analyzed these limitations concluding that the structure of the fuzzy linguistic *IF–THEN* rule is subject to certain restrictions because of the use of linguistic variables:

- There is a lack of flexibility in the **FRBS** due to the rigid partitioning of the input and output spaces.

- When the input variables are mutually dependent, it becomes difficult to find a proper fuzzy partition of the input space.
- The homogeneous partition of the input and output space becomes inefficient and does not scale well as the dimensionality and complexity of the input–output mapping increases.
- The size of the **KB** increases rapidly with the number of variables and linguistic terms in the system. This problem is known as the *course of dimensionality*. In order to obtain an accurate **FRBS**, a fine level of granularity is needed, which requires additional linguistic terms. This increase in granularity causes the number of rules to grow, which complicates the interpretability of the system by a human. Moreover, in the vast majority of cases, it is possible to obtain an equivalent **FRBS** that achieves the same accuracy with a fewer number of rules whose fuzzy sets are not restricted to a fixed input space partition.

Both variants of linguistic Mamdani **FRBSs** described in this section attempt to solve the said problems by making the linguistic rule structure more flexible.

#### DNF Mamdani Fuzzy Rule-Based Systems

The first extension to Mamdani **FRBSs** aims at a different rule structure, the so-called *disjunctive normal form (DNF) fuzzy rule*, which has the following form [13.26, 27]:

$$\begin{aligned} &\text{IF } X_1 \text{ is } \tilde{A}_1 \text{ and } \dots \text{ and } X_n \text{ is } \tilde{A}_n \\ &\text{THEN } Y \text{ is } B, \end{aligned} \quad (13.19)$$

where each input variable  $X_i$  takes as its value a set of linguistic terms  $\tilde{A}_i$ , whose members are joined by a disjunctive operator, while the output variable remains a usual linguistic variable with a single label associated. Thus, the complete syntax for the antecedent of the rule is

$$\begin{aligned} X_1 \text{ is } \tilde{A}_1 &= \{A_{11} \text{ or } \dots \text{ or } A_{1l_1}\} \text{ and } \dots \\ \text{and } X_n \text{ is } \tilde{A}_n &= \{A_{n1} \text{ or } \dots \text{ or } A_{nl_n}\}. \end{aligned} \quad (13.20)$$

An example of this kind of rule is shown as follows. Let us suppose we have three input variables,  $X_1$ ,  $X_2$ , and  $X_3$ , and one output variable,  $Y$ , such that the linguistic

term sets  $D_i$  ( $i = 1, 2, 3$ ) and  $F$ , associated with each variable, are

$$\begin{aligned} D_1 &= \{A_{11}, A_{12}, A_{13}\} \\ D_2 &= \{A_{21}, A_{22}, A_{23}, A_{24}, A_{25}\} \\ D_3 &= \{A_{31}, A_{32}\} \quad F = \{B_1, B_2, B_3\}. \end{aligned} \quad (13.21)$$

In this case, an example of **DNF** rule will be

$$\begin{aligned} \text{IF } X_1 \text{ is } \{A_{11} \text{ or } A_{12}\} \text{ and } X_2 \text{ is } \{A_{23} \text{ or } A_{24}\} \\ \text{and } X_3 \text{ is } \{A_{31} \text{ or } A_{32}\} \text{ THEN } Y \text{ is } B_2. \end{aligned} \quad (13.22)$$

This expression contains an additional *connective* different than the *and* considered in all previous rules. The *or* connective is computed through a t-conorm, the maximum being the most commonly used.

The main advantage of this rule structure is its ability to integrate in a single expression (a single **DNF** rule) the information corresponding to several elemental rules (the rules commonly used in Mamdani **FRBSs**). In this example, (13.22) corresponds to 8 ( $2 \times 2 \times 2$ ) rules of the equivalent system expressed as (13.1). This property produces a certain level of compression of the rule base, being quite helpful when the number of input variables increases, alleviating the effect of the curse of dimensionality.

### Approximate Mamdani-Type Fuzzy Rule-Based Systems

While the previous **DNF** fuzzy rule structure does not involve an important loss in the linguistic Mamdani

**FRBS** interpretability, the point of departure for the second extension is to obtain an **FRBS** which achieves a better accuracy at the cost of reduced interpretability. These systems are called *approximate Mamdani-type FRBSs* [13.1, 25, 28–30], in opposition to the previous *descriptive* or *linguistic Mamdani FRBSs*.

The structure of an approximate **FRBS** is similar to that of a descriptive one shown in Fig. 13.1. The difference is that in this case, the rules do not refer in their definition to predefined fuzzy partitions of the linguistic variables. In an approximate **FRBS**, each rule defines its own fuzzy sets instead of using a linguistic label pointing to a particular fuzzy set of the partition of the underlying linguistic variable. Thus, an approximate fuzzy rule has the following form:

$$\text{IF } X_1 \text{ is } A_1 \text{ and } \dots \text{ and } X_n \text{ is } A_n \text{ THEN } Y \text{ is } B. \quad (13.23)$$

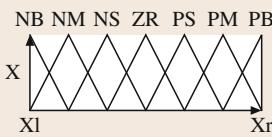

The major difference with respect to the rule structure considered in linguistic Mamdani **FRBSs** is the fact that the input variables  $X_i$  and the output one  $Y$  are fuzzy variables instead of linguistic variables and, thus,  $A_i$  and  $B$  are not linguistic terms ( $LT_i$ ) as they were in (13.1), but independently defined fuzzy sets that elude an intuitive linguistic interpretation. In other words, rules of approximate nature are *semantic free*, whereas descriptive rules operate in the context formulated by means of the linguistic terms semantics.

Therefore, approximate **FRBSs** do not rely on fuzzy partitions defining a semantic context in the form of linguistic terms. The fuzzy partitions are somehow integrated into the fuzzy rule base in which each rule subsumes the definition of its underlying input and output fuzzy sets, as shown in Fig. 13.3(b).

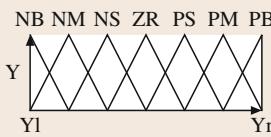

Approximate **FRBSs** demonstrate some specific advantages over linguistic **FRBSs** making them particularly useful for certain types of applications [13.25]:

- The major advantage of the approximate approach is that each rule employs its own distinct fuzzy sets resulting in additional degrees of freedom and an increase in expressiveness. It means that the tuning of a certain fuzzy set in a rule will have no effect on other rules, while changing a fuzzy set of a fuzzy partition in a descriptive model affects all rules considering the corresponding linguistic label.
- Another important advantage is that the number of rules can be adapted to the complexity of the problem. Simple input–output relationships are modeled with a few rules, but still more rules can be added as

#### a) Descriptive Knowledge base

- R1: If  $X$  is NB then  $Y$  is NB  
 R2: If  $X$  is NM then  $Y$  is NM  
 R3: If  $X$  is NS then  $Y$  is NS  
 R4: If  $X$  is ZR then  $Y$  is ZR

- R5: If  $X$  is PS then  $Y$  is PS  
 R6: If  $X$  is PM then  $Y$  is PM  
 R7: If  $X$  is PB then  $Y$  is PB

#### b) Approximate fuzzy rule base

- R1: If  $X$  is then  $Y$  is   
 R2: If  $X$  is then  $Y$  is   
 R3: If  $X$  is then  $Y$  is   
 R4: If  $X$  is then  $Y$  is

**Fig. 13.3a,b** Comparison between a descriptive KB and an approximate fuzzy rule base

the complexity of the problem increases. Therefore, approximate FRBSs constitute a potential remedy to the course of dimensionality that emerges when scaling to multidimensional systems.

These properties enable approximate FRBSs to achieve a better accuracy than linguistic FRBS in complex problem domains. However, despite their benefits, they also come with some drawbacks:

- Their main drawback compared to the descriptive FRBS is the degradation in terms of interpretability of the RB as the fuzzy variables no longer share a unique linguistic interpretation. Still, unlike other kinds of approximate models such as neural networks that store knowledge implicitly, the knowledge in an approximate FRBS remains explicit as the system behavior is described by local rules. Therefore, approximate FRBSs can be considered as a compromise between the apparent interpretability of descriptive FRBSs and the type of black-box behavior, typical for nondescriptive, implicit models.
- The capability to approximate a set of training data accurately can lead to over-fitting and therefore to a poor generalization capability to cope with previously unseen input data.

According to their properties, fuzzy modeling [13.1] constitutes the major application of approximate FRBSs, as model accuracy is more relevant than description ability. Approximate FRBSs are usually not the first choice for linguistic modeling and fuzzy control problems. Hence, descriptive and approximate FRBSs are considered as complementary rather than competitive approaches. Depending on the problem domain and requirements on the obtained model, one should use one or the other approach. Approximate FRBSs are recommendable in case one wants to trade interpretability for improved accuracy.

### 13.2.3 Takagi–Sugeno–Kang Fuzzy Rule-Based Systems

Instead of working with linguistic rules of the kind introduced in the previous section, Sugeno et al. [13.31, 32] proposed a new model based on rules whose antecedent is composed of linguistic variables and the consequent is represented by a function of the input variables. The most common form of this kind of rules is the one in which the consequent expression consti-

tutes a linear combination of the variables involved in the antecedent

$$\begin{aligned} & \text{IF } X_1 \text{ is } A_1 \text{ and } \dots \text{ and } X_n \text{ is } A_n \\ & \text{THEN } Y = p_0 + p_1 \cdot X_1 + \dots + p_n \cdot X_n, \end{aligned} \quad (13.24)$$

where  $X_i$  are the input variables,  $Y$  is the output variable, and  $p = (p_0, p_1, \dots, p_n)$  is a vector of real parameters. Regarding  $A_i$ , they are either a direct specification of a fuzzy set (thus  $X_i$  being fuzzy variables) or a linguistic label that points to a particular member of a fuzzy partition of a linguistic variable. These rules, and consequently the systems using them, are usually called **TSK fuzzy rules**, in reference to the names of their first proponents.

The output of a TSK FRBS, using a KB composed of  $m$  rules, is obtained as a weighted sum of the individual outputs provided by each rule,  $Y_i$ ,  $i = 1, \dots, m$ , as follows:

$$\frac{\sum_{i=1}^m h_i \cdot Y_i}{\sum_{i=1}^m h_i}, \quad (13.25)$$

in which  $h_i = T(A_{i1}(x_1), \dots, A_{in}(x_n))$  is the matching degree between the antecedent part of the  $i$ th rule and the current inputs to the system,  $x_0 = (x_1, \dots, x_n)$ .  $T$  stands for a conjunctive operator modeled by a t-norm. Therefore, to design the inference engine of TSK FRBSs, the designer only selects this conjunctive operator  $T$ , with the most common choices being the minimum and the product. As a consequence, TSK systems do not need defuzzification, being their outputs real numbers.

This type of FRBS divides the input space in several fuzzy subspaces and defines a linear input–output relationship in each one of these subspaces [13.31]. In the inference process, these partial relationships are combined in the said way for obtaining the global input–output relationship, taking into account the dominance of the partial relationships in their respective areas of application and the conflicts emerging in the overlapping zones. As a result, the overall system performs as a sort of interpolation of the local models represented by each individual rule.

TSK FRBSs have been successfully applied to a large variety of practical problems. The main advantage of these systems is that they present a set of compact system equations that allows the parameters  $p_i$  to be estimated by means of classical regression methods, which facilitates the design process. However, the main drawback associated with TSK FRBSs is the form

of the rule consequents, which does not provide a natural framework for representing expert knowledge that is afflicted with uncertainty. Still, it becomes possible to integrate expert knowledge in these **FRBSs** by slightly modifying the rule consequent: for each linguistic rule with consequent  $Y$  is  $B$ , provided by an expert, its consequent is substituted by  $Y = p_0$ , with  $p_0$  standing for the modal point of the fuzzy set associated with the label  $B$ . These kinds of rules are usually called *simplified TSK rules* or *zero-order TSK rules*.

However, **TSK FRBSs** are more difficult to interpret than Mamdani **FRBSs** due to two different reasons:

- The structure of the rule consequents is difficult to be understood by human experts, except for zero-order **TSK**.
- Their overall output simultaneously depends on the activation of the rule antecedents and on the evaluation of the function defining rule consequent, that depends itself on the crisp inputs as well, rather than being constant.

**TSK FRBSs** are used in fuzzy modeling [13.4, 31] as well as control problems [13.31, 33].

As with Mamdani **FRBSs**, it is also possible to build descriptive as well as approximate **TSK** systems.

### 13.2.4 Singleton Fuzzy Rule-Based Systems

The singleton **FRBS**, where the rule consequent takes a single real-valued number, may be considered as a particular case of the linguistic **FRBS** (the consequent is a fuzzy set where the membership function is one for a specific value and zero for the remaining ones) or of the **TSK**-type **FRBS** (the previously described zero-order **TSK** systems).

Its rule structure is the following

$$\begin{aligned} & \text{IF } X_1 \text{ is } A_1 \text{ and } \dots \text{ and } X_n \text{ is } A_n \\ & \text{THEN } Y \text{ is } y_0 . \end{aligned} \quad (13.26)$$

Since the single consequent seems to be more easily interpretable than a polynomial function, the singleton **FRBS** may be used to develop linguistic fuzzy models. Nevertheless, compared with the linguistic **FRBS**, the fact of having a different consequent value for each rule (no global semantic is used for the output variable) worsens the interpretability.

### 13.2.5 Fuzzy Rule-Based Classifiers

Previous sections have implicitly considered **FRBSs** working with inputs and, what is more important, out-

puts which are real variables. These kinds of fuzzy systems show an interpolative behavior where the overall output is a combination of the individual outputs of the fired rules. This interpolative behavior is explicit in **TSK** models but it is also present in Mamdani systems. This situation gives **FRBSs** a sort of smooth output, generating soft transitions between rules, and being one of the significant properties of **FRBSs**.

A completely different situation is that of having a problem where the output takes values from a finite list of possible values representing categories or classes. Under those circumstances, the interpolative approach of previously defined aggregation and defuzzification methods, makes no sense. As a consequence, some additional comments will be added to highlight the main characteristics of fuzzy rule-based classifiers (**FRBCs**), and the differences with other **FRBSs**.

A fuzzy rule-based classifier is an automatic classification system that uses fuzzy rules as knowledge representation tool. Therefore, the fuzzy classification rule structure is as follows

$$\begin{aligned} & \text{IF } X_1 \text{ is } A_1 \text{ and } \dots \text{ and } X_n \text{ is } A_n \\ & \text{THEN } Y \text{ is } C , \end{aligned} \quad (13.27)$$

with  $Y$  being a categorical variable, so  $C$  being a class label. The processing structure is similar to that previously described in what concerns to the evaluation of matching degree between each rule's antecedent and current input, i.e., for each rule  $R_i$  we obtain  $h_i = T(A_{i1}(x_1), \dots, A_{in}(x_n))$ . Once obtained  $h_i$ , the winner rule criteria could be applied so that the overall output is assigned with the consequent of the rule achieving the highest matching degree (highest value of  $h_i$ ). More elaborated evaluations as voting are also possible.

Other alternative representations that include a certainty degree or weight for each rule have also been considered [13.34]. In this case, the previously described rule will also include a rule weight  $w_i$  that weights the matching degree during the inference process. The effect will be that the winning rule will be that achieving the highest value of  $h_i \cdot w_i$ , or in the case of voting schemes, the influence of the vote of the rule will be proportional to this value.

### 13.2.6 Type-2 Fuzzy Rule-Based Systems

The idea of extending fuzzy sets by allowing membership functions to include some kind of uncertainty was already mentioned by Zadeh in early papers [13.6–8]. The idea, that was not really exploited for a long period,

has achieved now a significant presence in the literature with the proposal of Type-2 fuzzy systems and Interval type-2 fuzzy systems [13.35]. The main concept is that the membership degree is not a value but a fuzzy set or an interval, respectively. The effect is obtaining additional degrees of freedom being available in the design process, but increasing the complexity of the processing structure that requires now a type-reduction step added to the overall process described in previous section. As the complexity of the type reduction process is much lower for Interval type-2 fuzzy systems than in the general case of type-2 fuzzy systems, interval approaches are the most widely considered now in the area of Type-2 fuzzy sets.

### 13.2.7 Fuzzy Systems with Implicative Rules

Rule-based systems mentioned to this point consider rules that, having the form *if X is A then Y is B*, model the inference through a t-norm, usually minimum or product (Sect. 13.1.2). With this interpretation, rules are

described as conjunctive rules, representing joint sets of possible input and output values. As mentioned in the chapter devoted to fuzzy control, these rules should be seen not as logical implications but rather as input–output associations.

That kind of rule is the one commonly used in real applications to the date. However, different authors have pointed out that the same rule will have a completely different meaning when modeled in terms of material implications (the approach for Boolean *if–then* statements in propositional logic) [13.18]. As a result, in addition to the common interpretation of fuzzy rules that is widely considered in the literature, some authors are exploring the modeling of fuzzy rules (with exactly the same structure previously mentioned) by means of *material implications* [13.36]. Even being in a quite preliminary stage of development, it is interesting to mention this ideas since it constitutes a completely different interpretation of **FRBSs**, offering so new possibilities to the field.

## 13.3 Hierarchical Fuzzy Rule-Based Systems

The knowledge structure of **FRBSs** offers different options to introduce hierarchical structures. Rules, partitions, or variables can be distributed at different levels according to their specificity, granularity, relevance, etc. This section will introduce different approaches to hierarchical **FRBSs**.

It would be possible to consider hierarchical fuzzy systems as a different type of **FRBS**, so including it in previous section, or as a design option to build *simpler* **FRBSs**, being then included as part of the next section. Including it in previous section could be a little bit confusing since it is possible to combine the hierarchical approach with several of the structural models defined there, it seems better to consider it independently devoting a section to analyze them.

The definition of hierarchical fuzzy systems as a method to solve problems with a higher level of complexity than those usually focused on with **FRBSs**, has produced some good results. In most of the cases, the underlying idea is to cope with the complexity of a problem by applying some kind of decomposition that generates a hierarchy of lower complexity systems [13.37].

Several methods to establish hierarchies in fuzzy controllers have been proposed. These methods

could be grouped according to the way they structure the inference process, and the knowledge applied.

A first approach defines the hierarchy as a prioritization of rules in such a way that rules with a different level of specificity receive a different priority, having higher priority those rules being more specific [13.38, 39]. With this kind of hierarchy, a generic rule is applied only when no suitable specific rule is available. In this case, the hierarchy is the effect of a particular implication mechanism applying the rules by taking into account its priority. This methodology defines the hierarchy (the decomposition) at the level of rules. The rules are grouped into prioritized levels to design a hierarchical fuzzy controller.

Another option is that of considering a hierarchy of fuzzy partitions with different granularity [13.40]. From that point, an **FRBS** is structured in layers, where each layer contains fuzzy partitions with a different granularity, as well as the rules using those fuzzy partitions. Usually, every partition in a certain layer has the same number of fuzzy terms. In this case, rules at different layers have different granularity, being somehow related to the idea of specificity of the previous paragraph. It is even possible to generate a multilevel grid-like

partition where only for some specific regions of the input space (usually those regions showing poor performance) a higher granularity is considered [13.41], with a similar approach to that already considered in some neuro-fuzzy systems [13.42].

A completely different point of view is that of introducing the decomposition at the level of variables. In this case, the input space is decomposed into subspaces of lower dimensionality, and each input variable is only considered at a certain level of the hierarchy. The result is a cascade structure of **FRBSs** where, in addition to a subset of the input variables, the output of each level is considered as one of the inputs to the following level [13.43]. As a result, the system is decomposed into a finite number of reduced-order subsystems, eliminating the need for a large-sized inference engine. This decomposition is usually stated as a way to maintain under control the problems generated by the so-called course of dimensionality, the exponential growth of the number of rules related to the number of variables of the system.

The number of rules of an **FRBS** with  $n$  input variables and  $l$  linguistic terms per variable, will be  $l^n$ . In this approach to hierarchical **FRBSs**, the variables (and rules) are divided into different levels in such a way that those considered the most influential variables are chosen as input variables at the first level, the next most important variables are chosen as input variables at the

second level, and so on. The output variable of each level is introduced as input variable at the following level.

With that structure, the rules at first level of the **FRBS** have a similar structure to any Mamdani **FRBS**, i.e., that describe by (13.1), but at  $k$ -th level ( $k > 1$ ), rules include the output of the previous level as input

$$\text{IF } X_{N_k+1} \text{ is } LT_{N_k+1} \text{ and } \dots \text{ and } X_{N_k+n_k} \text{ is } LT_{N_k+n_k} \\ \text{and } O_{k-1} \text{ is } LT_{O_{k-1}} \text{ THEN } O_k \text{ is } LT_{O_k}, \quad (13.28)$$

where the value  $N_k$  determines the input variables considered in previous levels

$$N_k = \sum_{t=1}^{k-1} n_t, \quad (13.29)$$

with  $n_t$  being the number of system variables applied at level  $t$ . Variable  $O_k$  represent the output of the  $k$  level of the hierarchy. All outputs are intermediate variables except for the output of the last level that will be  $Y$  (the overall output of the system).

With this structure it is shown [13.43] that the number of rules in a complete rule base could be reduced to a linear function of the number of variables, while in a conventional **FRBS** it was an exponential function of the number of variables.

## 13.4 Fuzzy Rule-Based Systems Design

Once defined the components and functioning of an **FRBS**, it is time to consider its design, i.e., how to built an **FRBS** to solve a certain problem while showing some specific properties. The present section will focus on this question.

An **FRBS** can be characterized according to its structure and its behavior. When referring to its structure, we can consider questions as the dimension of the system (number of variables, fuzzy sets, rules, etc.) as well as other aspects related to properties of its components (distinguishability of the fuzzy sets, redundancy of the fuzzy rules, etc.). On the other hand, the characterization related to the behavior mostly analyzes properties considering the input–output relation defined by the **FRBS**. In this area, we can include questions as stability or accuracy. Finally, there is a third question that simultaneously involves structure and behavior. This question is interpretability, a central aspect

in fuzzy systems design that is considered in an independent chapter.

### 13.4.1 FRBS Properties

All the structural properties to be mentioned are related to properties of the **KB**, and basically cover characteristics related to the individual fuzzy sets, the fuzzy partitions related to each input and output variable, the fuzzy rules, and the rule set as a whole.

The elemental components of the **KB** are fuzzy sets. At this level, we have several questions to be analyzed as normality, convexity, or differentiability of fuzzy sets; all of them being related to the properties of the membership function ( $\mu_A(x)$ ) defining the fuzzy set ( $A$ ). In most applications the considered fuzzy sets adopt predefined shapes as triangular, trapezoidal, Gaussian, or bell; the fuzzy sets are then defined by only changing

some parameters of these *parameterized functions*. In summary, most fuzzy sets considered in **FRBS**s are normal and convex sets belonging to one of two possible families: piecewise linear functions and differentiable functions. Piecewise linear functions are basically triangular and trapezoidal functions offering a reduced complexity from the processing point of view. On the other hand, differentiable functions are mainly Gaussian, bell, and sigmoidal functions being better adapted to some kind of differential learning approaches as those used in neuro-fuzzy systems, but adding complexity from the processing point of view.

Once individual fuzzy sets have been considered, the following level is that of fuzzy partitions related to each variable. The main characteristics of a fuzzy partition are cardinality, coverage, and distinguishability. Cardinality corresponds to the number of fuzzy sets that compose the fuzzy partitions. In most cases, this number ranges from 3 to 9, with 9 being an upper limit commonly accepted after the ideas of *Miller* [13.44]. The larger the number of fuzzy sets in the partition, the most difficult the design and interpretation of the **FRBS**. Coverage corresponds to the minimum membership degree with which any value of the variable ( $x$ ), through its universe of discourse ( $U$ ), will be assigned to at least a fuzzy set ( $A_i$ ) in the partition. Coverage is then defined as

$$\min_{x \in U} \max_{i=1 \dots n} \mu_{A_i}(x), \quad (13.30)$$

being  $n$  the cardinality of the partition. As an example, the fuzzy partition in Fig. 13.2 has a coverage of 0.5. Finally, distinguishability of fuzzy sets is related to the level of overlapping of their membership functions, being analyzed with different expressions.

On the basis of the fuzzy sets and fuzzy partitions, the fuzzy rules are built. The first structural question regarding fuzzy rules is the type of fuzzy rule to be considered: Mamdani, **TSK**, descriptive or approximate, **DNF**, etc. If we consider now the interaction between the different fuzzy rules of a fuzzy system, questions as knowledge consistency or redundancy appear, i. e., does a fuzzy system include pieces of knowledge (usually rules) providing contradictory (or redundant) information for a specific situation. Finally, when considering the rule base as a whole, completeness and complexity are to be considered. Completeness refers to the fact that any potential input value will fire at least one rule.

Considering now behavioral properties, the most widely analyzed are stability and accuracy. It is also

possible to take into account other properties as continuity or robustness, but we will concentrate in those having the larger presence in the literature. Behavioral properties are related to the overall system, i. e., to the processing structure as well as to the **KB**.

Stability is a key aspect of dynamical systems analysis, and plays a central role in control theory. **FRBS**s are nonlinear dynamical systems, and after its early application to control problems, the absence of a formal stability analysis was seriously criticized. As a consequence, the stability question received significant attention from the very beginning, at present being a widely studied problem [13.45] for both Mamdani and **TSK** fuzzy systems, considering the use of different approaches as Lyapunov's methods, Popov criterion or norm-based analysis among others.

Another question with a continuous presence in the literature is that of accuracy and the somehow related concept of universal approximation. The idea of fuzzy systems as universal approximators states that, given any continuous real-valued function on a compact subset of  $R^n$ , we can, at least in theory, find an **FRBS** that approximates this function to any degree. This property has been established for different types of fuzzy systems [13.46–48]. On this basis, the idea of building fuzzy models with an unbounded level of accuracy can be considered. In any case, it is important to notice that previous papers proof the existence of such a model but assuming at the same time an unbounded complexity, i. e., the number of fuzzy sets and rules involved in the fuzzy system will usually grow as the accuracy improves. That means that improving accuracy is possible but always with a cost related either to the complexity of the system or to the relaxation of some of its properties (usually interpretability).

### 13.4.2 Designing **FRBS**s

Given a modeling, classification, or control problem to be solved, and assumed it will be focused on through an **FRBS**, there are several steps in the process of design. The first decision is the choice between the different types of systems mentioned in Sect. 13.2, particularly Mamdani and **TSK** approaches. They offer different characteristics related to questions as their accuracy and interpretability, as well as different methods for the derivation of its **KB**.

Once chosen a type of **FRBS**, its design implies the construction of its processing structure as well as the derivation of its **KB**. Even considering that there are several options to modify the

processing structure of the system (Sect. 13.1.2), most designers consider a standard inference engine and concentrate on the knowledge extraction problem.

Going now to the knowledge extraction problem, some of its parts are common to any modeling process (being fuzzy or not). Questions as the selection of the input and output variables and the determination of the range of those variables are generic to any modeling approach. The specific aspects related to the fuzzy environment are the definition of the fuzzy sets or the fuzzy partition related to each of those variables, and the derivation of a suitable set of fuzzy rules. These two components can be jointly derived in a single process, or sequentially performed by considering first the design of the fuzzy partition associated with each variable and then the fuzzy rules. The design process can be based on two main sources of information: expert knowledge and experimental data.

If we first consider the definition of fuzzy sets and fuzzy partitions, quite different approaches [13.49] can be applied. Even the idea of simply generating a uni-

formly distributed strong fuzzy partition of a certain cardinality is widely considered.

Going now to rules, Mamdani **FRBSs** are particularly adapted to expert knowledge extraction, and knowledge elicitation for that kind of system has been widely considered in the literature. In any case, there is not a standard methodology for fuzzy knowledge extraction from experts and at present most practical works consider either a direct data-driven approach, or the integration of expert and data-driven knowledge extraction [13.50].

When considering data-driven knowledge extraction, there is an almost endless list of approaches. Some options are the use of ad-hoc methods based on data covering measures (as [13.46]), the generation of fuzzy decisions trees [13.51], the use of clustering techniques [13.52], and the use of hybrid systems where genetic fuzzy systems [13.53] and neuro fuzzy systems [13.54] represent the most widely considered approaches to fuzzy systems design. Some of those techniques produce both the partitions (or fuzzy sets) and the rules in a single process.

## 13.5 Conclusions

Fuzzy rule-based systems constitute a tool for representing knowledge and reasoning on it. Jointly with fuzzy clustering techniques, **FRBSs** are probably the developments of fuzzy sets theory leading to the larger number of applications. These systems, being a kind of rule-based system, can be analyzed as knowledge-based systems showing a structure with two main components: knowledge and processing. The processing structure relays on many concepts presented in previous chapters as fuzzy implications, connectives, relations and so on. In addition, some new concepts as fuzzification and defuzzification are required when constructing a fuzzy rule-based system. But the central concept of fuzzy rule-based systems are fuzzy rules. Different types of fuzzy rules have been considered, particularly those having a fuzzy (or not) consequent, producing different types of **FRBS**. In addition, new formulations are being considered, e.g., implicative rules. Eventually, the representation capabilities of fuzzy sets have been considered as too limited to represent some specific kinds of knowledge or information, and some extended types of fuzzy sets have been defined. Type-2 fuzzy sets are an example of extension of fuzzy sets.

Having been said that **FRBSs** are knowledge-based systems, and as a consequence, its design involves, apart from aspects related to the processing structure, the elicitation of a suitable **KB** properly describing the way to solve the problem under consideration. Even considering the large number of problems solved using **FRBSs**, there is not a clear design methodology defining a well-established design protocol. In addition, two completely different sources of knowledge, requiring different extraction approaches, have been considered when building **FRBSs**: expert knowledge and data. Many expert and data-driven knowledge extraction techniques and methods are described in the literature and can be considered. Connected to this question, as part of the process to provide automatic knowledge extraction capabilities to **FRBSs**, many hybrid approaches have been proposed, genetic fuzzy systems and neuro-fuzzy systems being the most widely considered.

In summary, **FRBSs** are a powerful tool to solve real world problems, but many theoretical aspects and design questions remain open for further investigation.

# 14. Interpretability of Fuzzy Systems: Current Research Trends and Prospects

**Jose M. Alonso, Ciro Castiello, Corrado Mencar**

Fuzzy systems are universally acknowledged as valuable tools to model complex phenomena while preserving a readable form of knowledge representation. The resort to natural language for expressing the terms involved in fuzzy rules, in fact, is a key factor to conjugate mathematical formalism and logical inference with human-centered interpretability. That makes fuzzy systems specifically suitable in every real-world context where people are in charge of crucial decisions. This is because the self-explanatory nature of fuzzy rules profitably supports expert assessments. Additionally, as far as interpretability is investigated, it appears that (a) the simple adoption of fuzzy sets in modeling is not enough to ensure interpretability; (b) fuzzy knowledge representation must confront the problem of preserving the overall system accuracy, thus yielding a trade-off which is frequently debated. Such issues have attracted a growing interest in the research community and became to assume a central role in the current literature panorama of computational intelligence. This chapter gives an overview of the topics related to fuzzy system interpretability, facing the ambitious goal of proposing some answers to a number of open challenging questions: What is interpretability? Why interpretability is worth considering? How to ensure interpretability, and how to assess (quantify) it? Finally, how to design interpretable fuzzy models?

The objective of this chapter is to provide some answers for the questions posed above. Section 14.1 deals with the challenging task of setting a proper definition of interpretability. Section 14.2 introduces the main constraints and criteria that can be adopted to ensure interpretability when designing interpretable fuzzy systems. Section 14.3 gives a brief overview of the soundest indexes for

assessing interpretability. Section 14.4 presents the most popular approaches for designing fuzzy systems endowed with a good interpretability-accuracy trade-off. Section 14.5 enumerates some application fields where interpretability is a main concern. Section 14.6 sketches a number of challenging tasks which should be addressed in the near future. Finally, some conclusions are drawn in Sect. 14.7.

The key factor for the success of fuzzy logic stands in the ability of modeling and processing *perceptions* instead of measurements [14.1]. In most cases, such perceptions are expressed in natural language. Thus, fuzzy logic acts as a mathematical underpinning for modeling and processing perceptions described in natural language.

Historically, it has been acknowledged that fuzzy systems are endowed with the capability to conjugate a complex behavior and a simple description in terms of linguistic rules. In many cases, the compilation of fuzzy systems has been accomplished *manually*; with human knowledge purposely injected in fuzzy rules in order to model the desired behavior (the rules could be eventually tuned to improve the system accuracy). In addition, the great success of fuzzy logic led to the development of many algorithms aimed at acquiring knowledge from data (expressing it in terms of fuzzy rules). This made the automatic design of fuzzy systems (through data-driven design techniques) feasible. Moreover, theoretical studies proved the universal approximation capabilities of such systems [14.2].

The adoption of data-driven design techniques is a common practice nowadays. Nevertheless, while fuzzy sets can be generally used to model perceptions, some of them do not lead to a straight interpretation in natural language. In consequence, the adoption of accuracy-driven algorithms for acquiring knowledge from data often results in unintelligible models. In those cases, the fundamental plus of fuzzy logic is lost and the derived models are comparable to other measurement-based models (like neural networks) in terms of knowledge interpretability.

In a nutshell, interpretability is not granted by the adoption of fuzzy logic which represents a necessary yet not a sufficient requirement for modeling and processing perceptions. However, interpretability is a quality that is not easy to define and quantify. Several open and challenging questions arise while considering interpretability in fuzzy modeling: *What* is interpretability? *Why* interpretability is worth considering? How to *ensure* interpretability? How to *assess* (quantify) interpretability? How to *design* interpretable fuzzy models? And so on.

## 14.1 The Quest for Interpretability

Answering the question *What is interpretability?* is not straightforward. Defining interpretability is a challenging task since it deals with the analysis of the relation occurring between two heterogeneous entities: a model of the system to be designed (usually formalized through a mathematical definition) and a human user (meant not as a passive beneficiary of a system's outcome, but as an active reader and interpreter of the model's working engine). In this sense, interpretability is a quality which is inherent in the model and yet it refers to an act performed by the user who is willing to grasp and explain the meaning of the model.

To pave the way for the definition of such a relation, a common ground must be settled. This could be represented by a number of fundamental properties to be incorporated into a model, so that its formal description becomes compatible with the user's knowledge representation. In this way, the human user may interface the mathematical model resting on concepts that appear to be suitable to deal with it. The quest for interpretability, therefore, calls for the identification of several features. Among them, resorting to an appropriate framework for knowledge representation is a crucial element and the adoption of a fuzzy inference engine based on fuzzy

rules is straightforward to approach the linguistic-based formulation of concepts which is typical of the human abstract thought.

A distinguishing feature of a fuzzy rule-based model is the double level of knowledge representation. The lower level of representation is constituted by the formal definition of the fuzzy sets in terms of their membership functions, as well as the aggregation functions used for inference. This level of representation defines the *semantics* of a fuzzy rule-based model as it determines the behavior of the model, i.e. the input/output mapping for which it is responsible.

On the higher level of representation, knowledge is represented in the form of rules. They define a formal structure where linguistic variables are involved and reciprocally connected by some formal operators, such as *AND*, *THEN*, and so on. Linguistic variables correspond to the inputs and outputs of the model. The (symbolic) values they assume are related to linguistic terms which, in turn, are mapped to the fuzzy sets defined in the lower level of representation. The formal operators are likewise mapped to the aggregation functions. This mapping provides the interpretative transition that is quite common in the mathematical context: a formal

structure is assigned semantics by mapping symbols (linguistic terms and operators) to objects (fuzzy sets and aggregation functions).

In principle, the mapping of linguistic terms to fuzzy sets is arbitrary. It just suffices that identical linguistic terms are mapped to identical fuzzy sets. Of course, this is not completely true for formal operators (e.g.,  $t$ -norms, implications, etc.). The corresponding aggregation functions should satisfy a number of constraints; however some flexibility is possible. Nevertheless, the mere use of symbols in the high level of knowledge representation implies the establishment of a number of semiotic relations that are fundamental for the quest of interpretability of a fuzzy model. In particular, linguistic terms – as usually picked from natural language – must be fully meaningful for the expected reader since they denote concepts, i. e. mental representations that allow people to draw appropriate inferences about the entities they encounter.

Concepts and fuzzy sets, therefore, are both denoted by linguistic terms. Additionally, concepts and fuzzy sets play a similar role: the former (being part of the human knowledge) contribute to determine the behavior of a person; the latter (being the basic elements of a fuzzy rule base) contribute to determine the behavior of a system to be modeled. As a consequence, concepts and fuzzy sets are implicitly connected by means of common linguistic terms they are related to, which refer to object classes in the real world. The key essence of interpretability is therefore the property of *cointension* [14.3] between fuzzy sets and concepts, consisting in the possibility of referring to similar classes of objects: such a possibility is assured by the use of common linguistic terms.

Semantic cointension is a key issue when dealing with interpretability of fuzzy systems. It has been introduced and centered on the role of fuzzy sets, but it can be easily extended to refer to some more complex structures, such as fuzzy rules or the whole fuzzy models. In this regard, a crisp assertion about the importance of cointension pronounced at the level of the whole model is given by the *Michalski's Comprehensibility Postulate* [14.4]:

*The results of computer induction should be symbolic descriptions of given entities, semantically and structurally similar to those a human expert might produce observing the same entities. Components of these descriptions should be comprehensible as single chunks of information, directly interpretable in natural language, and should relate*

*quantitative and qualitative concepts in an integrated fashion.*

It should be observed that the above postulate has been formulated in the general area of machine learning. Nevertheless, the assertion made by Michalski has important consequences in the specific area of fuzzy modeling (FM) too. According to the Comprehensibility Postulate, results of computer induction should be described symbolically. Symbols are necessary to communicate information and knowledge; hence, pure numerical methods, such as neural networks, are not suited for meeting interpretability unless an interpretability-oriented postprocessing of the resulting knowledge is performed.

The key point of the Michalski's postulate is the human centrality of the results of a computer induction process. The importance of the human component implicitly suggests a novel aspect to be taken into account in the quest for interpretability. Actually, the semantic cointension is related to one facet of the interpretability process, which can be referred to as *comprehensibility* of the content and behavior of a fuzzy model. In other words, cointension concerns the semantic interpretation performed by a user determined to comprehend such a model. On the other hand, when we turn to consider the cognitive capabilities of human brains and their intrinsic limitations, then a different facet of the interpretability process can be defined in terms of *readability* of the bulk of information conveyed by a fuzzy model. In that case, simplicity is required to perform the interpretation process because of the limited ability to store information in the human brain's short-term memory [14.5]. Therefore, structural measures concerning the complexity of a rule base affect the cognitive efforts of a user determined to read and interpret a fuzzy model.

Comprehensibility and readability represent two facets of a common issue and both of them are to be considered while assessing the interpretability process. In particular, this distinction should be acknowledged when criteria are specifically designed to provide a quantitative definition of interpretability.

### 14.1.1 Why Is Interpretability So Important?

A great number of inductive modeling techniques are currently available to acquire knowledge from data. Many of these techniques provide predictive models that are very accurate and flexible enough to be applied

in a wide range of applications. Nevertheless, the resulting models are usually considered as black boxes, i.e. models whose behavior cannot be easily explained in terms of the model structure. On the other hand, the use of fuzzy rule-based models is a matter of design choice: whenever interpretability is a key factor, fuzzy rule-based models should be naturally preferred. It is worth noting that interpretability is a distinguishing feature of fuzzy rule-based models. Several reasons justify a choice inclined toward interpretability. They include but are not limited to:

- *Integration*: In an interpretable fuzzy rule-based model the acquired knowledge can be easily verified and related to the domain knowledge of a human expert. In particular, it is easy to verify if the acquired knowledge expresses new and interesting relations about the data; also, the acquired knowledge can be refined and integrated with expert knowledge.
- *Interaction*: The use of natural language as a mean for knowledge communication enables the possibility of interaction between the user and the model. Interactivity is meant to explore the acquired knowledge. In practice, it can be done at symbolical level (by adding new rules or modifying existing ones) and/or at numerical level (by modifying the fuzzy sets denoted by linguistic terms; or by adding new linguistic terms denoting new fuzzy sets).
- *Validation*: The acquired knowledge can be easily validated against common-sense knowledge and domain-specific knowledge. This capability enables the detection of semantic inconsistencies that may have different causes (misleading data involved in the inductive process, local minimum where the inductive process may have been trapped, data overfitting, etc.). This kind of anomaly detection is important to drive the inductive process toward a qualitative improvement of the acquired knowledge.
- *Trust*: The most important reason to adopt interpretable fuzzy models is their inherent ability to convince end users about the reliability of a model (especially those users not concerned with knowledge acquisition techniques). An interpretable fuzzy rule-based model is endowed with the capability of explaining its inference process so that users may be confident on how it produces its outcomes. This is particularly important in such domains as medical diagnosis, where a human expert is the ultimate responsible for a decision.

### 14.1.2 A Historical Review

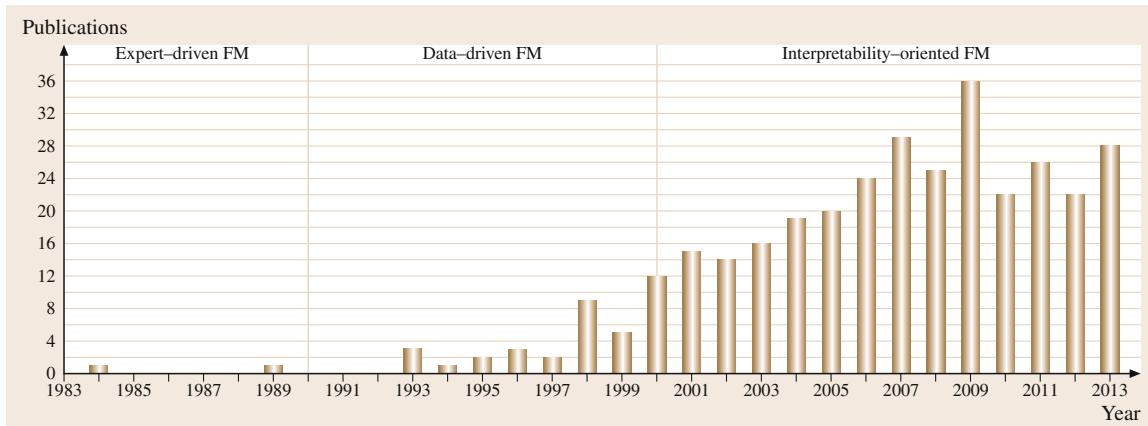

It has been long time since Zadeh's seminal work on fuzzy sets [14.6] and nowadays there are lots of fruitful research lines related to fuzzy logic [14.7]. Hence, we can state that fuzzy sets and systems have become the subjects of a mature research field counting several works both theoretical and applied in their scope. Figure 14.1 shows the distribution of publications per year regarding interpretability issues. Three main phases can be identified taking into account the historical evolution of FM.

#### From 1965 to 1990

During this initial period, interpretability emerged naturally as the main advantage of fuzzy systems. Researchers concentrated on building fuzzy models mainly working with expert knowledge and a few simple linguistic variables [14.8–10] and linguistic rules usually referred to as *Mamdani* rules [14.11]. As a result, those designed fuzzy models were characterized by their high interpretability. Moreover, interpretability is assumed as an intrinsic property of fuzzy systems. Therefore, there are only a few publications regarding interpretability issues. Note that the first proposal of a fuzzy rule-based system (**FRBS**) was presented by Mamdani who was able to augment Zadeh's initial formulation allowing the application of fuzzy systems to a control problem. These kinds of fuzzy systems are also referred to as *fuzzy logic controllers*, as proposed by the author in his pioneering paper. In addition, Mamdani-type **FRBS**s soon became the main tool to develop linguistic models. Of course, many other rule formats were arising and gaining importance. In addition to Mamdani **FRBS**s, probably the most famous **FRBS**s are those proposed by *Takagi and Sugeno* [14.12], the popular **TSK** fuzzy systems, where the conclusion is a function of the input values. Due to their current popularity, in the following we will use the term *fuzzy system* to denote Mamdani-type **FRBS**s and their subsequent extensions.

#### From 1990 to 2000

In the second period the focus was set on accuracy. Researchers realized that expert knowledge was not enough to deal with complex systems. Thus, they explored the use of fuzzy machine learning techniques to automatically extract knowledge from data [14.13, 14]. Accordingly, those designed fuzzy models became composed of extremely complicated fuzzy rules with high accuracy but at the cost of disregarding inter-

**Fig. 14.1** Publications per year related to interpretability issues

pretability as a side effect. Obviously, automatically generated rules were rarely as readable as desired. Along this period some researchers started claiming that fuzzy models are not interpretable per se. Interpretability is a matter of careful design. Thus, interpretability issues must be deeply analyzed and seriously discussed. Although the amount of publications related to interpretability issues is still small in this period, please pay attention to the fact that publications begin to grow exponentially at the end of this second phase.

#### From 2000 to 2013

After the two previous periods, researchers realized that both expert-driven (from 1965 to 1990) and data-driven (from 1990 to 2000) design approaches have their own advantages and drawbacks, but they are somehow complementary. For instance, expert knowledge is general and easy to interpret but hard to formalize. On the contrary, knowledge derived from data can be extracted automatically but it becomes quite specific and its interpretation is usually hard [14.15]. Moreover, researchers were aware of the need of taking into account simultaneously interpretability and accuracy during the design of fuzzy models. As a result, during this third phase the main challenge was how to combine expert knowledge and knowledge extracted from data, with the aim of designing compact and robust systems with a good interpretability–accuracy trade-off. When considering both interpretability and accuracy in **FM**, two main strategies turn up naturally [14.16]: *linguistic fuzzy modeling (LFM)* and *precise fuzzy modeling (PFM)*. On the one hand, in **LFM**, designers first focus on the interpretability of the model, and then they try to improve its accuracy [14.17]. On the other hand, in **PFM**, design-

ers first build a fuzzy model maximizing its accuracy, and then they try to improve its interpretability [14.18]. As an alternative, since accuracy and interpretability represent conflicting goals by nature, multiobjective fuzzy modeling strategies (considering accuracy and interpretability as objectives) have become very popular [14.19, 20].

At the same time, there has been a great effort for formalizing interpretability issues. As a result, the number of publications has grown. Researchers have actively looked for the right definition of interpretability. In addition, several interpretability constraints have been identified. Moreover, interpretability assessment has become a hot research topic. In fact, several interpretability indexes (able to guide the **FM** design process) have been defined. Nevertheless, a universal index widely admitted is still missing. Hence, further research on interpretability issues is demanded.

Unfortunately, although the number of publications was growing exponentially until 2009, later it started decreasing. We would like to emphasize the impact of the two pioneer books [14.17, 18] edited in 2003. They contributed to make the fuzzy community aware of the need to take into account again interpretability as a main research concern. It is worth noting that the first formal definition of interpretability (in the fuzzy literature) was included in [14.18]. It was given by *Bodenhofer and Bauer* [14.21] who established an axiomatic treatment of interpretability at the level of linguistic variables.

We encourage the fuzzy community to keep paying attention to interpretability issues because there is still a lot of research to be done. Interpretability must be the central point on system modeling. In fact, some of the hottest and most recent research topics like pre-

ciliated natural language, computing with words, and human centric computing strongly rely on the interpretability of the designed models. The challenge is to better exploit fuzzy logic techniques for improving

the human-centric character of many intelligent systems. Therefore, interpretability deserves consideration as a main research concern and the number of publications should grow again in the next years.

## 14.2 Interpretability Constraints and Criteria

Interpretability is a quality of fuzzy systems that is not immediate to quantify. Nevertheless, a quantitative definition is required both for assessing the interpretability of a fuzzy system and for designing new fuzzy systems. This requirement is especially stringent when fuzzy systems are automatically designed from data, through some knowledge extraction procedure.

A common approach for defining interpretability is based on the adoption of a number of constraints and criteria that, taken as a whole, provide for a definition of interpretability. This approach is inherent to the subjective nature of interpretability, because the validity of some conditions/criteria is not universally acknowledged and may depend on the application context.

In the literature, a large number of interpretability constraints and criteria can be found. Some of them are widely accepted, while others are controversial. The nature of these constraints and criteria is also diverse. Some are neatly defined as a mathematical condition, others have a fuzzy character and their satisfaction is a matter of degree. This section is addressed to give a brief yet homogeneous outline of the best known interpretability constraints and criteria. The reader is referred to the specialized literature for deeper insights on this topic [14.22, 23].

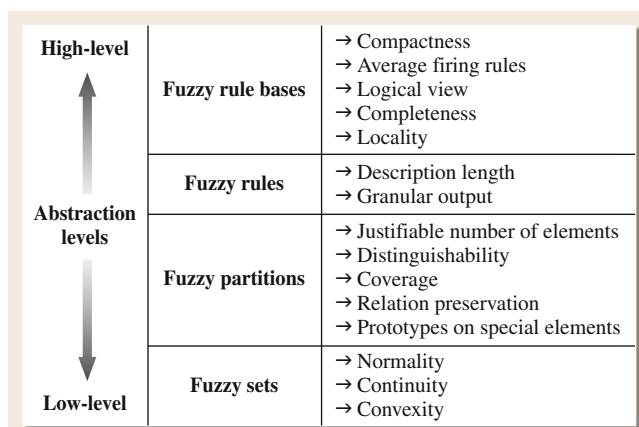

Several ways are available to categorize interpretability constraints and criteria. It could be possible to refer to their specific nature (e.g., crisp vs. fuzzy), to the components of the fuzzy system where they are applied, or to the description level of the fuzzy system itself. Here, as depicted in Fig. 14.2, we choose a hierarchical organization that starts from the most basic components of a fuzzy system, namely the involved fuzzy sets, and goes on toward more complex levels, such as fuzzy partitions, fuzzy rules, up to considering the model as a whole.

### 14.2.1 Constraints and Criteria for Fuzzy Sets

Fuzzy sets are the basic elements of fuzzy systems and their role is to express elementary yet imprecise concepts that can be denoted by linguistic labels. Here we assume that fuzzy sets are defined on a universe of discourse represented by a closed interval of the real line (this is the case of most fuzzy systems, especially those acquired from data). Thus, fuzzy sets are the building blocks to translate a numerical domain in a linguistically quantified domain that can be used to communicate knowledge.

Generally speaking, single fuzzy sets are employed to express elementary concepts and, through the use of connectives, are combined to represent more complex concepts. However, not all fuzzy sets can be related to elementary concepts, since the membership function of a fuzzy set may be very awkward but still legitimate from a mathematical viewpoint. Actually, a subclass of fuzzy sets should be considered, so that its members can be easily associated with elementary concepts and tagged by the corresponding linguistic labels. Fuzzy sets of this subclass must verify a number of basic interpretability constraints, including:

- **Normality:** At least one element of the universe of discourse is a prototype for the fuzzy set, i.e. it is characterized by a full membership degree.

**Fig. 14.2** Interpretability constraints and criteria in different abstraction levels

A normal fuzzy set represents a concept that fully qualifies at least one element of the universe of discourse, i. e. the concept has at least one example that fulfills it. On the other hand, a subnormal fuzzy set is usually a consequence of a partial contradiction (it is easy to show that the degree of inclusion of a subnormal fuzzy set in the empty set is nonzero).

- *Continuity:* The membership function is continuous on the universe of discourse. As a matter of fact, most concepts that can be naturally represented through fuzzy sets derive from a perceptual act, which comes from external stimuli that usually vary in continuity. Therefore, continuous fuzzy sets are better in accordance with the perceptive nature of the represented concepts.
- *Convexity:* In a convex fuzzy set, given three elements linearly placed on the axis related to the universe of discourse, the degree of membership of the middle element is always greater than or equal to the minimum membership degree of the side elements [14.24]. This constraint encodes the rule that if a property is satisfied by two elements, then it is also satisfied by an element settled between them.

### 14.2.2 Constraints and Criteria for Fuzzy Partitions

The key success factor of fuzzy logic in modeling is the ability of expressing knowledge *linguistically*. Technically, this is realized by linguistic variables, i. e. variables that assume symbolic values called linguistic terms. The peculiarity of linguistic variables with respect to classical symbolic approaches is the interpretation of linguistic terms as fuzzy sets. The collection of fuzzy sets used as interpretation of the linguistic terms of a linguistic variable forms a fuzzy partition of the universe of discourse.

To understand the role of a fuzzy partition, we should consider that it is meant to define a relation among fuzzy sets. Such a relation must be co-intensive with the one connecting the elementary concepts represented by the fuzzy sets involved in the fuzzy partition. That is the reason why the design of fuzzy partitions is so crucial for the overall interpretability of a fuzzy system. The most critical interpretability constraints for fuzzy partitions are:

- *Justifiable number of elements:* The number of fuzzy sets included in a linguistic variable must be small enough so that they can be easily remembered

and recalled by users. Psychological studies suggest at most nine fuzzy sets or even less [14.5, 25]. Usually, three to five fuzzy sets are convenient choices to set the partition cardinality.

- *Distinguishability:* Since fuzzy sets are denoted by distinct linguistic terms, they should refer to well-distinguished concepts. Therefore, fuzzy sets in a partition should be well separated, although some overlapping is admissible because usually perception-based concepts are not completely disjoint. Several alternatives are available to quantify distinguishability, including similarity and possibility [14.26].
- *Coverage:* Distinguishable fuzzy sets are necessary, but if they are too much separated they risk to under-represent some subset of the universe of discourse. The coverage constraint requires that each element of the universe of discourse must belong to at least one fuzzy set of the partition with a membership degree not less than a threshold [14.22]. This requirement involves that each element of the universe of discourse has some quality that is well represented in the fuzzy partition. On the other hand, the lack of coverage is a signal of incompleteness of the fuzzy partition that may hamper the overall comprehensibility of the system's knowledge. Coverage and distinguishability are somewhat conflicting requirements that are usually balanced by fuzzy partitions that enforce the intersection of adjacent fuzzy sets to elements whose maximum membership degree is equal to a threshold (usually the value of this threshold is set to 0.5).
- *Relation preservation:* The concepts that are represented by the fuzzy sets in a fuzzy partition are usually cross related. The most immediate relation which can be conceived among concepts is related to the order (e.g., *Low* preceding *Medium*, preceding *High*, and so on). Relations of this type must be preserved by the corresponding fuzzy sets in the fuzzy partition [14.27].
- *Prototypes on special elements:* In many problems, some elements of the universe of discourse have some special meaning. A common case is the meaning of the bounds of the universe of discourse, which usually represent some extreme qualities (e.g., *Very Large* or *Very Small*). Other examples are possible, which could be aside from the bounds of the universe of discourse being, instead, more problem-specific (e.g., prototypes could be conceived for the icing point of water, the typical

human body temperature, etc.). In all these cases, the prototypes of some fuzzy sets of the partition must coincide with such special elements.

### 14.2.3 Constraints and Criteria for Fuzzy Rules

In most cases, a fuzzy system is defined over a multi-dimensional universe of discourse that can be split into many one-dimensional universes of discourse, each of them associated with a linguistic variable. A subset of these linguistic variables is used to represent the input of a system, while the remaining variables (usually only one variable) are used to represent the output. The input/output behavior is expressed in terms of rules. Each rule prescribes a linguistic output value when the input matches the rule condition (also called rule premise), usually expressed as a logical combination of soft constraints. A soft constraint is a linguistic proposition (specification) that ties a linguistic variable to a linguistic term (e.g., *Temperature is High*). Furthermore, the soft constraints combined in a rule condition may involve different linguistic variables (e.g., *Temperature is High AND Pressure is Low*).

A fuzzy rule is a unit of knowledge that has the twofold role of determining the system behavior and communicating this behavior in a linguistic form. The latter feature urges to adopt a number of interpretability constraints which are to be added up to the constraints required for fuzzy sets and fuzzy partitions. Some of the most general interpretability constraints and criteria for fuzzy rules are as follows:

- **Description length:** The description length of a fuzzy rule is the sum of the number of soft constraints occurring in the condition and in the consequent of the rule (it is usually known as *total rule length*). In most cases, only one linguistic variable is represented in a rule consequent, therefore the description length of a fuzzy rule is directly related to the complexity of the condition. A small number of soft constraints in a rule implies both high readability and semantic generality; hence, short rules should be preferred in fuzzy systems.
- **Granular outputs:** The main strength of fuzzy systems is their ability to represent and process imprecision in both data and knowledge. Imprecision is part of fuzzy inference, therefore the inferred output of a fuzzy system should carry information about the imprecision of its knowledge. This can be accomplished by using fuzzy sets as outputs. De-
- fuzzification collapses fuzzy sets into single scalars; it should be therefore used only when strictly necessary and in those situations where outputs are not the object of user interpretation.

### 14.2.4 Constraints and Criteria for Fuzzy Rule Bases

As previously stated, the interpretability of a rule base taken as a whole has two facets: (1) a structural facet (*readability*), which is mainly related to the easiness of reading the rules; (2) a semantic facet (*comprehensibility*), which is related to the information conveyed to the users who are willing to understand the system behavior. The following interpretability constraints and criteria are commonly defined to ensure the structural and semantic interpretability of fuzzy rule bases.

- **Compactness:** A compact rule base is defined by a small number of rules. This is a typical structural constraint that advocates for simple representation of knowledge in order to allow easy reading and understanding. Nevertheless, a small number of rules usually involves low accuracy; it is therefore very common to balance compactness and accuracy in a trade-off that mainly depends on user needs.
- **Average firing rules:** When an input is applied to a fuzzy system, the rules whose conditions are verified to a degree greater than zero are *firing*, i.e. they contribute to the inference of the output. On an average, the number of firing rules should be as small as possible, so that users are able to understand the contributions of the rules in determining the output.
- **Logical view:** Fuzzy rules resemble logical propositions when their linguistic description is considered. Since linguistic description is the main mean for communicating knowledge, it is necessary that logical laws are applicable to fuzzy rules; otherwise, the system behavior may result counter intuitive. Therefore, the validity of some basic laws of the propositional logic (like *Modus Ponens*) and the truth-preserving operations (e.g., application of distributivity, De Morgan laws, etc.) should also be verified for fuzzy rules.
- **Completeness:** The behavior of a fuzzy system is well defined for all inputs in the universe of discourse; however, when the maximum firing strength determined by an input is too small, it is not easy to justify the behavior of the system in terms of the

activated rules. It is therefore required that for each possible input at least one rule is activated with a firing strength greater than a threshold value (usually set to 0.5) [14.22].

- **Locality:** Each rule should define a local model, i.e. a fuzzy region in the universe of discourse where the behavior of the system is mainly due to the rule and only marginally by other rules that are simultaneously activated [14.28]. This requirement is necessary to avoid that the final output of the system is a consequence of an interpolative behavior of different rules that are simultaneously activated with high firing strengths. On the other hand, a moderate overlapping of local models is admissible in order to enable a smooth transition from a local model to another when the input

values gradually shift from one fuzzy region to another.

In summary, a number of interpretable constraints and criteria apply to all levels of a fuzzy system. This section highlights only the constraints that are general enough to be applied independently on the modeling problem; however, several problem-specific constraints are also reported in the literature (e.g., attribute correlation). Sometimes interpretability constraints are conflicting (as exemplified by the dichotomy distinguishability versus coverage) and, in many cases, they conflict with the overall accuracy of the system. A balance is therefore required, asking in its turn for a way to assess interpretability in a qualitative but also quantitative way. This is the main subject of the next section.

## 14.3 Interpretability Assessment

The interpretability constraints and criteria presented in previous section belong to two main classes: (1) structural constraints and criteria referring to the static description of a fuzzy model in terms of the elements that compose it; (2) semantic constraints and criteria quantifying interpretability by looking at the behavior of the fuzzy system. Whilst structural constraints address the *readability* of a fuzzy model, semantic constraints focus on its *comprehensibility*.

Of course, interpretability assessment must regard both global (description readability) and local (inference comprehensibility) points of view. It must also take into account both structural and semantic issues when considering all components (fuzzy sets, fuzzy partitions, linguistic partitions, linguistic propositions, fuzzy rules, fuzzy operators, etc.) of the fuzzy system under study.

Thus, assessing interpretability represents a challenging task mainly because the analysis of interpretability is extremely subjective. In fact, it clearly depends on the feeling and background (knowledge, experience, etc.) of the person who is in charge of making the evaluation. Even though having subjective indexes would be really appreciated for personalization purposes, looking for a universal metric widely admitted also makes the definition of objective indexes mandatory. Hence, it is necessary to consider both objective and subjective indexes. On the one hand, objective indexes are aimed at making feasible fair comparisons among different fuzzy models designed for solving

the same problem. On the other hand, subjective indexes are thought for guiding the design of customized fuzzy models, thus making easier to take into account users' preferences and expectations during the design process.

The rest of this section gives an overview on the most popular interpretability indexes which turn out from the specialized literature. Firstly, Zhou and Gan [14.29] established a two-level taxonomy regarding interpretability issues. They distinguished between low-level (also called fuzzy set level) and high-level (or fuzzy rule level). This taxonomy was extended by Alonso et al. [14.30] who introduced a conceptual framework for characterizing interpretability. They considered both fuzzy partitions and fuzzy rules at several abstraction levels. Moreover, in [14.31] Mencar et al. remarked the need to distinguish between readability (related to structural issues) and comprehensibility (related to semantic issues). Later, Gacto et al. [14.32] proposed a double axis taxonomy regarding semantic and structural properties of fuzzy systems, at both partition and rule base levels. Accordingly, they pointed out four groups of indexes. Below, we briefly introduce the two most sounded indexes inside each group (they are summarized in Fig. 14.3):

### G1. Structural-based interpretability at fuzzy partition level:

- *Number of features.*
- *Number of membership functions.*

	Fuzzy partition level	Fuzzy rule base level
Structural-based interpretability	G1 Number of features Number of membership functions	G2 Number of rules Number of conditions
	G3 Context-adaptation-based index GM3M index	G4 Semantic-cointension-based index Co-firing-based-comprehensibility index

**Fig. 14.3** Interpretability indexes considered in this work

G2. *Structural-based interpretability at fuzzy rule base level:*

- *Number of rules.* This index is the most widely used [14.30].
- *Number of conditions.* This index corresponds to the previously mentioned *total rule length* which was coined by Ishibuchi et al. [14.33].

G3. *Semantic-based interpretability at fuzzy partition level:*

- *Context-adaptation-based index* [14.34]. This index was introduced by Botta et al. with the aim of guiding the so-called context adaptation approach for multiobjective evolutionary design of fuzzy rule-based systems. It is actually an interpretability index based on fuzzy ordering relations.
- *GM3M index* [14.35]. Gacto et al. proposed an index defined as the geometric mean of three single metrics. The first metric computes the displacement of the tuned membership functions with respect to the initial ones. The second metric evaluates the changes in the shapes of membership functions in terms of lateral amplitude rate. The third metric measures the area similarity. This index was used to preserve the semantic interpretability of fuzzy partitions along multiobjective evolutionary rule selection and tuning processes aimed at designing fuzzy models with a good interpretability-accuracy trade-off.

G4. *Semantic-based interpretability at fuzzy rule base level:*

- *Semantic-cointension-based index* [14.36]. This index exploits the cointension concept coined by Zadeh [14.3]. In short, two different concepts referring almost to the same entities are taken as cointensive. Thus, a fuzzy system is deemed as comprehensible only when the explicit semantics (defined by fuzzy sets attached to linguistic

terms as well as fuzzy operators) embedded in the fuzzy model is cointensive with the implicit semantics inferred by the user while reading the linguistic representation of the rules. In the case of classification problems, semantic cointension can be evaluated through a *logical view* approach, which evaluates the degree of fulfillment of a number of logical laws exhibited by a given fuzzy rule base [14.31]. The idea mainly relies on the assumption that linguistic propositions resemble logical propositions, for which a number of basic logical laws are expected to hold.

- *Co-firing-based comprehensibility index* [14.37]. It measures the complexity of understanding the fuzzy inference process in terms of information related to co-firing rules, i.e. rules firing simultaneously with a given input vector. This index emerges in relation with a novel approach for fuzzy system comprehensibility analysis, based on visual representations of the fuzzy rule-based inference process. Such representations are called fuzzy inference-grams (fingrams) [14.38, 39]. Given a fuzzy rule base, a fingram plots it graphically as a social network made of nodes representing fuzzy rules and edges connecting nodes in terms of rule interaction at the inference level. Edge weights are computed by paying attention to the number of co-firing rules. Thus, looking carefully at all the information provided by a fingram it becomes easy and intuitive understanding the structure and behavior of the fuzzy rule base it represents.

Notice that, most published interpretability indexes only deal with structural issues, so they correspond to groups G1 and G2. Indexes belonging to these groups are mainly quantitative. They essentially analyze the

structural complexity of a fuzzy model by counting the number of elements (membership functions, rules, etc.) it contains. As a result, these indexes can be deemed as objective ones. Although these indexes are usually quite simple (that is the reason why we have just listed them above), they are by far the most popular ones. On the contrary, only a few interpretability indexes are able to assess the comprehensibility of a fuzzy model dealing with semantic issues (they belong to groups G3 and G4). This is mainly due to the fact that these indexes must take into account not only quantitative but also qualitative aspects of the modeled fuzzy system. They are inherently subjective and therefore not easy to formalize (that is the reason why we have provided more details above). Anyway, the interested reader is referred to the cited papers for further information. Moreover, a much more exhaustive list of indexes can be found in [14.32].

Even though there has been a great effort in the last years to propose new interpretability indexes, a universal index is still missing. Hence, defining such an index remains a challenging task. Anyway, we would like to highlight the need to address another encouraging challenge which is a careful design of interpretable fuzzy systems guided by one or more of the already existing interpretability indexes.

## 14.4 Designing Interpretable Fuzzy Systems

Linguistic (Mamdani-type) fuzzy systems are widely known as a powerful tool to develop linguistic models [14.11]. They are made up of two main components:

- The *inference engine*, that is the component of the fuzzy system in charge of the fuzzy processing tasks.
- The *knowledge base (KB)*, that is the component of the fuzzy system that stores the knowledge about the problem being solved. It is composed of:
  - The *fuzzy partitions*, describing the linguistic terms along with the corresponding membership functions defining their semantics, and
  - The *fuzzy rule base*, constituted by a collection of linguistic rules with the following structure

IF  $X_1$  is  $A_1$  and ... and  $X_n$  is  $A_n$   
THEN  $Y_1$  is  $B_1$  and ... and  $Y_m$  is  $B_m$

with  $X_i$  and  $Y_j$  being input and output linguistic variables, respectively, and  $A_i$  and  $B_j$  being linguistic terms defined by the corresponding fuzzy partitions. This structure provides a natural framework to include expert knowledge in the form of linguistic fuzzy rules. In addition to expert knowledge, induced knowledge automatically extracted from experimental data (describing the relation between system input and output) can also be easily formalized in the same rule base. Expert and induced knowledge are complementary. Furthermore, they are represented in a highly interpretable structure. The fuzzy rules are composed of input and output linguistic variables which take values from their term sets having a meaning associated with each

linguistic label. As a result, each rule is a description of a condition-action statement that offers a clear interpretation to a human.

The accuracy of a fuzzy system directly depends on two aspects, the composition of the **KB** (fuzzy partitions and fuzzy rules) and the way in which it implements the fuzzy inference process. Therefore, the design process of a fuzzy system includes two main tasks which are going to be further explained in the following subsections, regarding both interpretability and accuracy:

- *Generation of the KB* in order to formulate and describe the knowledge that is specific to the problem domain.
- *Conception of the inference engine*, that is the choice of the different fuzzy operators that are employed by the inference process.

Mamdani-type fuzzy systems favor interpretability. Therefore, they are usually considered when looking for interpretable fuzzy systems. However, it is important to remark that they are not interpretable per se. Notice that designing interpretable fuzzy systems is a matter of careful design.

### 14.4.1 Design Strategies for the Generation of a KB Regarding the Interpretability-Accuracy Trade-Off

The two main objectives to be addressed in the **FM** field are the *interpretability* and *accuracy*. Of course,

the ideal aim would be to satisfy both objectives to a high degree but, since they represent conflicting goals, it is generally not possible. Regardless of the approach, a common scheme is found in the existing literature:

- Firstly, the main objective (interpretability or accuracy) is tackled defining a specific model structure to be used, thus setting the **FM** approach.
- Then, the modeling components (model structure and/or modeling process) are improved by means of different mechanisms to achieve the desired ratio between interpretability and accuracy.

This procedure resulted in four different possibilities:

1. **LFM** with improved interpretability,
2. **LFM** with improved accuracy,
3. **PFM** with improved interpretability, and
4. **PFM** with improved accuracy.

Option (1) gives priority to interpretability. Although a fuzzy system designed by **LFM** uses a model structure with high descriptive power, it has some problems (curse of dimensionality, excessive number of input variables or fuzzy rules, garbled fuzzy sets, etc.) that make it not as interpretable as desired. In consequence, there is a need of interpretability improvements to restore the pursued balance.

On the contrary, option (4) considers accuracy as the main concern. However, obtaining more accuracy in **PFM** does not pay attention to the interpretability of the model. Thus, this approach goes away from the aim of this chapter. It acts close to black-box techniques, so it does not follow the original objective of **FM** (not taking profit from the advantages that distinguish it from other modeling techniques).

Finally, the two remaining options, (2) and (3), propose improvement mechanisms to compensate for the initial imbalance in the quest for the best trade-off between interpretability and accuracy. In summary, three main approaches exist depending on how the two objectives are optimized (sequentially or at once):

- First interpretability then accuracy (**LFM** with improved accuracy).
- First accuracy then interpretability (**PFM** with improved interpretability).
- Multiobjective design. Both objectives are optimized at the same time.

The rest of this section provides additional details related to each of these approaches.

### First Interpretability Then Accuracy

**LFM** has some inflexibility due to the use of linguistic variables with global semantics that establishes a general meaning of the used fuzzy sets [14.40]:

1. There is a lack of flexibility in the fuzzy system because of the rigid partitioning of the input and output spaces.
2. When the system input variables are dependent, it is very hard to find out right fuzzy partitions of the input spaces.
3. The usual homogeneous partitioning of the input and output spaces does not scale to high-dimensional spaces. It yields to the well-known curse of dimensionality problem that is characteristic of fuzzy systems.
4. The size of the **KB** directly depends on the number of variables and linguistic terms in the model. The derivation of an accurate linguistic fuzzy system usually requires a big number of linguistic terms. Unfortunately, this fact causes the number of rules to rise significantly, which may cause the system to lose the capability of being readable by human beings. Of course, in most cases it would be possible to obtain an equivalent fuzzy system with a much smaller number of rules by renouncing to that kind of rigidly partitioned input space.

However, it is possible to make some considerations to face the disadvantages enumerated above. Basically, two ways of improving the accuracy in **LFM** can be considered by performing the improvement in:

- The *model structure*, slightly changing the rule structure to make it more flexible, or in
- The *modeling process*, extending the model design to other components beyond the rule base, such as the fuzzy partitions, or even considering more sophisticated derivations of it.

Note that, the so-called strong fuzzy partitions are widely used because they satisfy most of the interpretability constraints introduced in Sect. 14.2.2. The design of fuzzy partitions may be integrated within the whole derivation process of a fuzzy system with different schemata:

- *Preliminary design*. It involves extracting fuzzy partitions automatically by induction (usually per-

formed by nonsupervised clustering techniques) from the available dataset.

- *Embedded design.* Following a meta-learning process, this approach first derives different fuzzy partitions and then samples its efficacy running an embedded basic learning method of the entire KB [14.41].
- *Simultaneous design.* The process of designing fuzzy partitions is developed together with the derivation of other components such as the fuzzy rule base [14.42].
- *A posteriori design.* This approach involves tuning of the previously defined fuzzy partitions once the remaining components have been obtained. Usually, the tuning process changes the membership function shapes with the aim of improving the accuracy of the linguistic model [14.43]. Nevertheless, sometimes it also takes care of getting better interpretability (e.g., merging membership functions [14.44]).

It is also possible to opt for using more sophisticated rule base learning methods while the fuzzy partitions and the model structure are kept unaltered. Usually, all these improvements have the final goal of enhancing the *interpolative reasoning* the fuzzy system develops. For instance, the COR (cooperative rules) method follows the primary objective of inducing a better cooperation among linguistic rules [14.45].

As an alternative, other authors advocate the extension of the usual linguistic model structure to make it more flexible. As Zadeh highlighted in [14.46], a way to do so without losing the description ability to a high degree is to use linguistic hedges (also called *linguistic modifiers* in a wider sense). In addition, the rule structure can be extended through the definition of double-consequent rules, weighted rules, rules with exceptions, hierarchical rule bases, etc.

### First Accuracy Then Interpretability

The birth of more flexible fuzzy systems such as TSK or approximate ones (allowing the FM to achieve higher accuracy) entailed the eruption of PFM. Nevertheless, the modeling tasks with these kinds of fuzzy systems increasingly resembled black-box processes. Consequently, nowadays several researchers share the idea of rescuing the seminal intent of FM, i.e. to preserve the good interpretability advantages offered by fuzzy systems. This fact is usually attained by reducing the complexity of the model [14.47]. Furthermore, there are

approaches aimed at improving the local description of TSK-type fuzzy rules:

- *Merging/removing fuzzy sets in precise fuzzy systems.* The interpretability of TSK-type fuzzy systems may be improved by removing those fuzzy sets that, after an automatic adaptation and/or acquisition, do not contribute significantly to the model behavior. Two aspects must be considered:
  - *Redundancy.* It refers to the coexistence of similar fuzzy sets representing compatible concepts. In consequence, models become more complex and difficult to understand (the distinguishability constraint is not satisfied).
  - *Irrelevancy.* It arises when fuzzy sets with a constant membership degree equal to 1, or close to it, are used. These kinds of fuzzy sets do not furnish relevant information.
- The use of similarity measures between fuzzy sets has been proposed to automatically detect these undesired fuzzy sets [14.48]. Through first merging/removing fuzzy sets and then merging fuzzy rules, the precise fuzzy model goes through an interpretability improvement process that makes it less complex (more compact) and more easily interpretable (more transparent).
- *Ordering/selecting TSK-type fuzzy rules.* An efficient way to improve the interpretability in FM is to select a subset of significant fuzzy rules that represent in a more compact way the system to be modeled. Moreover, as a side effect this selection of important rules reduces the possible redundancy existing in the fuzzy rule base, thus improving the generalization capability of the system, i.e., its accuracy. For instance, resorting to orthogonal transformations [14.49] is one of the most successful approaches in this sense.
- *Exploiting the local description of TSK-type fuzzy rules.* TSK-type fuzzy systems are usually considered as the combination of simple models (the rules) that describe local behaviors of the system to be modeled. Hence, insofar as each fuzzy rule is either forced to have a smoother consequent polynomial function or to develop an isolated action, the interpretability will be improved:
  - *Smoothing the consequent polynomial function* [14.50]. Through imposing several constraints to the weights involved in the polynomial function of each rule consequent then a convex combination of the input variables is

performed. This contributes to a better understanding of the model.

- *Isolating the fuzzy rule actions* [14.47]. The description of each fuzzy rule is improved when the overlapping between adjacent input fuzzy sets is reduced. Note that the performance region of a rule is more clearly defined by avoiding that other rules have high firing degree in the same area.

### Multiojective Design

Since interpretability and accuracy are widely recognized as conflicting goals, the use of multiojective evolutionary (**MOE**) strategies is becoming more and more popular in the quest for the best interpretability-accuracy trade-off [14.19, 51]. *Ducange and Marcelloni* [14.52] proposed the following taxonomy of multiojective evolutionary fuzzy systems:

- **MOE Tuning.** Given an already defined fuzzy system, its main parameters (typically membership function parameters but also fuzzy inference parameters) are refined through **MOE** strategies [14.53, 54].
- **MOE Learning.** The components of a fuzzy system **KB**, the both fuzzy partitions forming the database (**DB**) and fuzzy rules forming the rule-base (**RB**), are automatically generated from experimental data.
  - **MOE DB Learning.** The most relevant variables are identified and the optimum membership function parameters are defined from scratch. It usually wraps a **RB** heuristic-based learning process [14.55].
  - **MOE RB Selection.** Starting from an initial **RB**, a set of nondominated **RBs** is generated by selecting subsets of rules exhibiting different trade-offs between interpretability and accuracy [14.56]. In some works [14.35, 57], **MOE RB** selection and **MOE** tuning are carried out together.
  - **MOE RB Learning.** The entire set of fuzzy rules is fully defined from scratch. In this approach, uniformly distributed fuzzy partitions are usually considered [14.58].
  - **MOE KB Learning.** Simultaneous evolutionary learning of all **KB** components (**DB** and **RB**). Concurrent learning of fuzzy partitions and fuzzy rules proved to be a powerful tool in the quest for a good balance between interpretability and accuracy [14.59].

It is worthy to note that for the sake of clarity we have only cited some of the most relevant papers in the field of **MOE** fuzzy systems. For further details, the interested reader is referred to [14.51, 52] where a much more exhaustive review of related works is carried out.

### 14.4.2 Design Decisions at Fuzzy Processing Level

Although there are studies analyzing the behavior of the existing fuzzy operators for different purposes, unfortunately this question has not been considered yet as a whole from the interpretability point of view. Keeping in mind the interpretability requirement, the implementation of the inference engine must address the following careful design choices:

- *Select the right conjunctive operator to be used in the antecedent of the rule.* Different operators (belonging to the  $t$ -norm family) are available to make this choice [14.60].
- *Select the operator to be used in the fuzzy implication of IF-THEN rules.* Mamdani proposed to use the minimum operator as the  $t$ -norm for implication. Since then, various other  $t$ -norms have been suggested as implication operator [14.60], for instance the algebraic product. Other important family of implication operators are the fuzzy implication functions [14.61], one of the most usual being the Lukasiewicz's one. Less common implication operators such as force-implications [14.62],  $t$ -conorms and operators not belonging to any of the most known implication operator families [14.63, 64] have been considered too.
- *Choose the right inference mechanism.* Two main strategies are available:
  - **FATI** (*First Aggregation Then Inference*). All antecedents of the rules are aggregated to form a multidimensional fuzzy relation. Via the composition principle the output fuzzy set is derived. This strategy is preferred when dealing with implicative rules [14.65].
  - **FITA** (*First Inference Then Aggregation*). The output of each rule is first inferred, and then all individual fuzzy outputs are aggregated. This is the common approach when working with the usual conjunctive rules. This strategy has become by far the most popular, especially in case of real-time applications. The choice for an output aggregation method (in some cases this is called the *also* operator) is closely related to

the considered implication operator since it has to be related to the interpretation of the rules (which is connected to the kind of implication).

- *Choose the most suitable defuzzification interface operation mode.* There are different options being the most widely used the center of area, also called

center of gravity, and the mean of maxima. Even though most methods are based on geometrical or statistical interpretations, there are also parametric methods, adaptive methods including human knowledge, and even evolutionary adaptive methods [14.66].

## 14.5 Interpretable Fuzzy Systems in the Real World

Interpretable fuzzy systems have an immediate impact on real-world applications. In particular, their usefulness is appreciable in all application areas that put humans at the center of computing. Interpretable fuzzy systems, in fact, conjugate knowledge acquisition capabilities with the ability of communicating knowledge in a human-understandable way.

Several application areas can take advantage from the use of interpretable fuzzy systems. In the following, some of them are briefly outlined, along with a few notes on specific applications and potentialities.

- *Environment:* Environmental issues are often challenging because of the complex dynamics, the high number of variables and the consequent uncertainty characterizing the behavior of subjects under study. Computational intelligence techniques come into play when tolerance for imprecision can be exploited to design convenient models that are suitable to understand phenomena and take decisions. Interpretable fuzzy systems show a clear advantage over black-box systems in providing knowledge that is capable of explaining complex and nonlinear relationships by using linguistic models. Real-world environmental applications of interpretable fuzzy systems include: harmful bioaerosol detection [14.67]; modeling habitat suitability in river management [14.68]; modeling pesticide loss caused by meteorological factors in agriculture [14.69], and so on.
- *Finance:* This is a sector where human-computer cooperation is very tight. Cooperation is carried out in different ways, including the use of computers to provide business intelligence for decision support in financial operations. In many cases financial decisions are ultimately made by experts, who can benefit from automated analyses of big masses of data flowing daily in markets. To this pursuit, Computational intelligence approaches are spreading among the tools used by financial experts in their decisions, including interpretable fuzzy systems for

stock return predictions [14.70], exchange rate forecasting [14.71], portfolio risk monitoring [14.72], etc.

- *Industry:* Industrial applications could take advantage from interpretable fuzzy systems when there is the need of explaining the behavior of complex systems and phenomena, like in fault detection [14.73]. Also, control plans for systems and processes can be designed with the help of fuzzy systems. In such cases, a common practice is to start with an initial expert knowledge (used to design rules which are usually highly interpretable) that is then tuned to increase the accuracy of the controller. However, any unconstrained tuning could destroy the original interpretability of the knowledge base, whilst, by taking into account interpretability, the possibility of revising and modifying the controller (or the process manager) can be enhanced [14.74].
- *Medicine and Health-care:* As a matter of fact, in almost all medical contexts intelligent systems can be invaluable decision support tools, but people are the ultimate actors in any decision process. As a consequence, people need to rely on intelligent systems, whose reliability can be enhanced if their outcomes may be explained in terms that are comprehensible by human users. Interpretable fuzzy systems could play a key role in this area because of the possibility of acquiring knowledge from data and communicating it to users. In the literature, several approaches have been proposed to apply interpretable fuzzy systems in different medical problems, like assisted diagnosis [14.75], prognosis prediction [14.76], patient subgroup discovery [14.77], etc.
- *Robotics:* The complexity of robot behavior modeling can be tackled by an integrated approach where a first modeling stage is carried out by combining human expert and empirical knowledge acquired from experimental trials. This integrated approach requires that the final knowledge base is provided to experts for further maintenance: this task could be done effectively only if the acquired knowledge

is interpretable by the user. Some concrete applications of this approach can be found in robot localization systems [14.78] and motion analysis [14.79, 80].

- *Society:* The focus of intelligent systems for social issues has noticeably increased in recent years. For

reasons that are common to all the previous application areas, interpretable fuzzy systems have been applied in a wide variety of scopes, including quality of service improvement [14.81], data mining with privacy preservation [14.82], social network analysis [14.37], and so on.

## 14.6 Future Research Trends on Interpretable Fuzzy Systems

Research on interpretable fuzzy systems is open in several directions. Future trends involve both theoretical and methodological aspects of interpretability. In the following, some trends are outlined amongst the possible lines of research development [14.7].

- *Interpretability definition:* The blurred nature of interpretability requires continuous investigations on possible definitions that enable a computable treatment of this quality in fuzzy systems. This requirement casts the research on interpretable fuzzy systems toward cross-disciplinary investigations. For instance, this research line includes investigations on computable definitions of some conceptual qualities, like *vagueness* (which has to be distinguished from imprecision and fuzziness). Also, the problem of interpretability of fuzzy systems can be intended as a particular instance of the more general problem of communication between granular worlds [14.83], where many aspects of interpretability could be treated in a more abstract way.
- *Interpretability assessment:* A prominent objective is the adoption of a common framework for characterizing and assessing interpretability with the aim of avoiding misleading notations. Within such a framework, novel metrics could be devised, especially for assessing subjective aspects of interpretability, and integrated with objective interpretability measures to define more significant interpretability indexes.
- *Design of interpretable fuzzy models:* A current research trend in designing interpretable fuzzy models makes use of multiobjective genetic algorithms in

order to deal with the conflicting design objectives of accuracy and interpretability. The effectiveness and usefulness of these approaches, especially those concerning advanced schemes, have to be verified against a number of indexes, including indexes that integrate subjective measures. This verification process is particularly required when tackling high-dimensional problems. In this case, the combination of linguistic and graphical approaches could be a promising approach for descriptive and exploratory analysis of interpretable fuzzy systems.

- *Representation of fuzzy systems:* For very complex problems the use of novel forms of representation (different from the classical rule based) may help in representing complex relationship in comprehensible ways thus yielding a valid aid in designing interpretable fuzzy systems. For instance, a multilevel representation could enhance the interpretability of fuzzy systems by providing different granularity levels for knowledge representation. On the one hand, the highest granulation levels give a coarse (yet immediately comprehensible) description of knowledge, while lower levels provide for more detailed knowledge.

As a final remark, it is worth observing that interpretability is one aspect of the multifaceted problem of *human-centered* design of fuzzy systems [14.84]. Other facets include acceptability (e.g., according to ethical rules), interestingness of fuzzy rules, applicability (e.g., with respect to law), etc. Many of them are not yet in the research mainstream but they clearly represent promising future trends.

## 14.7 Conclusions

Interpretability is an indispensable requirement for designing fuzzy systems, yet it cannot be assumed to hold by the simple fact of using fuzzy sets for modeling. Interpretability must be encoded in some computational

methods in order to drive the design of fuzzy systems, as well as to assess the interpretability of existing models. The study of interpretability issues started about two decades ago and led to a number of theoretical

and methodological results of paramount value in fuzzy modeling. Nevertheless, research is still open both in depth – through new ways of encoding and assessing

interpretability – and in breadth, by integrating interpretability in the more general realm of human centered computing.

# 15. Fuzzy Clustering – Basic Ideas and Overview

# Fuzzy cluster

Sadaaki Miyamoto

This chapter overviews basic formulations as well as recent studies in fuzzy clustering. A major part is devoted to the discussion of fuzzy  $c$ -means and their variations. Recent topics such as kernel-based fuzzy  $c$ -means and clustering with semi-supervision are mentioned. Moreover, fuzzy hierarchical clustering is overviewed and fundamental theorem is given.

## 15.1 Fuzzy Clustering

Data clustering is an old subject [15.1–4] but recently more researchers are developing different techniques and application fields are enlarging. Fuzzy clustering [15.5–10] is also popular in a variety of fuzzy systems. This chapter reviews basic ideas of fuzzy clustering, and provides a brief overview of recent studies. First, we consider the most popular method in fuzzy clustering, i.e., fuzzy  $c$ -means. There are many variations, extensions and applications of fuzzy  $c$ -means,

some of which are described here. Recent studies on kernel-based methods and clustering with semisupervision are also discussed in relation to fuzzy  $c$ -means.

Moreover, another fuzzy clustering is briefly mentioned which uses the transitive closure of fuzzy relations [15.10]. This method is shown to be equivalent to the well-known methods of the single linkage of agglomerative hierarchical clustering [15.11].

## 15.2 Fuzzy $c$ -Means

We begin with basic notations and then introduces the method of fuzzy  $c$ -means by Dunn [15.5, 6] and Bezdek [15.7, 8].

### 15.2.1 Notations

The set of objects for clustering is denoted by  $X = \{x_1, \dots, x_N\}$  where each objects is a point of  $p$ -dimensional Euclidean space  $\mathbf{R}^p$ :  $x_k = (x_k^1, \dots, x_k^p)$ ,  $k = 1, \dots, N$ . Clusters are denoted either by  $G_i$  or simply by  $i$  when no confusion arises. Clustering uses a similarity or dissimilarity measure. In this section, a dissimilarity measure denoted by  $D(x, y)$ ,  $x, y \in \mathbf{R}^p$ , is used.

Although we have different choices for dissimilarity measure, a standard measure is the squared Euclidean distance

$$D(x, y) = \|x - y\|^2 = \sum_{j=1}^p (x^j - y^j)^2. \quad (15.1)$$

In fuzzy  $c$ -means and related methods, the number of clusters, denoted by  $c$  is assumed to be given beforehand. The membership of object  $x_k$  to cluster  $i$  is assumed to be given by  $u_{ki}$ . Moreover, the collection of all memberships is denoted by matrix  $U = (u_{ki})$ . It is natural to assume that  $u_{ki} \in [0, 1]$  for all  $1 \leq i \leq c$

and  $1 \leq k \leq N$ , and, moreover,  $\sum_{j=1}^c u_{kj} = 1$ , for all  $1 \leq k \leq N$ .

The method of fuzzy  $c$ -means also uses a center for a cluster, which is denoted by  $v_i = (v_i^1, \dots, v_i^p) \in \mathbf{R}^p$  for cluster  $i$ . For the ease of reference, all cluster centers are summarized into  $V = (v_1, \dots, v_c)$ .

### Basic K-Means Algorithm

Many studies of clustering handles  $K$ -means [15.12] as a standard method.

#### Algorithm 15.1 KM: Basic K-means algorithm

- KM0: Generate randomly  $c$  cluster centers.
- KM1: Allocate each object  $x_k$  ( $k = 1, \dots, N$ ) to the cluster of the nearest center.
- KM2: Calculate new cluster centers as the centroid (the center of gravity). If all cluster centers are convergent, stop. Otherwise, go to KM1.

End KM.

Note that the centroid of a cluster  $G_i$  is given by  $v_i = \frac{1}{|G_i|} \sum_{x_k \in G_i} x_k$ , where  $|G_i|$  is the number of objects in  $G_i$ .

### 15.2.2 Fuzzy $c$ -Means Algorithm

It should first be noted that the basic idea of fuzzy  $c$ -means is an alternative optimization of an objective function proposed by Dunn [15.5, 6] and Bezdek [15.7, 8].

$$J(U, V) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m D(x_k, v_i) \quad (m > 1), \quad (15.2)$$

where  $D(x_k, v_i)$  is the squared Euclidean distance (15.1).

Using this objective function, the following alternative optimization is carried out.

#### Algorithm 15.2 FCM: Fuzzy $c$ -means algorithm

- FCM0: Generate randomly initial fuzzy clusters. Let the solutions be  $(\bar{U}, \bar{V})$
- FCM1: Minimize  $J(U, \bar{V})$  with respect to  $U$ . Let the optimal solution be a new  $\bar{U}$ .
- FCM2: Minimize  $J(\bar{U}, V)$  with respect to  $V$ . Let the optimal solution be a new  $\bar{V}$ .

FCM3: If the solution  $(\bar{U}, \bar{V})$  is convergent, stop.  
Else go to FCM1.

End FCM.

Note that optimization with respect to  $U$  is with the constraint

$$\begin{aligned} u_{ki} &\in [0, 1], \quad \forall 1 \leq i \leq c, 1 \leq k \leq N, \\ \sum_{j=1}^c u_{kj} &= 1, \quad \forall 1 \leq k \leq N, \end{aligned} \quad (15.3)$$

while optimization with respect to  $V$  is without any constraint.

It is not difficult to have the optimal solutions as follows

$$\bar{u}_{ki} = \frac{1}{\sum_{j=1}^c \frac{1}{D(x_k, \bar{v}_j)^{\frac{1}{m-1}}}}, \quad (15.4)$$

$$\bar{v}_i = \frac{\sum_{k=1}^N (\bar{u}_{ki})^m x_k}{\sum_{k=1}^N (\bar{u}_{ki})^m}. \quad (15.5)$$

The derivations are omitted; the readers should refer to [15.8] or other textbooks.

Note also that (15.4) appears ill-defined when  $x_k = v_i$ . In such a case, we use

$$\bar{u}_{ki} = \frac{1}{1 + \sum_{j \neq i} \frac{1}{D(x_k, \bar{v}_j)^{\frac{1}{m-1}}}}, \quad (15.6)$$

which has the same value as (15.4) without a singular point.

Moreover, we write these equations without the use of bars like

$$\begin{aligned} u_{ki} &= \frac{1}{\sum_{j=1}^c \frac{1}{D(x_k, v_j)^{\frac{1}{m-1}}}} \\ v_i &= \frac{\sum_{k=1}^N (u_{ki})^m x_k}{\sum_{k=1}^N (u_{ki})^m}, \end{aligned}$$

for simplicity and without any confusion.

### 15.2.3 A Natural Classifier

These solutions lead us to the following natural fuzzy classifier with a given set of cluster centers  $V$

$$U_i(x; V) = \frac{1}{1 + \sum_{j \neq i} \frac{1}{D(x, \bar{v}_j)^{\frac{1}{m-1}}}}. \quad (15.7)$$

There is nothing strange in (15.7), since  $U_i(x; V)$  has been derived from  $u_{ki}$  simply by replacing object  $x_k$  by the variable  $x$ .

This replacement appears rather trivial and it also appears that  $U_i(x; V)$  has no further information than  $u_{ki}$ . On the contrary, this function is important if we wish to observe theoretical properties of fuzzy  $c$ -means.

The following propositions are not difficult to prove and hence the proofs are omitted [15.13]. In particular, the first proposition is trivial.

### Proposition 15.1

$U_i(x_k; V) = u_{ki}$ , i.e., the fuzzy classifier interpolates the membership value  $u_{ki}$ .

### Proposition 15.2

When  $|x|$  go to infinity,  $U_i(x; V)$ ,  $i = 1, \dots, c$ , approaches the same value of  $1/c$

$$\lim_{\|x\| \rightarrow \infty} U_i(x; V) = \frac{1}{c}.$$

### Proposition 15.3

The maximum value of  $U_i(x; V)$ ,  $i = 1, \dots, c$ , is at  $x = v_i$

$$\max_{x \in R^p} U_i(x; V) = U_i(v_i, V) = 1.$$

The significance of the function  $U_i(x; V)$  is shown in these propositions. An object  $x_k$  is a fixed point, while  $x$  is a variable. Without such a variable, we cannot observe theoretical properties of fuzzy  $c$ -means.

### 15.2.4 Variations of Fuzzy $c$ -Means

Many variations of fuzzy  $c$ -means have been studied, among which we first mention fuzzy  $c$ -varieties [15.8], fuzzy  $c$ -regressions [15.14], and the method of Gustafson and Kessel [15.15] to take clusterwise covariance into account. Note that these are relatively old variations and they all are based on variations of objective functions including the change of  $D(x, v)$ .

In this section, we use the additional symbols  $\langle x, y \rangle = x^\top y = y^\top x$ , which is the standard scalar product of the Euclidean space  $R^p$ . Moreover, we introduce

$$D(x, v; S) = (x - v)^\top S^{-1} (x - v),$$

which is the squared Mahalanobis distance.

### Fuzzy $c$ -Varieties

Let us first consider a  $q$ -dimensional subspace

$$\begin{aligned} \text{span}\{s_1, \dots, s_q\} &= \{a_1 s_1 + \dots + a_q s_q : \\ &\quad -\infty < a_j < +\infty, \\ &\quad k = 1, \dots, q\}, \end{aligned}$$

where  $s_1, \dots, s_q$  is a set of orthonormal set of vectors with  $q < p$ .  $s_0$  is a given vector of  $R^p$ . A linear variety  $L$  in  $R^p$  is represented by

$$\begin{aligned} L &= \{l = s_0 + a_1 s_1 + \dots + a_q s_q : \\ &\quad -\infty < a_j < +\infty, k = 1, \dots, q\}. \end{aligned}$$

Let

$$P(x, l) = \arg \max_{l \in L} \langle x - s_0, l - s_0 \rangle$$

be the projection of  $x$  onto  $L$ . We then define

$$D(x_k, l_i) = \|x_k - s_0\|^2 - P(x_k, l_i)^2.$$

We consider the objective function for fuzzy  $c$ -varieties

$$J(U, L) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m D(x_k, l_i) \quad (m > 1), \quad (15.8)$$

where  $L = (l_1, \dots, l_c)$ .

The derivation of the solutions is omitted here, but the solutions are as follows:

$$u_{ki} = \frac{\frac{1}{D(x_k, l_i)^{\frac{1}{m-1}}}}{\sum_{j=1}^c \frac{1}{D(x_k, l_j)^{\frac{1}{m-1}}}}, \quad (15.9)$$

$$\bar{s}_0^{(i)} = \frac{\sum_{k=1}^N (u_{ki})^m x_k}{\sum_{k=1}^N (u_{ki})^m}, \quad (15.10)$$

while  $\bar{s}_j^{(i)}$  ( $j = 1, \dots, q$ ) is the normalized eigenvector corresponding to the  $q$  maximum eigenvalues of the matrix

$$A_i = \sum_{k=1}^N (u_{ki})^m (x_k - \bar{s}_0^{(i)}) (\bar{s}_0^{(i)})^\top. \quad (15.11)$$

Note that the superscript  $s_j^{(i)}$  shows those vectors for cluster  $i$ .

Therefore, alternative optimization of (15.8) is done by calculating (15.9), (15.10), and the eigenvectors for (15.11) repeatedly until convergence.

### Fuzzy $c$ -Regression Models

In this section, we assume that  $x = (x^1, \dots, x^p)$  is a  $p$ -dimensional independent variable, while  $y$  is a scalar-valued dependent variable. Hence data set  $\{(x_1, y_1), \dots, (x_N, y_N)\}$  is handled. We consider  $c$  regression models

$$y = \sum_{j=1}^p \beta_i^j x^j + \beta_i^{p+1}, \quad i = 1, \dots, c.$$

Hence, the squared error is taken to be the dissimilarity

$$D((x_k, y_k), B_i) = \left( y_k - \sum_{j=1}^p \beta_i^j x_k^j - \beta_i^{p+1} \right)^2$$

and an objective function

$$J(U, B) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m D((x_k, y_k), B_i) \quad (m > 1), \quad (15.12)$$

is considered, where  $B_i = (\beta_i^1, \dots, \beta_i^{p+1})$  and  $B = (B_1, \dots, B_c)$ . To express the solutions in a compact manner, we introduce two vectors

$$z_k = (x_k^1, \dots, x_k^p, 1), \quad \hat{\beta}_i = (\beta_i^1, \dots, \beta_i^{p+1}).$$

Then we have

$$u_{ki} = \frac{1}{\sum_{j=1}^c \frac{1}{D((x_k, y_k), B_i)^{\frac{1}{m-1}}}}, \quad (15.13)$$

$$\hat{\beta}_i = \left( \sum_{k=1}^N (u_{ki})^m z_k z_k^\top \right)^{-1} \sum_{k=1}^N (u_{ki})^m y_k z_k. \quad (15.14)$$

Thus the alternative optimization of  $J(U, B)$  is to calculate (15.13) and (15.14) iteratively until convergence.

#### The Method of Gustafson and Kessel

The method of Gustafson and Kessel enables us to incorporate clusterwise covariance variables denoted by  $S_1, \dots, S_c$ . We consider

$$J(U, V, S) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m D(x_k, v_i; S_i) \quad (m > 1), \quad (15.15)$$

where a simplified symbol  $S = (S_1, \dots, S_c)$  and the clusterwise squared Mahalanobis distance  $D(x_k, v_i; S_i)$  is used. Note also that  $S_i$  is with the constraint

$$|S_i| = \rho_i \quad (\rho_i > 0) \quad (15.16)$$

where  $\rho_i$  is a fixed parameter and  $|S_i|$  is the determinant of  $S_i$ . We assume, for simplicity,  $\rho_i = 1$  [15.16].

The solutions are as follows

$$u_{ki} = \left\{ \sum_{j=1}^c \left( \frac{D(x_k, v_i; S_i)}{D(x_k, v_j; S_j)} \right)^{\frac{1}{m-1}} \right\}^{-1}, \quad (15.17)$$

$$v_i = \frac{\sum_{k=1}^N (u_{ki})^m x_k}{\sum_{k=1}^N (u_{ki})^m}, \quad (15.18)$$

$$S_i = \frac{1}{|\hat{S}_i|^{\frac{1}{p}}} \sum_{k=1}^N (u_{ki})^m (x_k - v_i)(x_k - v_i)^\top. \quad (15.19)$$

where  $\hat{S}_i = \sum_{k=1}^N (u_{ki})^m (x_k - v_i)(x_k - v_i)^\top$ .

Since three types of variables are used for the method of Gustafson and Kessel, the alternative optimization iteratively calculates (15.17–15.19) until convergence.

#### 15.2.5 Possibilistic Clustering

The possibilistic clustering [15.17, 18] proposed by Krishnapuram and Keller does not use the constraint (15.3) in the alternative optimization algorithm **FCM**. Rather, the optimization with respect to  $U$  is without any constraint. To handle  $\arg \min_U J(U, \bar{V})$  of (15.2) without a constraint leads to the trivial solution of  $U = O$  (the zero matrix), and hence they proposed a modified objective function

$$J_{\text{pos}}(U, V) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m D(x_k, v_i) + \sum_{i=1}^c \eta_i \sum_{k=1}^N (1 - u_{ki})^m \quad (m > 1), \quad (15.20)$$

where  $\eta_i$  ( $i = 1, \dots, c$ ) is a positive constant.

We easily have the optimal  $U$

$$u_{ki} = \frac{1}{1 + \left( \frac{D(x_k, v_i)}{\eta_i} \right)^{\frac{1}{m-1}}}, \quad (15.21)$$

while optimal  $V$  is given by (15.5).

The natural fuzzy classifier derived from the possibilistic clustering is

$$U_i(x; v_i) = \frac{1}{1 + \left(\frac{D(x, v_i)}{\eta_i}\right)^{\frac{1}{m-1}}}, \quad i = 1, \dots, c. \quad (15.22)$$

This classifier has the following properties:

#### Proposition 15.4

$U_i(x_k; v_i) = u_{ki}$  by (15.21), i.e., the possibilistic classifier interpolates the membership value  $u_{ki}$ .

#### Proposition 15.5

When  $|x|$  go to infinity,  $U_i(x; v_i)$  ( $i = 1, \dots, c$ ) approaches zero

$$\lim_{\|x\| \rightarrow \infty} U_i(x; v_i) = 0.$$

#### Proposition 15.6

The maximum value of  $U_i(x; v_i)$  ( $i = 1, \dots, c$ ) is at  $x = v_i$

$$\max_{x \in \mathbb{R}^p} U_i(x; v_i) = U_i(v_i, v_i) = 1.$$

### 15.2.6 Kernel-Based Fuzzy $c$ -Means

The support vector machines [15.19, 20] is now one of the most popular methods of supervised classification. Since positive definite kernels are frequently used in support vector machines, the study of kernels has also been done by many researchers (e.g., [15.21]). The positive definite kernels can also be used for fuzzy  $c$ -means, as we see in this section.

The reason why we use kernels for clustering is that essentially the  $K$ -means and fuzzy  $c$ -means have linear boundaries between clusters.

Note that the  $K$ -means classifier uses the nearest center allocation rule for a given  $x \in \mathbb{R}^p$

$$x \rightarrow G_i \iff i = \arg \min_{1 \leq j \leq c} D(x, v_j),$$

and hence the rules generates the Voronoi region [15.22] with the centers  $v_1, \dots, v_c$  which has piecewise linear boundaries.

For fuzzy  $c$ -means, the classifiers are fuzzy but if we introduce simplification of the rules by crisp reallocation [15.13] by

$$x \rightarrow G_i \iff i = \arg \max_{1 \leq j \leq c} U_i(x; V).$$

Then we again have the Voronoi regions with the centers  $v_1, \dots, v_c$ .

The introduction of the covariance variables enables the cluster boundaries to be quadratic, but more flexible nonlinear boundaries cannot be obtained.

In order to have clusters with nonlinear boundaries, we can use positive-definite kernels. Kernels are introduced by using a high-dimensional mapping  $\Phi: \mathbb{R}^p \rightarrow H$ , where  $H$  is a Hilbert space with the inner product  $\langle \cdot, \cdot \rangle_H$  and the norm  $\|\cdot\|_H$ .

Given objects  $x_1, \dots, x_N$ , we consider its images by the mapping  $\Phi: \Phi(x_1), \dots, \Phi(x_N)$ . Note that the method of kernels does not assume that an explicit form of  $\Phi(x_1), \dots, \Phi(x_N)$  is known, but their inner product  $\langle \Phi(x_i), \Phi(x_j) \rangle_H$  is assumed to be known. Specifically, a positive-definite function  $K(x, y)$  is given and we assume

$$K(x, y) = \langle \Phi(x_i), \Phi(y) \rangle_H.$$

This assumption seems abstract, but if we are given an actual kernel function, the method becomes simple, for example, a well-known kernel is the Gaussian kernel

$$K(x, y) = \exp(-C\|x - y\|^2).$$

Then what we handle is  $\langle \Phi(x_i), \Phi(x_j) \rangle_H = \exp(-C\|x_i - x_j\|^2)$ .

We now proceed to consider kernel-based fuzzy  $c$ -means [15.23]. The objective function uses  $\Phi(x_1), \dots, \Phi(x_N)$  and cluster centers  $w_1, \dots, w_c$  of  $H$

$$J(U, V) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^m \|\Phi(x_k) - w_i\|_H^2 \quad (m > 1), \quad (15.23)$$

where  $W = (w_1, \dots, w_c)$ . We have

$$u_{ki} = \frac{1}{\sum_{j=1}^c \frac{1}{\|\Phi(x_k) - w_j\|_H^{\frac{2}{m-1}}}} \quad (15.24)$$

$$w_i = \frac{\sum_{k=1}^N (u_{ki})^m \Phi(x_k)}{\sum_{k=1}^N (u_{ki})^m}. \quad (15.25)$$

Note, however, that the explicit form of  $\Phi(x_k)$  and hence  $w_i$  is not available. Therefore, we eliminate  $w_i$  from the iterative calculation. Thus, the updating  $w_i$  is replaced by the update of

$$D_H(x_k, w_i) = \|\Phi(x_k) - w_i\|^2.$$

We then have

$$\begin{aligned} D_H(x_k, w_i) &= K(x_k, x_k) \\ &\quad - \frac{2}{\sum_{k=1}^N (u_{ki})^m} \sum_{j=1}^N (u_{ji})^m K(x_j, x_k) \\ &\quad + \frac{1}{\left(\sum_{k=1}^N (u_{ki})^m\right)^2} \\ &\quad \times \sum_{j=1}^N \sum_{\ell=1}^N (u_{ji} u_{\ell i})^m K(x_j, x_\ell). \end{aligned} \quad (15.26)$$

Using (15.26), we calculate

$$u_{ki} = \frac{\frac{1}{D_H(x_k, w_i)^{\frac{1}{m-1}}}}{\sum_{j=1}^c \frac{1}{D_H(x_k, w_j)^{\frac{1}{m-1}}}}. \quad (15.27)$$

Thus the alternative optimization repeats (15.26) and (15.27) until convergence.

Fuzzy classifiers of kernel-based fuzzy  $c$ -means can also be derived [15.13]. We omit the details and show the function in the following

$$\begin{aligned} D(x; v_i) &= K(x, x) - \frac{2}{\sum_{k=1}^N (u_{ki})^m} \sum_{j=1}^N (u_{ji})^m K(x, x_j) \\ &\quad + \frac{1}{\left(\sum_{k=1}^N (u_{ki})^m\right)^2} \\ &\quad \times \sum_{j=1}^N \sum_{\ell=1}^N (u_{ji} u_{\ell i})^m K(x_i, x_\ell), \end{aligned} \quad (15.28)$$

$$U_i(x) = \left[ \sum_{j=1}^c \left( \frac{D(x; v_j)}{D(x; v_i)} \right)^{\frac{1}{m-1}} \right]^{-1}. \quad (15.29)$$

### A Simple Numerical Example

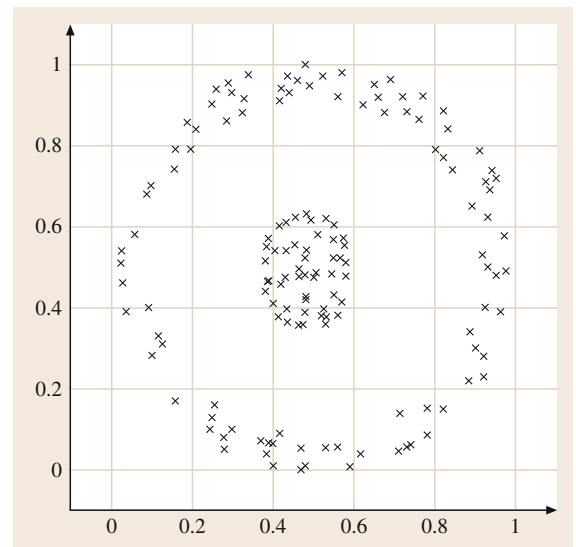

A well-known and simple example to see how the kernel method work to produce clusters with nonlinear boundaries is given in Fig. 15.1. There is a circular cluster inside another group of objects of a ring shape. We call it *ring around circle* data.

Figure 15.2 shows the shape of a fuzzy classifier (15.29) with  $m = 2$  and  $c = 2$  obtained from the *ring around circle* data. Thus the ring and the circle inside the ring are perfectly separated.

### 15.2.7 Clustering with Semi-Supervision

Recently many studies consider semisupervised learning (e.g., [15.24, 25]). In this section we briefly overview literature in fuzzy clustering with semi-supervision.

We begin with two classes of semisupervised learning after Zhu and Goldberg [15.25]. They defined *semisupervised classification* that has a set of labeled samples and another set of unlabeled samples. Another class is called constrained clustering which has two sets of *must-links*  $ML = \{(x, y), \dots\}$  and *cannot-links*  $CL = \{(z, w), \dots\}$ . Two objects  $x$  and  $y$  in the must-link set has to be allocated in the same cluster, while  $z$  and  $w$  in the cannot-link set has to be allocated to different clusters.

**Fig. 15.1** An example of a circle and a ring around the circle

Let us briefly mention two studies in the first class of semisupervised classification. *Bouchachia and Pedrycz* [15.26] used the following objective function that has an additional term

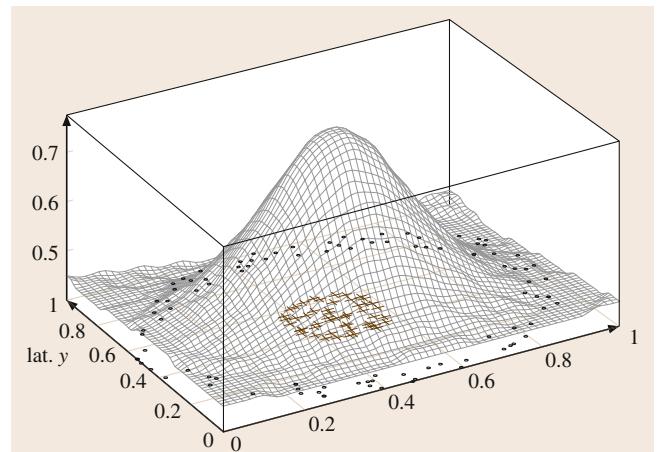

$$J(U, V) = \sum_{i=1}^c \sum_{k=1}^N \left\{ (u_{ki})^m D(x_k, v_i) + \alpha (u_{ki} - \tilde{u}_{ki})^m D(x_k, v_i) \right\}.$$

where  $\tilde{u}_{ki}$  is a given membership showing semisupervision.

*Miyamoto* [15.27] proved that an objective function with entropy term [15.13, 28–31] can generalize the EM solution of the mixture of Gaussian densities with semisupervision [15.25, p. 27].

Another class of constrained clustering [15.32, 33] has also been studied using a modified objective function [15.34] with additional terms of the must-link and cannot-link

$$J(U, V) = \sum_{i=1}^c \sum_{k=1}^N (u_{ki})^2 D(x_k, v_i) + \alpha \sum_{k=1}^N \left( \sum_{(x_k, x_j) \in ML} \sum_{i \neq l} u_{ki} u_{lj} + \sum_{(x_k, x_j) \in CL} \sum_{i=1}^c u_{ki} u_{lj} \right).$$

**Fig. 15.2** Two clusters and a fuzzy classifier from the *ring around circle* data; fuzzy  $c$ -means with  $m = 2$  is used

To summarize, the method of fuzzy  $c$ -means with semisupervision including constrained clustering has not yet gained wide popularity, due to the limited number of studies comparing with those in another field of machine learning where many papers and a number of books have been published [15.24, 25, 32]. Hence more results can be expected in this area of studies.

## 15.3 Hierarchical Fuzzy Clustering

There is still another method of fuzzy clustering that is very different from the above fuzzy  $c$ -means which is related to the single linkage in agglomerative hierarchical clustering.

In this section, we assume that objects  $X = \{x_1, \dots, x_N\}$  are not necessarily in an Euclidean space. Rather, a relation  $S(x, y)$  satisfying reflexivity and symmetry

$$S(x, x) = 1, \quad \forall x \in X, \quad (15.30)$$

$$S(x, y) = S(y, x), \quad \forall x, y \in X \quad (15.31)$$

is assumed, where a larger value of  $S(x, y)$  means that  $x$  and  $y$  are more similar.

We then describe the general algorithm of agglomerative hierarchical clustering as follows:

### Algorithm 15.3 AHC: Algorithm of Agglomerative Hierarchical Clustering

AHC1: Let initial clusters be individual objects  $G_i = \{x_i\}, i = 1, \dots, N$  and put  $K = N$ .

AHC2: Find pair of clusters of maximum similarity

$$(G_p, G_q) = \arg \max_{i,j} S(G_i, G_j).$$

Merge  $G_r = G_p \cup G_q$ .  $K = K - 1$  and if  $K = 1$ , stop.

AHC3: Update  $S(G_r, G')$  for all other clusters  $G'$ . Go to AHC1.

End AHC.

The updating step of AHC3 admits different choices of similarity between clusters, among which the single linkage methods uses

$$S(G, G') = \max_{x \in G, y \in G'} S(x, y).$$

Although there are other choices, discussion in this section is focused upon the single linkage.

On the other hand, studies in the 1970s including *Zadeh's* [15.10] proposed hierarchical clustering using

the transitive closure of fuzzy relations  $S(x, y)$ . To define the transitive closure, we introduce the max–min composition

$$(S \circ T)(x, z) = \max_{y \in X} \min\{S(x, y), T(y, z)\},$$

where  $S$  and  $T$  are the fuzzy relations of  $X$ . Using the max–min composition, we can define the transitive closure  $S^*$  of  $S$

$$S^*(x, y) = \max\{S(x, y), S^2(x, y), S^3(x, y), \dots\},$$

where  $S^2 = S \circ S$  and  $S^k = S \circ S^{k-1}$ . It also is not difficult to see  $S^* = S^{N-1}$  when  $S$  is reflexive and symmetric.

When  $S$  is reflexive and symmetric, the transitive closure  $S^*$  is also reflexive and symmetric, and moreover transitive

$$S^*(x, y) \geq \min\{S^*(x, z), S^*(z, y)\}, \quad \forall z \in X.$$

If a fuzzy relation is reflexive, symmetric, and transitive, then it is called a fuzzy equivalence relation: it has a property that every  $\alpha$ -cut is a crisp equivalence relation

$$[S^*]_\alpha(x, x) = 1, \quad \forall x \in X, \quad (15.32)$$

$$[S^*]_\alpha(x, y) = [S^*]_\alpha(y, x), \quad \forall x, y \in X, \quad (15.33)$$

$$\begin{aligned} [S^*]_\alpha(x, y) &= 1, [S^*]_\alpha(y, z) = 1 \\ \Rightarrow [S^*]_\alpha(x, z) &= 1, \end{aligned} \quad (15.34)$$

where  $[S^*]_\alpha(x, y)$  is the  $\alpha$ -cut of  $S^*(x, y)$

$$[S^*]_\alpha(x, y) = 1 \iff S^*(x, y) \geq \alpha;$$

$$[S^*]_\alpha(x, y) = 0 \iff S^*(x, y) < \alpha.$$

Thus each  $\alpha$ -cut of  $S^*$  induces an equivalence class of  $X$ , and moreover if  $\alpha$  decreases, the equivalence class

becomes coarser, and therefore  $S^*$  defines a hierarchical clusters.

We now can describe a fundamental theorem on fuzzy hierarchical clustering.

### Theorem 15.1 Miyamoto [15.11]

Given a set of objects  $X = \{x_1, \dots, x_N\}$  and a similarity measure  $S(x, y)$  for all  $x, y \in X$ , the following four methods give the same hierarchical clusters:

1. Clusters by the single linkage,
2. Clusters by the transitive closure  $S^*$ ,
3. Clusters as vertices of connected components of fuzzy graph with vertices  $X$  and edges  $X \times X$  with membership values  $S(x, y)$ , and
4. Clusters generated from the maximum spanning tree of the network with vertices  $X$  and edges  $X \times X$  with weight  $S(x, y)$ .

The above theorem needs some more explanations. Connected components of a fuzzy graph means the family of those connected components of all  $\alpha$ -cuts of the fuzzy graph. Since connected components grows with decreasing  $\alpha$ , those sets of vertices form hierarchical clusters. The minimum spanning tree is well known, but the maximum spanning tree is used instead. The way in which hierarchical clusters are generated is the same as the connected components of the fuzzy graph.

Although this theorem shows the importance of fuzzy hierarchical clustering, it appears that no new results that are useful in applications are included in this theorem. Miyamoto [15.35] showed, however, that other methods of DBSCAN [15.36] and Wishart's mode analysis [15.37] have close relations to the above results, and he discusses the possibility of further application of this theorem, e.g., to nonsymmetric similarity measure.

## 15.4 Conclusion

We overviewed fuzzy  $c$ -means and related studies. Kernel-based clustering algorithm and clustering with semisupervision were also discussed. Moreover, fuzzy hierarchical clustering which is based on fuzzy graphs and very different from fuzzy  $c$ -means was briefly reviewed.

New methods and algorithms based on the idea of fuzzy  $c$ -means are still being developed, as the fundamental idea has enough potential to produce many new techniques. On the other hand, fuzzy hierarchical clustering is rarely mentioned in the literature. However, there are possibilities for having new theory, methods,

and applications in this area, as the fundamental mathematical structure is well established.

Many important studies were not mentioned in this overview, for example, *Ruspini's method* [15.38] and cluster validation measures are important. Read-

ers may read books on fuzzy clustering [15.8, 9, 13, 16, 39] for details of fuzzy clustering. Also, *Miyamoto* [15.11] can still be used for studying the fundamental theorem on fuzzy hierarchical clustering.

# An Algebraic Model of Reasoning to Support Zadeh's CWW

Enric Trillas

In the very wide setting of a Basic Fuzzy Algebra, a formal algebraic model for Commonsense Reasoning is presented with fuzzy and crisp sets including, in particular, the usual case of the Standard Algebras of Fuzzy Sets. The aim with which the model is constructed is that of, first, adding to Zadeh's *Computing with Words* a wide perspective of ordinary reasoning in agreement with some basic characteristics of it, and second, presenting an operational ground on which linguistic terms can be represented, and schemes of inference posed. Additionally, the chapter also tries to express the author's belief that reasoning deserves to be studied like an Experimental Science.

## 16.1 A View on Reasoning

Thinking is a yet not scientifically well-known natural and complex neurophysiological phenomenon that, shown by people and given thanks to their brains, is mostly and significantly externalized in some observable physical ways, like it is the case of talking by means of uttered or written words. Only recently the functioning of the brain's systems started to be studied with the current methods of experimental science, and made some knowledge on its internal working possible.

Talking acquires full development with a typically social human manifestation called telling with, at least, its two modalities of discourse and narrative that, either in different oral, spatial hand's signs, or written forms, not only support telling but, together with abstraction, could be considered among the highest expressions of brain's capability of thinking, surely reinforced during evolution by the physical possibilities of the humans to tackle and to consider the possible usefulness of ob-

jects. Telling can be roughly described as consisting in chains of sentences organized with some purpose.

Thinking and telling are but names for abstract concepts covering the totality of those human actions designated by *to think*, *to tell*, and *to discuss*, of which only the last two can be directly observed by a layperson. With telling and discussing not only reasoning is shown, but also abstraction is conveyed. In this sense, it can be said that telling and discussing cannot exist without reasoning, and that they are intermingled in some inextricable form that allows us to guess for foreseeing what will come in the future, to imagine what could happen in it, and to express it by words. At this point, the human capability of conjecturing appears as something fundamental [16.1].

Foreseeing and imagining resulted essential for the growing and expanding of mankind on Earth, and are assisted by the human capabilities of guessing (or conjecturing), and refuting, for saying nothing on those

emotions that so often drive human reasoning toward *creative thinking*. Of course, as thinking comprises more features than reasoning, like they are the case of feelings and imagining with sounds, images, etc., both concepts should not be confused.

This Introduction only refers generically and just in a co-lateral form, to telling as supporting discourse and narrative in natural language, and for whose understanding the context-dependent and purpose-driven concept of the meaning of statements [16.2], their semantics, is essential. This chapter mainly deals with an algebraic analysis of the reasoning that, generated by the physical processes in the brain thinking consists in, is externalized by means of the language of signs, oral or written expressions, figures, etc. It pretends nothing else than to be a first trial toward a possible and more general algebra of reasoning than are Boolean algebras, orthomodular lattices, and standard algebras of fuzzy sets, the algebraic structures in which classical propositional calculus, quantum physics' reasoning, and approximate reasoning are, respectively, represented and formally presented [16.3, 4].

Reasoning is considered the manifestation of rationality [16.5], a concept that comes from the Latin word *ratio* (namely, referred to comparing statements), and from very old, allowed to believe in a clear cut existing among the living species and under which the human one is the unique that is rational, that can reason. Reasoning is also, at its turn, an abstract concept referring to several ways for obtaining conclusions from a previous knowledge, or information, or evidence, given by statements that are called the premises; it is sometimes said that the premises are the reasons for the conclusions, or the reasons that support them. Conclusions are also statements, and without a previous knowledge neither reasoning, nor understanding, is possible.

Apparent processes of reasoning is what, to some extent, is observable and can be submitted to a Menger's kind of *exact thinking* [16.6], by analyzing

them in general enough algebraic terms. This is actually the final goal of this chapter, whose aim is to be placed at the ground of Zadeh's *Computing with Words* (CWW) [16.7], helping to adopt in it the point of view of ordinary reasoning and not only that of the deductive one, and for a viewing of CWW close to the mathematical modeling of natural language and ordinary reasoning.

### Note

Due, in a large part, to the author's lack of knowledge, there are many topics appearing as manifestations of thinking and, up to some extent, matching with reasoning, that cannot even be slightly taken into account in a paper that is, in itself, of a very limited scope, and only contains generic reflections in its nontechnical Sects. 16.1–16.4. Among these topics, there are some that, as far as the author knows, are not yet submitted to a systematic scientific study. It is the case, for instance, of what could be called *sudden direct action*, or *action under pressing*, as well as those concerning thinking and reasoning in both the *beaux arts*, and the music's creation [16.8].

Those topics can still deserve some scientific and subsequent philosophical reflections. In some of them like it is, for instance, the case in modern painting, it appears a yet mysterious kind of play between actual or virtual situations, and where the same objects of reasoning can be seen as unfinished, but not as not-finished [16.9]. That is, in which, the antonym seems to play a role different from that of the negate [16.10].

Being those topics yet open to more analysis, perhaps some of the methodologies of analogical or case-based reasoning could suggest some ways for an exploration of them in terms of fuzzy sets [16.11], and in view of a possible computational mechanization of some of their aspects.

## 16.2 Models

The pair telling–reasoning can be completed to a triplet of philosophically essential concepts with that of *modeling* that, facilitated by abstraction, is one among the best ways people have for capturing the basics of the phenomena appearing in some reality by not only taking some perspective and distance with them, but, after observation, recognizing their more basic traits. Thanks

to *models*, not only the terms or words employed in the linguistic description of a phenomenon can be well enough understood by bounding its meaning in a formal frame, but only thanks to mathematical models the use of the safest type of reasoning, formal deduction, can be used for its study. In addition and currently, models are often useful formalisms through which the possibility

of coping with human reasoning by means of computers can be done. This chapter essentially presents a new mathematical (algebraic) model for reasoning that is neither directly based on *truth*, but on *contradiction*, nor confuses reasoning and deducing, a confusion CWW should not fall in, since people mainly reason in non-formal and nondeductive ways.

If Experimental Science can be roughly described as an art for building plausible specific models of some reality with the aim of intellectually capturing it, in no case they (namely, the algebraic ones) are established forever but do change with time, something that shows they cannot be always confused with a time-cut of the reality tried to be modeled. On the other side, good models do warrant, at least, to preserve what already hold in them once new evidence on the corresponding reality is known.

Even if models are not to be confused with what they represent, same as an architect's mockup that should not be confused with a building following

from it, mathematical and computational modeling are among the greatest human acquisitions coming from abstraction and safe reasoning. Actually, a good deal of what characterizes the current civilization derives from models, and mathematical ones are usually considered at the very top of rationality since they had proven to allow for a good comprehension of several and important realities previously recognized as actually existing.

Models are a good help for a better understanding of the reality they model, and mathematical ones show the so-called *unreasonable effectiveness of mathematics* [16.12] for the understanding of reality thanks, in a good part, to formal deduction, the safest form of reasoning they allow to use. If it can metaphorically be said that if reality is in color, a model of this reality is a simplification of it in black and white; of course and up to some extent, modeling is an art with whose simplifications it should not be avoided what is essential for the description of the corresponding reality.

## 16.3 Reasoning

To give a definition of reasoning is very difficult, if not impossible since, at the end, it is a family of natural processes generated in the brain. A first operational question that can be posed is, *What is reasoning for?* of which, in a first approach, can be just said that reasoning is actually intermingled with the will of people to ask and to answer questions, to influence, to inform, to teach, to convince, or just to communicate with other people. Something usually managed by means of reciprocal telling, or dialogue, or conversation, between people.

In a second and perhaps complementary approach, it should also be said that reasoning also serves for satisfying human's will of searching new ideas that are not immediately seen in the evidence, and that can help for a further exploring of the reality to which the premises refer to. The human will for communicating and influencing, for foreseeing and for exploring, are made possible by means of reasoning that, in this perspective, seems to be a capability acquired thanks to the brain complexity once it, and through the senses, is in contact with the world and can try to understand what is and what happens in it by means of the neuronal/synaptic representations reached in the brain thanks, in part, to the external receptors of the human nervous system.

To answer a more scientifically sensitive and less psychological question, *What does reasoning appear to be?* let us place ourselves in two different, although overlapping, points of view: those from the premises and those from the conclusions. From the first, reasoning can try to confirm, to explain, to enlarge, or to refute, the information conveyed by the premises. From the second, and in confrontation with the context of the premises, conclusions can be classified in either necessary, or contingent. At its turn, the last can be either explanations or speculations that is, conclusions trying to foresee, either backward or forward and perhaps by *jumps* from the premises and without clear rules for it, respectively, something new and currently unknown, but that eventually can be *suggested* by the premises and, very often, reached thanks to some additional background knowledge. All this is what conducts to the typically human capability called *creativity*, many times obtained through either hypotheses (backward case), or speculations (forward jumping case). It even helps to take rational, pondered decisions, that are among the essential characteristics shown by the *intelligence* attributed to people.

For what concerns necessary conclusions, they are not usually for capturing something radically new since, in general, what is not included, or hidden, in the

premises, but is external to them, is changing. From necessary premises not only necessary conclusions follow under some rules of inference, but also contingent ones that, in addition, cannot be always deployed from the premises under some well-known precise rules. Necessary conclusions are surely useful for arriving at a better understanding of what is strictly described by the premises, and for deploying what they contain, as it happens in formal sciences, and also to show what cannot be the case if the given premises do not perfectly reflect the reality. In this sense, refutation of either a part of the evidence, or of hypotheses, etc., is actually important [16,13].

### 16.3.1 A Remark on the Mathematical Reasoning

In the case of mathematics, where the only certified knowledge is furnished by the theorems proved by formal deduction, the former statement *necessary conclusions are not for capturing something radically new*, could be actually surprising, especially if it could mean that nothing *new* can be deductively deployed from some supposedly necessary premises. For instance, from the Peano's axioms defining the set  $\mathbb{N}$  of natural numbers, a big amount of new and fertile concepts and theorems are deductively deployed and successfully applied to fields outside mathematics.

To quote a case: The not easily captured – for nonmathematicians – abstract concept of the real number is constructed after that of rational number (whose set is  $\mathbb{Q}$ ), that comes from an equivalence between pairs of integers (set  $\mathbb{Z}$ ), after defining the concept of the integer number from another equivalence between pairs of natural numbers and that, at the end and with a jump from pairs to some infinite sequences of rational numbers, makes of each equivalence's class of such sequences a real number (set  $\mathbb{R}$ ). Not only real numbers are very useful in maths and outside them, but many more concepts arise after the real number is constructed in such a classificatory way, like, for instance, the two classifications of  $\mathbb{R}$  in rational/irrational, and in algebraic/transcendental, from which a big amount of useful certified knowledge arises. Some hints on how all that happened are the following.

The just described process for knowing through classifying came along a large period of time in which the same concept of number suffered changes. For instance, irrational numbers were not seen as actual numbers by some old Greek thinkers for whom numbers were only the rational ones. Also, the natural

number concept came from the counting of objects in the real world, the integer from indexing units in scales above and below some point, and the rational ones from systematically fractioning segments. Even for a long time the number 0 was neither known, nor latter on considered as an actual number, and the interest in irrational numbers grown from the necessity of managing expressions composed by roots of rational numbers, essentially in the solution of polynomial equations, as well as from the relevance of some *rare* numbers like  $\pi$  and  $e$ . Since along this process, math was involved in many practical problems, those mathematicians who finally constructed the real numbers in just pure mathematical terms and under the deductive procedures characterizing math, and including in it integers, rational, and irrationals, were strongly influenced by that large history. A hint on this influence is shown, for instance, by the names assigned to some classes of natural numbers: prime, quadratic, cubic, friend, etc., not to speak of the concept of a complex number coming from the so-called imaginary numbers.

The above-mentioned equivalences allowing to pass from  $\mathbb{N}$  to  $\mathbb{Z}$ ,  $\mathbb{Z}$  to  $\mathbb{Q}$ , and  $\mathbb{Q}$  to  $\mathbb{R}$ , are classifications in some sets that, at each case, are derived from the former one and that, once well formally constructed, and hence being of an increasingly abstract character and named with more or less common names, all of them are based, at the end, on the Peano's definition of  $\mathbb{N}$ . This definition makes  $\mathbb{N}$  a very intriguing set, which curious and often surprising certified properties generated one of the more complex branches of maths, Number Theory, in which study many concepts of mathematical analysis and probability theory are used. Let us just remember the sophisticated proof that changed the old Fermat's conjecture into a theorem, that is, into certified mathematical knowledge. Before deductively proven, mathematical conjectures, and in particular those in Number Theory, are but speculations well based on many positive instances.

Even accepting that math is freely created by mathematicians from some accepted minimal number of noncontradictory and independent axioms, and that the only way of certifying its knowledge is by deductive proof, it should not be forgotten that to imagine what at each case can be deduced from the premises, and that is often done by analogy with a previously solved, or at least considered, case, is a sample of commonsense reasoning. In addition, the *beauty* mathematicians attribute to their results not only play an important role in the development of math, but also show how mathematicians do reason same as cultured people do. A nice example

of the fact that mathematicians also do reason through commonsense reasoning, is shown by the typical statement *How beautiful this (supposed) concept or theorem is*, claimed before a deductive proof fails and avoids to accept it as mathematical knowledge.

Mathematicians such as philosophers, detectives, writers, businessmen, scientists, physicians, etc., reason thanks to their brains and with the experiential background knowledge stored in it. They are moved by curiosity, supported in imagination and conjecturing, and with the will of reaching new knowledge in their respective field. In addition, a high level of creativity seems to be a remarkable characteristic of great mathematicians. All that originated Wigner's famous *unreasonable effectiveness of mathematics in the natural sciences* [16.12].

A way for obtaining a *positive confirmation against reality* of a reasoning, can be searched for through those conclusions showing a good level of agreement with the reality to which the information refers to, and a *negative* one through the refutations, or conclusions contradicting either the premises, or what necessarily follows from them. With respect to explanations, or hypotheses, from them not only necessarily should follow the premises, but also all that necessarily follows from them. Of course, all that can be qualified as necessary should not be only as *safe* as the premises could be, but obtained by means of precise rules allowing anybody to totally reproduce the processes going from the premises to the conclusions. In this sense, perhaps it could be better said that necessary conclusions are *safe* in the context of the premises, but that contingent conclusions are *unsafe*, and that the first should be obtained in a way showing that they are just reproducibly deployed from the premises. It seems clear enough that confirmation with reality should be searched, in general, by means of some theoretic or experimental testing of the conclusions against the reality to which they refer to.

With respect to premises and to ensure its safety, its set should be bound to show some internal consistency, like it is for instance to neither contain contradictory pairs of them, nor self-contradictory ones, since in such a case it does not seem acceptable that the premises can jointly convey information that could be taken as admissible in the model. The same happens with the set of necessary conclusions directly deployed from the premises, since in this case the existence of contradictory conclusions will delete its necessity. The case of contingent conclusions is different, as it comes from everyday experience, since the existence of contradic-

tory explanations or contradictory speculations is not only not surprising at all, but it is sometimes the case of having contradictory hypotheses or speculations for or from the same phenomenon.

All that, if only expressed by words or linguistic terms, cannot facilitate by itself a clear, distinct, and complete comprehension on the subject of reasoning with fertility enough to go further. To increase the comprehension of the machinery of reasoning is for what a modeling of it in black and white [16.14] can be a good help toward a better understanding of what it is, or surrounds it, like mathematical models offer in experimental sciences from, at least, Newton's time. Of course, to establish a mathematical model for reasoning it is indeed necessary not only to be acquainted both with what reasoning is, and its different modalities, but to have a suitable frame of representation for all the involved linguistic terms, including the concept of contradiction.

The concept of representation in a suitable *formal frame* is essential for establishing models and, jointly with the use of the deductive (safe) reasoning the formal frame makes possible, is what not only marks an important frontier between Science and Philosophy, but also helps us to show the *unreasonable effectiveness of mathematics* in Science and Technology. For instance, like the set of rational numbers is a good enough formal frame for the shop's bill, the three-dimensional real space is a formal frame for 3D Euclidean geometry, the four-dimensional Riemann space is that for Relativity theory, and the infinite-dimensional Hilbert space is the frame for quantum physics. Mathematical models add to the study of reality the gift consisting in the possibility of systematically applying to its analysis the safest form of reasoning, that is, formal deduction.

When the linguistic terms translating the corresponding concepts are precise and, at least in principle, all the information that eventually can be needed is supposed to be available, like it is the case in the classical propositional calculus, the frame of Boolean algebras seems to be well suitable for representing these terms [16.3]. If the linguistic terms designating the involved basic concepts are precise but not all the information is always available, like it happens, for instance, in quantum physics, weaker structures than Boolean algebras, like orthomodular lattices are, could be taken into account. If there are involved essentially imprecise linguistic terms, like it happens in commonsense reasoning, then the so-called algebras of fuzzy sets seem to be suitable once the linguistic terms are well enough designed by fuzzy sets [16.15, 16].

The problem of selecting a convenient frame of representation for ordinary reasoning, defined by a minimal number of axioms, is a crucial point that should be established in agreement with both the methodological principle the Occam's Razor states by *Not introduce more entities than those strictly necessary*, and with the Menger's addenda, *Nor less than those with which some interesting results can be obtained* [16.17]. Such methodological principle and addenda are, of course, taken into account in what follows since, on the contrary, almost nothing could be added to which philosophers said. Two important features that *Menger's exact thinking* [16.6] offers through mathematical models are that it is always clear in it under which presuppositions the obtained results can hold, that deductive (safe) reasoning can be extensively used through a mathematical symbolism translating the basic treats of the subject, and that what is not yet included in it has a possibility of, at least, being clearly situated outside the model and, perhaps, latter on included in a new and larger model. This is what, at the end, happened with the old Euclid's Geometry and Linear Algebra.

### 16.3.2 A Remark on Medical Reasoning

The field of medicine [16.18], that is full of imprecise technical concepts, is one in which the ordinary reasoning used in it, deserves a careful consideration. In particular, it is important to know if a medical concept can or cannot be specified by a classical set, in the negative case, since it is not possible to conduct the corresponding reasoning in the classical Boolean frame. For instance, if two concepts  $D$  and  $B$ , are interpreted as fuzzy sets, the statement  $((D \text{ and } B) \text{ or } (D \text{ and not } B))$  is only equivalent to  $D$  in some standard algebras of fuzzy sets in which no law of duality holds [16.19].

In the typically clinical reasoning for diagnosing, there are many technical concepts that cannot be considered precise by being clearly subjected to degrees. It is hence the concept of *observed diabetes* that can be submitted to a (empirical) Sorites' process [16.20] to conclude that it cannot be represented by a classical set. For instance, a patient with 100 mg/dl of glucose in blood does not suffer diabetes, as well as with 101, 102, ..., and up to 120 mg/dl, in which moment the patient could be diagnosed with diabetes. Nevertheless, since the crisp mark 120 is not liable in all cases by being a somehow changing experimental threshold, it is better to frame the diagnose in the setting of fuzzy logic and by also taking into account the weight, the kind of job, the age, as well as the usual alimentation of the patient. That is, the physicians do reason on the basis of the complex imprecise predicate that could be written by: (Diabetes/Patient) (p) ~ glucose in blood (p) & weight (p) & job (p) & age (p) & alimentation (p), at its turn composed by *elemental* predicates, some of which are also imprecise.

The physicians cannot reason by only taking into account the amount of glucose in blood, and under the typical schemes of classical reasoning. Once the current medical concepts are translated into fuzzy terms, it is necessary to follow the reasoning under those schemes allowed in a suitable algebra of fuzzy sets [16.19], and once it is designed accordingly with the context where the concepts are inscribed in.

In addition, since what the processes conducting to diagnose try to find is a good enough hypothesis matching with the symptoms of the presumed illness, it is relevant for the researchers on medical reasoning to know about inductive abduction and speculation [16.18], and, mainly, for what respects to applying **CWW**. For all that the *laws* holding in the framework taken for representing the involved fuzzy terms is relevant.

## 16.4 Reasoning and Logic

Let us stop for a while at the question *Which is the relationship between reasoning and logic?* requiring to first stop at the concept of logic, classically understood as *the formal study of the laws of reasoning* and that, in addition and modernly, is basically understood by restricting reasoning to deduction. Today's logic is indeed the study of systems allowing the safest type of reasoning under which, and from a consistent set of premises, a consistent set of necessary conclusions, or logical

consequences, is derived in a step-by-step ruled process that can be fully reproduced by another person who masters the use of rules. Hence, nowadays logic consists in the study of the so-called deductive systems, and it mainly avoids other types of reasoning like those by analogy, by abduction, and by induction. After Tarski formalized deductive systems by means of consequence operators [16.21], a *logic* is defined, in mathematical terms, as a pair consisting in a set of statements and

a consequence operator that can be applied to some (selected) subset of these statements, and once all that is represented in a formal frame.

Nevertheless, it seems that in commonsense, everyday, or ordinary reasoning, people only make deductions in, at most, a 25% of the cases [16.22], and that many conclusions are just reached either by the help of analogy from a precedent and similar case, or just by speculating at each case accordingly with some rules of thumb. In addition, some properties and schemes of reasoning that were classically considered like *laws of reasoning*, today cannot be seen as universally valid as it is with the distributive law in the reasoning of quantum physics, and with the several schemes of reasoning with fuzzy sets studied in [16.4] in the line of analyzing what is sometimes known as the preservation of the *Aristotelian form*.

Consequently, the analysis of more than 75% of nondeductive reasoning processes should be considered of an upmost importance for a more complete study of reasoning. In some sense, such study began with the work of Peirce [16.23] for understanding scientific

thinking, and latter on was continued with the studies on nonmonotonic reasoning in the field of Artificial Intelligence for helping to mechanize some ordinary ways of reasoning [16.24, 25]. Since *Computing with Words* deals with ordinary reasoning in natural language, it seems obvious that the nondeductive ways of reasoning should be not only in the back of CWW, but also taken into account in it.

Toward a formal, algebraic, study of such 75% is mainly devoted to this chapter that, essentially, can be seen as a trial for enlarging logic from formal deductive to everyday reasoning with, perhaps, a kind of returning to Middle Age's logic, as it can be considered from the Occam's saying [16.26] that *demonstration is the noblest part of logic*, reflecting that logic was seen in that time as more than the study of deduction, even if it is considered a crucial form of reasoning. In the model presented in this chapter, based on *conjectures* (a term coming from [16.27]), deduction, as a modality of reasoning, plays a central role both in a weak and a strong form, respectively, corresponding to the formal, and to the ordinary ways of reasoning.

## 16.5 A Possible Scheme for an Algebraic Model of Commonsense Reasoning

It does not seem that the term *deduction* can refer to the same concept in formal and in ordinary reasoning, since in the first it appears more strict than in the second where, for instance, the conclusions (consequences) are not necessarily admissible like the premises. Think, for instance, on what basis philosophers consider is a deduction, and on what mathematicians refer to by a proof. Anyway, in both cases it should try to reflect a safe enough kind of reasoning, in the sense of attributing to the conclusions no less confidence than that attributed to the items of initial information. These items should also be admissible in the sense of being as safe as possible knowledge on some subject. The *good quality* of initial information is actually important in any process of reasoning.

Mathematics is considered the paradigm of deductive reasoning, but it does not mean (as it is remarked in Sect. 16.3) that mathematicians only reason deductively since when they search for something new they do reason like other people do, often by doing jumps from the initial information to unwarranted conclusions [16.22]. What is not at all accepted in mathematics are contradictions, and nondeductive proofs.

If for mathematicians the mathematical model, based on the admissibility of its axioms, is their reality, then for applied scientists or for engineers a model is just a representation of some reality. For instance, no engineer confuses the actual working of a machine with a dynamic model of it and, when launching a rocket, it is well known that the so-called *nominal* trajectory (computed from a mathematical model), is not exactly coincidental with the actual one, and the performance of the rocket's propulsion system is measured by taking into account the difference between these trajectories. In commonsense reasoning (CR) the situation yet shows currently sensible differences with these cases.

Some characteristics separating commonsense from formal deductive reasoning are as follows:

- CR does not consist in a single type of reasoning, but in several. A reasoning in CR can be schematized by  $P \vdash q$ , where P is a set of admissible items of information,  $q$  is a conclusion under the considered type of reasoning, and the symbol  $\vdash$  reflects the corresponding reasoning's process. Only in the case

of a deductive reasoning these processes are done under a strict regulation.

Alternatively, if  $AC(P)$  reflects the set of attainable conclusions, the scheme can be changed to  $q \in AC(P)$ .

- b) Often the items of information from which **CR** starts are expressed in natural language, with precise and imprecise linguistic terms, numbers, functions, pictures, etc. In addition and also often, such items of information are partial and/or partially liable with respect to the reality they are concerned with. In what follows, it will be supposed that no ambiguous terms are contained in these items, and that they are expressed by linguistic statements.
- c) Often **CR** lacks monotony. That is, when the number of initial information items increases, then either the number of conclusive items decreases (anti-monotony), or there is no law for its variation (non monotony). Deduction is always monotonic, that is, no less conclusive items are obtained when the number of items of initial information grows.
- d) It is typical of **CR** to *jump* from the initial information to some conclusions, that is, that no step-by-step/element-after-element way can be followed. Jumping is never the case in formal deduction, where the conclusions should be deployed from the initial items of information in a strict step-by-step manner and under previously known rules, even if the current *reasoner* avoids some trivial steps that, nevertheless, always can be easily recovered.
- e) In **CR**, people try to obtain either explanations, or refutations, or what is hidden in the given information, or new ideas lucubrate from what it is supposedly known (the initial information). Only the third of these kinds of conclusions are typical of deduction.
- f) A minimal limitation in **CR** is that of keeping some kind of *consistency* among the given items of initial information, like it is not containing two contradictory such items, and also between them and the conclusions.

Let us denote by  $P$  an accepted set of *items of admissible initial information* (premises), and by  $AC(P)$  the attainable conclusions under one of the last four types of **CR** in (e). It will be supposed that  $P$  is in some designated family  $F$  of sets able to consistently describe something, and that  $AC(P)$  is in a larger family  $C$  such that  $F \subset C$ . Hence,  $AC$  can be seen as a mapping  $AC: F \rightarrow C$ . The sets in  $F$  are supposed to contain items of

admissible information, but this is not the case for those sets in  $C - F$ . Then:

- a) To do an analysis of **CR** in mathematical terms, an algebraic frame for representing all that is involved in **CR** should be selected in a way of not introducing more objects and laws than those strictly necessary at each case like they are, for instance, a symbolic representation of the linguistic connectives *and*, *or*, *not*, and *IfThen*. The symbols that will be used in this chapter are  $,$ ,  $+$ ,  $',$  and  $\leq$ , of which the first two are binary operations, the third is a unary operation, and the fourth is a binary relation.
- b) Basic in all kind of reasoning is the concept of *consistency* even if it is not a unique way of seeing it. Three possible definitions of consistency are as follows:
  - Consistency is identified with noncontradiction: If  $p$ , then it is never  $\neg q$ , symbolically represented by  $p \not\leq q'$ .
  - Consistency is identified with joint noncontradiction: If  $(p \text{ and } q)$ , then it is never  $\neg(p \text{ and } q)$ , symbolically represented by  $p.q \not\leq (p.q)'$ .
  - Consistency is identified with incompatibility: It is never  $(p \text{ and } q)$ , symbolically represented by  $p.q = 0$ , provided there exist a symbol  $0$  like in set theory is the empty set  $\emptyset$ .

At each case a suitable definition of consistency should be chosen accordingly with the corresponding context but, in what follows is just taken the first one. Of course, no other and less formal ways of seeing at consistency should be excluded and, in any case, the concept of consistency between pairs of elements should be extended to sets of premises and sets of conclusions to make them consisting, respectively, in admissible premises and attainable conclusions.

Notice that in a Boolean algebra, since it is  $p.q = 0 \Leftrightarrow p \leq q' \Leftrightarrow p.q \leq (p.q)'$ , the former definitions are equivalent, and, for this reason in the reasoning with precise linguistic terms there is no discussion for what refers to the concept of consistency.

- c)  $p$  is *contradictory* with  $q$ , provided *If p, then not-q*, and  $p$  is *self-contradictory* when *If p, then not-p*. Notice that in ortholattices the only self-contradictory element is  $p = 0$ , and that with fuzzy sets endowed with the negation 1-id, the self-contradictory fuzzy sets are those such that  $A \leq A' = 1 - A \Leftrightarrow A(x) \leq \frac{1}{2}$ , for all  $x \in X$ .

- d) If  $P \subset AC(P)$ , for all  $P$  in  $F$ , it is said that  $AC$  is *extensive*, and  $AC(P)$  necessarily contains some items of admissible information.
- e) If  $P \subset Q$ , both in  $F$ , then if  $AC(P) \subset AC(Q)$ , it is said that  $AC$  is *monotonic*. If  $AC(Q) \subset AC(P)$ , *antimonotonic*, and if  $AC$  is neither monotonic, nor antimonotonic, it is said that  $AC$  is *nonmonotonic* and there can exist cases in which, being  $P \subset Q$ ,  $AC(P)$  and  $AC(Q)$  are not comparable under the set-inclusion  $\subset$ .
- f) Provided  $q$  represents a statement, and  $q'$  represents its negation  $\neg q$ : If  $q$  is in  $AC(P)$ , then  $q'$  is not in  $AC(P)$ , or  $q'$  is in  $AC(P)^c$ , it is said that  $AC$  is *consistent in P*.  $AC$  is just *consistent* if it is consistent in all  $P$  in  $F$ .
- g)  $AC$  is said to be a *closure*, if for all  $P \in F$  it is  $AC(P) \in F$ , and  $AC(AC(P)) = AC^2(P) = AC(P)$ .
- h)  $AC(P) \in C - F$  means that not all the elements in  $AC(P)$  show the characteristics that make admissible those items in  $F$ .

### Main Definitions

- 1) A mapping  $AC : F \rightarrow C$  is said to be a weak-deduction operator [16.28] if it is monotonic, and consistent under a suitable definition.
- 2) A mapping  $AC : F \rightarrow F$  is said to be a strong-deduction operator, or a Tarski's logical consequence operator [16.21], if it is a weak deduction one that is also extensive, and is a closure.

If  $AC$  is a weak-deduction operator, the elements in  $AC(P)$  are called weak consequences of  $P$ . If  $AC$  is a Tarski's operator, the elements in  $AC(P)$  are the strong or logical consequences of  $P$ . Since logicians universally consider that Tarski's operators translate the characteristics of formal deductive systems, or formal deduction, it will be here considered that weak-deduction operators translate those of (some kind of) commonsense deduction.

### Remarks 16.1

- a) Notice that, in the model,  $F$  represents the family of those sets whose elements are accepted as items of admissible initial information, and that such *admissibility*, once translated into a suitable definition of consistency, should be defined at each case. Hence, each time  $F$  should be conveniently chosen. For instance, a possible definition is:  $F$  is the family of those  $P$  for which there are no  $p$  and  $q$  in it and such that *If p, then not-p*.

- b) At each case, it should be defined to which ground-set  $W$  the sets  $F$  and  $C$  are included in, and  $W$  should be endowed with operations able to represent all that is necessary for the formalization of **CR**. For instance, it will be supposed that there is a binary relation  $\leq$  in  $W$  such that  $p \leq q$  translates into  $W$  the linguistic statement *If p, then q*. Analogously, and in the same vein in which ' represents the linguistic *not*, there should be binary operations  $\cdot$ , and  $+$ , representing, respectively, the linguistics *and*, and *or*.
- c) Basic in **CR** is the idea of *conjecture*, and that of *refutation*. Once a weak or strong consequence operator  $AC$  is adopted, the refutations of  $P$  could be defined as those elements  $r \in W$ , such that  $r' \in AC(P)$ , that is those whose negation is deducible from  $P$ . At its turn, the conjectures from  $P$  can be defined as those elements  $q \in W$  such that  $q' \notin AC(P)$ , that is, those whose negation is not deducible from  $P$ . In this sense, the conjectures are the elements that are not (deductive) refutations of  $P$ . Both concepts could be more precisely named  $AC$ -refutations, and  $AC$ -conjectures.

Since both precise and imprecise linguistic terms are usually managed in **CR**, in what follows  $W$  will be the set of all fuzzy sets in a universe of discourse  $X$ , that is,  $W = [0, 1]^X$ , the set of all functions  $A : X \rightarrow [0, 1]$ . This set will be endowed with the algebraic structure of a Basic Fuzzy Algebra, where the restriction of its operations to  $\{0, 1\}^X$  makes this set a Boolean algebra, isomorphic to the power set  $2^X$  endowed with the classical set-operations of intersection, union, and complement of subsets. Crisp sets allow us to represent precise linguistic terms as it is stated by the axiom of Specification in naïve set theory [16.29], an axiom that cannot be immediately extended to imprecise predicates since, for instance, they are not always represented by a single fuzzy set.

### Definition 16.1 [16.1]

If  $\cdot$  and  $+$  are binary operations and ' is a unary one, then  $([0, 1]^X, \cdot, +, ')$  is a Basic Fuzzy Algebra (**BFA**) provided it holds,

1.  $A_0 \cdot A = A \cdot A_0 = A_0, A_1 \cdot A = A \cdot A_1 = A, A_0 + A = A + A_0 = A, A + A_1 = A_1 + A = A_1$
2. If  $A \leq B$ , then  $CA \leq CB, A \cdot C \leq B \cdot C, C + A \leq C + B, A + C \leq B + C$ , and  $B' \leq A'$ .
3.  $A'_0 = A_1$ , and  $A'_1 = A_0$ .

4. If  $A, B \in \{0, 1\}^X$ , then  $A \cdot B = \min(A, B)$ ,  $A + B = \max(A, B)$ , and  $A' = 1 - A$ ,

where  $A_0$  is the function  $A_0(x) = 0$ ,  $A_1$  is the function  $A_1(x) = 1$ , and  $1 - A$  is  $(1 - A)(x) = 1 - A(x)$ , for all  $x \in X$ . Obviously, in  $2^X$ ,  $A_0$  represents the empty set  $\emptyset$ ,  $A_1$  the ground set  $X$ , and  $1 - A$  the complement  $A^c$  of  $A$ .

Of course, it is  $A \leq B$  if and only if  $A(x) \leq B(x)$ , for all  $x \in X$ , a partial order that with crisp sets reduces to  $A \subset B$ .

Notice that:

- a) The *formal connectives*., +, and ', in a **BFA** are neither presumed to be functionally expressible, nor associative, nor commutative, nor distributive, nor dual, etc.
- b) Only if . = min, and + = max, the **BFA** is a lattice that, if the negation ' is a strong one ( $A'' = A$ , for all  $A$ ), is a De Morgan–Kleene algebra. Hence, no **BFA** is a Boolean algebra, and not even an ortholattice.
- c) It is not difficult to prove [16.28] that it is always  $A \cdot B \leq \min(A, B) \leq \max(A, B) \leq A + B$ . Of course, the standard algebras of fuzzy sets are particular **BFA**s.
- d) It is also easy to prove that:
  - d.1) In a **BFA** with + = max, it holds the first law of semiduality:  $A' + B' \leq (A \cdot B)'$ , regardless of which are . and '.
  - d.2) In a **BFA** with . = min, it holds the second law of semiduality:  $(A + B)' \leq A' \cdot B'$ , regardless of which are + and '.
  - d.3) Regardless of ', in a **BFA** with . = min, and + = max, both semiduality laws hold.
- e) Obviously, all standard algebras of fuzzy sets [16.30] (those in which . is decomposed by a continuous *t*-norm, + by a continuous *t*-conorm, and ' by a strong negation function) are **BFA**s.

Since **BFA**s are defined by just a few axioms in principle only allowing very simple calculations, what can be proven in their framework has a very general validity that is not modified by the addition of new independent axioms. One of the weaknesses of Boolean and De Morgan algebras, as well as of orthomodular lattices, for representing **CR**, just lies in the big amount of laws they enjoy and make them too rigid to afford the flexibility natural language and **CR** show in front of any artificially constructed language, and of formal reasoning.

### Remarks 16.2

- For what concerns the representation of a linguistic predicate  $L$  in a universe of discourse  $X$  by a fuzzy set, it is of an actual interest to reflect on what can mean the values  $A_L(x)$ , for  $x \in X$  and  $A_L : X \rightarrow [0, 1]$ , the membership function of a fuzzy set labeled  $L$ . Just the expression *fuzzy set labeled L*, forces that the membership function  $A_L$  should translate something closely related to  $L$ , namely, to the meaning of  $L$  in  $X$ . It is not clear at all that all predicates can be represented by a function taking its values in the totally ordered unit interval of the real line: It should be added to the involved predicate the possibility of some numerical quantification of its meaning.

To well linguistically manage a numerically quantifiable predicate  $L$  in  $X$  it should, at least, be recognized when it is, or it is not, the case that  $x$  is *less P than y*, a linguistic (empirical and perceptively captured) relationship that can be translated into a binary relation  $x \leq_L y$ , with  $\leq_L \subset X \times X$ . This relation reflects how the *amount* of  $L$  varies on  $X$ , and once the pair  $(X, \leq_L)$  is known, a measure of the extent up to which each  $x \in X$ , is  $L$ , is a mapping  $M_L : X \rightarrow [0, 1]$  such that  $x \leq_L y \Rightarrow M_L(x) \leq M_L(y)$ , and those elements  $x$  such that  $M_L(x) = 1$ , if existing, can be called the prototypes of  $L$  in  $X$ . Analogously, those  $y$  such that  $M_L(y) = 0$  can be called the antiprototypes of  $L$  in  $X$ . Obviously, and in the same vein that there is not a single probability measuring a random event, there is not always a single measure  $M_L$ .

If the use of the predicate is precise in  $X$ , all their elements  $x$  should be prototypes, or antiprototypes, that is  $M_L(x)$  is in  $\{0, 1\}$ . When for some  $x$  it is  $0 < M_L(x) < 1$ , it is said that the use of  $L$  is imprecise in  $X$ . Once a triplet  $(X, \leq_L, M_L)$  is known, it is a quantity that can be understood as reflecting the meaning of  $L$  in  $X$  [16.2]. Calling  $M_L$  an *ideal membership function* of the fuzzy set labeled  $L$ , it can be said that it exists when the meaning of  $L$  in  $X$  is a quantity.

Notice that each measure  $M_L$  defines a new binary relation given by  $x \leq_{ML} y \Leftrightarrow M_L(x) \leq M_L(y)$ , obviously verifying  $\leq_L \subset \leq_{ML}$ , that is, the new relation is larger than the former that is directly drawn from the perceived linguistic behavior of  $L$  in  $X$ .

It is said that  $M_L$  perfectly reflects  $L$  whenever  $\leq_L = \leq_{ML}$ , but, since the second is always a linear relation – for all  $x, y$  in  $X$ , it is either  $M_L(x) \leq M_L(y)$ ,

or  $M_L(x) > M_L(y)$  –, and  $\leq_L$  is not usually so, not always can be the case that  $M_L$  perfectly reflects  $L$ . This is one of the reasons for which, being  $\leq_L$  often difficult to be completely known – for instance, if  $X$  is not finite – the designer just arrives to a function  $A_L$  (the membership function of the fuzzy set labeled  $L$ ) that is not usually the ideal membership function  $M_L$  but an approximation of it, obtained through the data on  $L$  that are available to the designer. Of course, a good design is reached when it can be supposed that the value  $\text{Sup}\{x \in X; /M_L(x) - A_L(x)/\}$  is minimized.

From all that it comes the importance of carefully designing [16.15, 16] the membership functions with which a fuzzy system is represented. Analogous comments can be made for what concerns the connectives., +, ', and the *axioms* they verify, to reach an election of the **BFA** ( $[0, 1]^X, ., +, '$ ) well linked to the currently considered problem.

2. The suitability of the wide structure of **BFA**s for representing **CR** comes from, for instance, the fact that the linguistic conjunction *and* is not always commutative specially when *time* intervenes, the laws of duality are not always valid when dealing with statements in natural language, the connectives' decomposability (or functional expressibility), is not always guaranteed, the distributive laws between . and + not always hold, etc.
3. When the linguistic terms are represented in a set  $W$  endowed with a partial order  $\leq$ , and with operations . of conjunction, + of disjunction, and ' of negation, respectively, representing the linguistic connectives If/Then, and, or, not, if  $(W, ., +)$  is a lattice (for all that concerns lattices, see [16.31]) at least the following five points do hold:
  - I. It is  $A \leq B \Leftrightarrow A.B = A \Leftrightarrow A + B = B$ : The conditional statement *If A, then B* should be equivalent to the statements *A and B coincides with A*, and *A or B coincides with B*.
  - II. If *and* is represented by the lattice's conjunction .,  $A.B$  is the greatest lower bound of both  $A$  and  $B$ : It should be known the set of all that is below  $A$  ( $C$  is below  $A$  means  $C \leq A$ ), the set of all that is below  $B$ , the intersection of these two sets, and that  $A.B$  is the greatest element in this last set (respect to the partial order  $\leq$ ).
  - III. Analogously, for the case of *or*, if represented by the lattice's disjunction +, there should be known the sets of elements in  $W$  that are greater than  $A$ , those that are greater than  $B$ , their inter-

section, and that  $A + B$  is the lowest element in this last set.

IV.  $A.B = B.A$ : The meaning of the statements *A and B*, and *B and A* cannot be different.

V.  $A + B = B + A$ : The meaning of the statements *A or B*, and *B or A* cannot be different.

All this shows that contrary to what usually happens in both **CR** and the applications, where all the previous information is not only costly in searching for, in money, and almost impossible to collect completely, a lot of structural information on the reasoning's context should be necessarily known for establishing the model. Something that is typical in formal sciences, but that in the case of **CR**, and also in many applications, produces some scepticism for the possibility of always taking  $(W, ., +)$  as a lattice.

To count with a representation's lattice for **CR** is but something to be considered rare or, at least, limited to some cases as it can be that of representing a formal-like type of reasoning with precise linguistic terms where the former five points are usually accepted. These are, for instance, the cases in Boolean algebras with  $A \rightarrow B = A' + B = 1 \Leftrightarrow A \leq B$ , and orthomodular lattices with  $A \rightarrow B = A' + A.B = 1 \Leftrightarrow A \leq B$ , with the respective implication operators  $\rightarrow$  translating the corresponding linguistic If/Then.

With the standard algebras of fuzzy sets, a lattice is only reached when the connectives are given by the greatest *t-norm* min, and the lowest *t-conorm* max [16.30]. In this case, the *implication functions* with which it is  $A \rightarrow B = A_1 \Leftrightarrow A \leq B$ , are the T-residuated ones [16.30], functionally expressible through the numerical functions  $J_T(a, b) = \text{Sup}\{r \in [0, 1]; T(a, r) \leq b\}$ , where  $T$  is a left-continuous *t-norm*, and that generalize the Boolean material conditional  $A \rightarrow B = A' + B$  since, in a complete Boolean algebra, it is  $A' + B = \text{Sup}\{C; A.C \leq B\}$ . The fuzzy implications given by  $(A \rightarrow B)(x, y) = J_T(A(x), B(y))$  enjoy many of the typical properties of Boolean algebras with the material conditional, and with them the standard algebra with min, max, and the strong negation 1-id, enjoys, among these algebras, the biggest amount of Boolean laws and makes of it a very particular algebra to be used for extensive use in **CR**.

Nevertheless, it should be remembered that what concerns **CR**, when time intervenes not always can coincide the meanings of the statements *A and B*,

and  $B$  and  $A$ , as it is the case *He sneezed and came to bed*, and *He came to bed and sneezed*.

4. The BFA's structure, based on  $[0, 1]^X$ , can yet be made more abstract. It simply requires to consider, instead of  $[0, 1]^X$ , once pointwise ordered by " $A \leq B \Leftrightarrow A(x) \leq B(x)$ , for all  $x$  in  $X$ , a poset  $(L, \leq)$ , with minimum 0 and maximum 1, endowed with two binary operations  $\cdot$  and  $+$ , and a unary one, containing a subset  $L_0$  ( $\{0, 1\} \subseteq L_0 \subseteq L$ ) that, with the restrictions of the three operations  $\cdot$ ,  $+$ , and  $'$ , is a Boolean algebra, and verifying anal-

ogous laws to the former in 1 to 4. These algebraic structures are called [16.32] Formal Basic Flexible Algebras, and they are a shell comprising ortholattices, De Morgan algebras, BFA's and, of course, orthomodular lattices, Boolean algebras, and standard algebras of fuzzy sets, as particular cases. By taking  $(W, ., +, ')$  as a Formal Flexible Algebra, what follows can be generalized, with a few restrictions, to such abstract and general shell.

## 16.6 Weak and Strong Deduction: Refutations and Conjectures in a BFA (with a Few Restrictions)

Let  $([0, 1]^X, ., +, ')$  be a BFA whose negation ' $'$  is a weak one, that is, restricted to verify the law  $A \leq A''$  for all  $A \in [0, 1]^X$ , and whose conjunction  $\cdot$  is associative, and commutative. No other properties are presumed and, hence, what follows contains by large the case with a standard algebra of fuzzy sets, and what can be obviously restricted to the Boolean algebra of crisp sets in  $\{0, 1\}^X$ .

Let us consider as the former family  $F$  of *admissible* premises, the  $F(.)$  comprising the finite sets (of premises)  $P = \{A_1, \dots, A_n\}$ , such that their *conjunction*  $A_P = A_1 \dots A_n$  is not self-contradictory, that is,  $A_P \not\leq A'_P$ . Of course,  $A_P \not\leq A'_P$  implies  $A_i \not\leq A'_j$ , for all  $A_i, A_j$  in  $P$ , and, obviously, it should be  $A_P \neq A_0$ . Hence, sets  $P \in F(.)$  neither contain contradictory premises, nor the *empty set*  $A_0$ . Notice that associativity and commutativity of the conjunction are presumed just to warrant a nonambiguous definition of  $A_P$ , and the restriction on the negation ' $'$  is just to allow some step in a proof. Under these conditions, the operator defined [16.28] by

$$C.(P) = \{B \in [0, 1]^X; A_P \leq B\},$$

translating into the BFA the statement *If  $A_1$  and  $A_2$  and ... and  $A_n$ , then  $B$ , or  $B$  follows from  $A_P$  in the order  $\leq$* , verifies the following:

- a) Usually,  $C.(P)$  is not in  $F(.)$ , for instance, it is not always finite. Hence, in general it has no sense to reapply the operator  $C.$  to  $C.(P)$ . That is, the operator  $C.^2$  cannot be usually defined, and less again to make  $C.$  a closure.
- b) Since  $A_P \leq A_i$ ,  $1 \leq i \leq n$ , it is  $P \subset C.(P)$ :  $C.$  is extensive.

- c) If  $P \subset Q$ , with  $Q = P \cup \{A_{n+1}, \dots, A_m\}$ , and since  $A_P \leq A_1 \dots A_n A_{n+1} \dots A_m$ , then it follows  $C.(P) \subset C.(Q)$ :  $C.$  is monotonic.
- d) If  $B \in C.(P)$ , it is not  $B' \in C.(P)$ :  $A_P \leq B$  and  $A_P \leq B' \Rightarrow B \leq B'' \leq A'_P$ , and it follows the absurd  $A_P \leq A'_P$ :  $C.$  is consistent in all  $P \in F(.)$ .
- e) Obviously,  $A_1 \in C.(P)$ , but  $A_0 \notin C.(P)$ . Hence,  $C.(P) \neq \emptyset$ . Analogously,  $C.(P)$  cannot coincide with the full set  $[0, 1]^X$  since it will imply the absurd  $A_P = A_0$ . Consequently, all operators  $C.$  are consistent and extensive weak-deduction operators.

In addition,

- f) If  $C.(P)$  is not finite, then it is obviously  $\text{Inf } C.(P) = A_P$ .
- g) No contradictory elements are in  $C.(P)$ : If  $B, C \in C.(P)$  and it were  $B \leq C'$ , from  $A_P \leq B, A_P \leq C$ , it follows  $B' \leq A'_P$  and  $C' \leq A'_P$ , and the absurd  $A_P \leq B \leq C' \leq A'_P$ .
- h) If  $\cdot_1 \leq \cdot_2$ , that is, the operation  $\cdot_1$  is weaker than the operation  $\cdot_2$ , it is obviously  $A_{1 \cdot_1 \dots \cdot_1 n} \leq A_{1 \cdot_2 \dots \cdot_2 n}$ , and hence  $C_{\cdot_2}(P) \subset C_{\cdot_1}(P)$ . That is, the bigger the operation  $\cdot$ , the smaller the set  $C.(P)$ . Consequently, if it can be selected the operation  $\min$ , it is  $C_{\min}(P) \subset C.(P)$ , for all operations  $\cdot$ , and all  $P \in F(\min)$ :  $C_{\min}$  is the smallest among the operators  $C.$ . Notice, that it is always  $F(\min) \subset F(.)$ : the family with  $\min$  is the smallest among those of admissible premises.
- i) Provided  $C.(P)$  is a finite set, and since  $C.$  is extensive, it is  $C.(P) = P \cup \{A_{n+1}, \dots, A_m\}$ , and then  $A_{C.(P)} = A_1 \dots A_n A_{n+1} \dots A_m = A_P A_{n+1}$

$\dots A_m \leq A_P$ . Thus, if  $\cdot = \min$ ,  $A_{C.(P)} = \min(A_P, \min(A_1, \dots, A_m)) = A_P$ , that means  $C\min(P) \in F(\min)$ , and has sense to reapply  $C\min$ . Since  $P \subset C\min(P) \Rightarrow C\min(P) \subset C\min(C\min(P))$ , and, if  $A \in C\min(C\min(P))$ , then  $A_{C\min(P)} = A_P \leq A$ , it is  $A \in C\min(P)$ , and from  $C\min(C\min(P)) \subset C\min(P)$ , it finally follows  $C\min^2(P) = C\min(P)$ . In conclusion, provided all the involved sets  $C\min(P)$ , with  $P \in F(\min)$ , were finite, it is  $C\min : F(\min) \rightarrow F(\min)$ , and  $C\min$  will be a strong, or Tarski's, consequence operator.

- i) Provided the family  $F$  of sets of premises is made free of only containing finite sets, since it always exist  $\text{Inf}$  and, bounding  $P$  to verify  $\text{Inf } P \not\leq (\text{Inf } P)'$ , for all  $P \in F$ , the operator

$$C_\infty(P) = \{B \in [0, 1]^X; \text{Inf } P \leq B\},$$

obviously verifying  $\text{Inf } C_\infty(P) = \text{Inf } P$ , is not only extensive, consistent, and monotonic, but it is also a closure: From  $C_\infty(P) \in F$ , and  $P \subset C_\infty(P)$ , it follows  $C_\infty(P) \subset C_\infty(C_\infty(P))$ , but if  $B \in C_\infty(C_\infty(P))$ , that is,  $\text{Inf } C_\infty(P) \leq B$ , from  $\text{Inf } C_\infty(P) = \text{Inf } P$ , follows  $B \in C_\infty(P)$ . Finally,  $C_\infty(C_\infty(P)) = C_\infty(P)$ .

$C_\infty$ , restricted to finite sets is just  $C\min$ , and restricted to all the crisp sets in  $\{0, 1\}^X$ , is the consequence operator on which classical propositional calculus is developed [16.3].

### Definition 16.2

Given a weak-deduction operator  $C$ . [16.28]:

1. The set of  $C$ -refutations of  $P$ , is  $\text{Ref.}(P) = \{B \in [0, 1]^X; B' \in C.(P)\}$ .
2. The set of  $C$ -conjectures of  $P$ , is  $\text{Conj.}(P) = \{B \in [0, 1]^X; B' \in C.(P)^c\}$ .

Namely, refutations are those fuzzy sets whose negation is weakly deducible from the premises, and conjectures those whose negation is not weakly deducible from them. Obviously,  $\text{Conj.}(P) = \text{Ref.}(P)^c$ .

Notice that it immediately follows that all operators  $\text{Ref.}$  are consistent, and monotonic, but not extensive, and that all operators  $\text{Conj.}$  are extensive, antimonotonic, not consistent, and consequently it cannot be stated that  $\text{Conj.}(P)$  is always in  $F(\cdot)$ . It is  $\text{Conj.} : F(\cdot) \rightarrow [0, 1]^X$ , and not all conjectures can be taken as items of admissible information.

It is also immediate that  $\text{Ref.}(P) \cup \text{Conj.}(P) = [0, 1]^X$ , and  $\text{Ref.}(P) \cap \text{Conj.}(P) = \emptyset$ , that is, both sets

constitute a partition of the set of all fuzzy sets in  $X$ , and  $\text{Conj.}(P) = \text{Ref.}(P)^c$ . Hence, the conjectures are those fuzzy sets that are nonrefutable in front of the information furnished by  $P$ .

Since,  $C\min(P) \subset C.(P)$ , it follows that:

- $\text{Ref.}\min(P) \subset \text{Ref.}(P)$ :  $\text{Ref.}\min$  is the smallest among refutation operators.
- $\text{Conj.}(P) \subset \text{Conj.}\min(P)$ :  $\text{Conj.}\min$  is the biggest among conjecture operators. Namely,

$$\begin{aligned} P &\subset C\min(P) \subset C.(P) \\ &\subset \text{Conj.}(P) \subset \text{Conj.}\min(P), \end{aligned}$$

a chain of inclusions showing that both weak and strong consequences are but a particular type of conjectures. Consequently, in the model deducing is but one of the forms of conjecturing as it is asked for in [16.27].

### Remarks 16.3

1. Only if it is  $\cdot = \min$ , it holds:  $\text{Ref.}\min(C\min(P)) = \text{Ref.}\min(P)$ , and  $\text{Conj.}\min(C\min(P)) = \text{Conj.}\min(P)$ , showing that strong consequences neither allow to obtain more refutations, nor more conjectures.
2. Since  $A_0 \in \text{Ref.}(P)$ , it is  $\text{Ref.}(P) \neq \emptyset$ . Nevertheless,  $\text{Ref.}(P)$  cannot coincide with the full set  $[0, 1]^X$ , since it will imply  $A = A_0$ .
3. The sets  $\text{Conj.}(P)$  cannot be empty since it will imply  $C.(P) = [0, 1]^X$ . On the other side, it is  $\text{Conj.}(P) = [0, 1]^X \Leftrightarrow C.(P) = \emptyset$ . Hence, it is always,

$$\emptyset \not\subset \text{Conj.}(P) \not\subseteq [0, 1]^X.$$

In this model, the empty set  $A_0$  cannot be taken for either conjecturing, or deducing, or refuting.

4. The particularization of the concept of conjecture to crisp sets, that is, to the fuzzy sets in  $\{0, 1\}^X \subset [0, 1]^X$ , reduces to take as  $F(\min)$  the set of those crisp sets that are nonempty, since with crisp sets it is  $A \subset A^c \Leftrightarrow A = \emptyset$ , and thus  $\text{Conj.}(P)$  is the set of those  $B \subset X$ , such that  $A \cap B \neq \emptyset$ , since with crisp sets it is  $A \subset B^c \Leftrightarrow A \cap B = \emptyset$ .

With classical sets, that is, in Boolean algebras, there is no distinction between contradiction, and incompatibility.

5. After the classical definition:  $B$  is decidable  $\Leftrightarrow$  either  $B$  is provable, or not  $B$  is provable, it can be defined the set of  $\cdot$ -weakly decidable elements for

$P$  by  $C.(P) \cup \text{Ref.}(P)$ , and the set of strongly decidable elements for  $P$  by  $C \min(P) \cup \text{Ref min}(P)$ . Obviously, and for all operations  $\cdot$ , strongly decidable elements are  $\cdot$ -weakly decidable ones, but not reciprocally [16.32].

The nonstrongly decidable elements are those fuzzy sets in the set

$$\begin{aligned} & (C \min(P) \cup \text{Ref min}(P))^c \\ &= C \min(P)^c \cap \text{Ref min}(P)^c \\ &= C \min(P)^c \cap \text{Conj min}(P), \end{aligned}$$

that is, they are the conjectures that are not strong consequences. Analogously, given  $P$ , the  $\cdot$ -weakly nondecidable elements are those fuzzy sets that are  $\cdot$ -weak conjectures, but not  $\cdot$ -weak consequences. Consequently, to obtain a classification of the difference sets  $\text{Conj.}(P) - C.(P)$ , and  $\text{Conj min}(P) - C \min(P)$ , is actually important.

6. Since  $\text{Ref.}$  is monotonic and consistent, it could be alternatively taken for defining conjectures [16.28] in the parallel form

$$\text{Conj} * .(P) = \{B \in [0, 1]^X ; B' \notin \text{Ref.}(P)\} = C.(P)^c,$$

where conjectures appear as just those fuzzy sets that are not  $\cdot$ -weak consequences instead of those that are not refutations. Under this new definition, it is  $\text{Ref.}(P) \subset \text{Conj} * .(P)$ . Notice that  $\cdot$ -refutations  $B$  can be defined without directly referring to  $C.$ , by

$$\text{Ref.}(P) = \{B \in [0, 1]^X ; A_P \leq B'\}.$$

7. With all that, a tentative formal definition for a model of (Commonsense) Reasoning (**CR**) could

be essayed by posing à la Popper [16.13],

$$\text{CR.}(P) = \text{Ref.}(P) \cup \text{Conj.}(P),$$

once the operations  $\cdot$ , and  $'$  are selected, and  $C.(P)$  defined with, at least,  $A \neq A_0$ . Anyway, this definition gives nothing else than  $\text{CR.}(P) = \text{Conj.}(P) \cup \text{Conj.}(P)^c = \text{Ref.}(P) \cup \text{Ref.}(P)^c$ , with which the formal model for **CR** appears as nothing else than either *conjecturing*, or *refuting* once  $\cdot$ -weak consequences are taken as the basic concept toward formalizing **CR**.

Thus, a new concept of strong **CR**, can be introduced by

$$\text{CR min}(P) = \text{Ref min}(P) \cup \text{Conj min}(P),$$

and in both cases deduction (weak and strong, respectively), is a type of conjecturing [16.27].

8. The imposed commutativity and associativity of the conjunction can be avoided by previously fixing an algorithm to define  $A_P$ . For instance, if  $P$  contains four premises, then the algorithm's steps can be the following: 1) Select an order for the premises and call them  $A_1, \dots, A_4$ . 2) Define  $A_P$  by  $A_1 \cdot (A_2 \cdot (A_3 \cdot A_4))$ . Then, of course, all that has been formerly said depends on the way chosen to define  $A_P$ .

For what refers to the restriction on the negation  $'$ , notice that it is already verified in the cases (usual in fuzzy logic) where it is strong:  $A'' = A$ , for all  $A \in [0, 1]^X$ , as it is the case in the standard algebras of fuzzy sets.

## 16.7 Toward a Classification of Conjectures

Provided it is  $\text{Conj.}(P) - C.(P) \neq \emptyset$ , it is clear that the left-hand difference set is equal to

$$\begin{aligned} & \{B \in \text{Conj.}(P) ; B < A_P\} \cup \{B \in \text{Conj.}(P) ; \\ & A_P \text{ is not } \leq -\text{comparable with } B\}. \end{aligned}$$

That is,

$$\begin{aligned} \text{Conj.}(P) = C.(P) \cup \{B \in [0, 1]^X ; \\ A_P \not\leq B' \& A_0 < B < A_P\} \\ \cup \{B \in [0, 1]^X ; A_P \not\leq B' \& A_P \text{ nc } B\}, \end{aligned}$$

with the symbol **nc** shortening *not*  $\leq$ -*comparable with*.

Notice that the second set in this union contains the fuzzy sets  $B$  being neither empty, nor contradictory with  $A_P$ , and for which *If B, then  $A_P$* . Consequently, it can be said that these fuzzy sets  $B$  *explain*  $A_P$ , or  $P$ , and, of course, they also *explain* any  $\cdot$ -weak consequence of  $P$ : If  $A_P \leq C$ , it follows  $B < C$ . Let us denote this set of conjectures by  $\text{Hyp.}(P)$ , and call it the set of explicative conjectures or, for short, hypotheses for  $P$ . If  $C.(P) \in F(\cdot)$ , it is clear that  $\text{Hyp.}(C.(P)) = \text{Hyp.}(P)$ , as it also happens with the strongest conjunction  $\cdot = \min$ .

For what concerns the third set in the last union, call it  $\text{Sp.}(P)$ , it is decomposable in the disjoint union

$$\{B \in [0, 1]^X; A_P < B' \& A_P \text{ nc } B\} \cup \{B \in [0, 1]^X; \\ A_P \text{ nc } B' \& A_P \text{ nc } B\},$$

whose elements will be called speculative conjectures or, for short, speculations. Let us, respectively, denote by  $\text{Sp.}_1(P)$  and  $\text{Sp.}_2(P)$ , the first and the second set in the decomposition. The elements in  $\text{Sp.}_i(P)$  will be called type- $i$  speculations ( $i = 1, 2$ ).

It should be pointed out that the symbol **nc** shows the *jumps* cited before, and that these jumps affect both types of speculations but, specially, those in the type-2. In the case in which  $B \in \text{Sp.}_1(P)$ , since  $A_P > B$  is equivalent to  $A'_P < B$ ,  $B$  could be captured by going forward from  $A'_P$ , but if  $B \in \text{Sp.}_2(P)$  a jump from either  $A_P$ , or from  $A'_P$ , is necessary to reach  $B$ .

It should also be pointed out that weak consequences are reached by *moving* forward from  $A_P$ , that hypotheses are reached by *moving* backward from  $A_P$ , but that for speculations a jump forward from either  $A_P$ , or  $A'_P$ , is required. It is clear, in addition, that  $\text{Conj.}(P) = \text{Conj.}(\{A_P\})$ ,  $C.(P) = C.(\{A_P\})$ ,  $\text{Hyp.}(P) = \text{Hyp.}(\{A_P\})$ , and  $\text{Sp.}(P) = \text{Sp.}(\{A_P\})$ , since  $\{A_P\} \in F(.)$ , and in this sense,  $A_P$  can be seen as the résumé of the information conveyed by  $P$ .

With all that, the set of conjectures from  $P$  is completely classified by the disjoint union

$$\text{Conj.}(P) = C.(P) \cup \text{Hyp.}(P) \cup \text{Sp.}_1(P) \cup \text{Sp.}_2(P),$$

since all the intersections  $C.(P) \cap \text{Hyp.}(P), \dots, \text{Sp.}_1(P) \cap \text{Sp.}_2(P)$ , are empty. Hence, conjectures are either weak consequences, or hypotheses, or type-1 speculations, or type-2 speculations. Consequently, and once given  $P \in F(.)$ , all the fuzzy sets in  $[0, 1]^X$  are classified in refutations, .-weak consequences, hypotheses, speculations of type-1 and of type-2, with strong consequences being a part of the weak ones. It should be pointed out that, in some particular cases, the sets  $\text{Hyp.}(P)$ , or  $\text{Sp.}(P)$ , can be empty.

### Note

It can be said that the above algebraic model for **CR** contains strong and weak deduction, abduction (the search for hypotheses), and also speculative reasoning.

What happens with hypotheses and speculations for what relates to monotony? Since given two enchainable sets of premises  $P \subset Q$ , both in  $F(.)$ , the conjunction

of their premises, call them respectively  $A_P$  and  $B_Q$ , obviously verify  $B_Q \leq A_P$ , it is  $\text{Hyp.}(Q) \subset \text{Hyp.}(P)$ : the operator  $\text{Hyp.} : F(.) \rightarrow [0, 1]^X$ , is antimonotonic. Notice that  $\text{Hyp.}$  is not a consistent operator and, consequently, it cannot be supposed that  $\text{Hyp.}(P)$  always contains admissible information. It is risky to take a hypothesis as a new premise.

Analogously,  $\text{Sp.}$  is also a mapping  $F(.) \rightarrow [0, 1]^X$ , that is nonconsistent, and, as it is easy to see by means of simple examples with crisp sets, it is neither monotonic, nor antimonotonic, nor elements in  $\text{Sp.}(P)$  can be always taken as admissible information. That is, since there is no law for the *growing* of  $\text{Sp.}$  with the *growing* of the premises, it can be said that speculations are peculiar among conjectures. Such peculiarity is somewhat clarified by what follows: If  $S \in \text{Sp.}(P)$ :

- a) If  $S$  is such that  $A_P.S \neq A_0$ , it is  $A_P.S < A_P$  since if it were  $A_P.S = A_P$ , then follows  $A_P \leq S$ , or the absurd  $S \in C.(P)$ . From  $A_0 < A_P.S < A_P$ , and provided  $A_P.S$  is a conjecture, it follows  $A_P.S \in \text{Hyp.}(P)$ .
- b) Since  $A_P \leq A_P + S$ , it is always  $A_P + S \in C.(P)$ .
- c) Provided the law of semiduality  $B' + C' \leq (B.C)'$ , holds in the **BFA**  $([0, 1]^X, ., +,')$ , as it happens with  $+ = \max$ , and since  $A_P \leq A_P + S' \leq (A'_P.S)'$ , it follows that  $A'_P.S$  is a refutation.

Hence, by means of speculations  $S$ , hypotheses  $A_P.S$  can be obtained provided  $A_P.S \neq A_0$  is a conjecture,  $A_P + S$  is always a weak consequence, and with semiduality it is  $A'_P.S$  a refutation. In this sense, speculations can serve as a tool for deducing, for abducing, and for refuting: They are *auxiliary conjectures* for either deploying what is hidden in the premises, or for refuting the premises, or to explain them. For this reason, to speculate is an important type of nonruled reasoning, and whose mastering should be encouraged to be learned.

### A Remark on Heuristics

Although the concept of *heuristics* is not yet formalized, from last paragraphs, and under a few and soft constraints, speculations can be seen as auxiliary conjectures that intermediate for advancing reasoning. Since to reach a speculation  $S$  a jump from  $A_P$  should be taken, since there are no direct and step-by-step links between  $A_P$  and  $S$ , the process to arrive by the intermediary of  $S$  to either a consequence  $A_P + S$ , or a hypothesis  $A_P.S$ , or a refutation  $A'_P.S$ , is a typically heuristic one, perhaps obtained at each case by some nonstep-by-step rule of thumb. For instance, a hy-

pothesis like  $H = A_P$ .  $S$  can be reached after some *heuristic path* conducting to  $S$  by some jumping from  $A_P$  that, additionally, can be done in several and different steps.

At this respect, the formal characterization of those hypotheses that are reducible to the form  $A_P.C$  for some fuzzy set  $C \in [0, 1]^X$  is yet an open problem. Since in the case of orthomodular lattices and, of course, of Boolean algebras, it was proven that all hypotheses are reducible [16.1], but that in the case of nonorthomodular ortholattices nonreducible ones should exist, given P it can be analogously supposed the existence in  $[0, 1]^X$  of nonreducible hypotheses. Consequently, if existing, such hypotheses can be seen as isolated ones that cannot be reached by the intermediary of a speculation, but only directly by a particular heuristic backward-track from  $A_P$ .

For what concerns hypotheses, and except in formal deductive reasoning where, in principle, they can be either safely accepted, or refused through deduction, in CR a crucial point is to know how a hypothesis can be deductively or inductively refuted [16.28, 33]. As it is well known, the idea of refuting a hypothesis is central in scientific research [16.13], and it can be formalized in the current model as follows [16.32].

Let us suppose that there is a doubt between which one of the two statements:  $H \in \text{Hyp.}(P)$ , and  $H \notin \text{Hyp.}(P)$ , is valid but knowing that  $H \not\leq H'$ , that the presumed hypothesis is not self-contradictory:

- a) Provided the first statement is valid, since  $H < A_P$  and  $A_P \leq C$  imply  $H < C$ , it is  $C.(P) \subset C.\{H\}$ . Thus, if there is  $D \in C.(P)$  such that  $D \notin C.\{H\}$ ,  $H$  cannot be a hypothesis for P: To *weak-deductively* refute  $H$  as a hypothesis for P, it suffices to find a weak consequence of P that is not a weak consequence of  $\{H\}$ .  
Of course, classical (strong) deductive refutation corresponds to the case in which it is possible to take  $\cdot = \min$ .
- b) In addition, it is  $C.(P) \subset \text{Conj.}(\{H\})$ . Indeed,  $A_P \leq B$ , and  $H < A_P$ , do not imply  $B \leq H'$  since, in this case it follows  $H \leq H'$ , it is  $B \notin \text{Conj.}(P)$ . Thus, it is  $B \not\leq H'$ , or  $B \in \text{Conj.}(\{H\})$ . Consequently, to *weak-inductively* refute  $H$  as a hypothesis for P it suffices to find a weak consequence of P that is not conjecturable from  $\{H\}$ .

All that can be, *mutatis mutandis*, repeated with the strongest conjunction  $\cdot = \min$ , and the concept of the strong-inductive refutation of  $H$  is reached.

## 16.8 Last Remarks

In former papers of the author [16.28, 32, 34], the concept of a conjecture was formalized in the settings of ortholattices, and De Morgan algebras. In the first, and since  $A_P \leq A'_P$  implies  $A_P = 0$ , it suffices to take  $A_P \neq 0$ . What lacked was the case of the standard algebras of fuzzy sets with a t-norm and a t-conorm different, respectively, of min and max, a case that is subsumed in what is presented in [16.28], and now is completed in this chapter.

With only crisp sets, the résumé  $A_P$  of the information conveyed by the premises in P, obviously verifies  $A_P \leq B' \Leftrightarrow A_P.B = A_0 \Leftrightarrow A_P.B \leq (A_P.B)'$ , but this chain of equivalences fails to hold if  $A_P$  or  $B$  are proper fuzzy sets. Consequently, and in addition to  $C.(P) = \{B; A_P \leq B\}$ , it can be also considered the two operators [16.32],

$$C.^1(P) = \{B; A_P.B' = A_0\}, \quad \text{and}$$

$$C.^2(P) = \{B; A_P.B' \leq (A_P.B')'\},$$

with which the corresponding conjecture operators could also be defined by

$$\text{Conj.}^i(P) = \{B \in [0, 1]^X; B' \notin C.^i(P)\}, \quad i = 1, 2,$$

by taking consistency in the other two forms cited in Sect. 16.5.

Both operators  $C.^i$  are not extensive, but monotonic, at least  $C_{\min}^1$  is consistent if the negation is functionally expressible, it is unknown which other  $C.^i$  ( $i = 1, 2$ ) is consistent,  $C.^1(P) \subset C.^2(P)$ , and it is not actually clear if in both cases it is, or it is not,  $C.^i(P) \subset \text{Conj.}^i(P)$  except when  $\cdot = \min$  [16.28].

Consequently, the door is open to consider alternative definitions for the concept of a conjecture depending on the way of defining when an element  $B \in [0, 1]^X$  is *consistent* with the résumé  $A_P$ . Anyway, what it seems actually difficult is how to imagine a kind of nonconsistent deduction.

It is well known that in **CR** conclusions are often obtained by some kind of *analogy* or *similitude* with a previously considered case. Without trying to completely *formalize* analogical reasoning, let us introduce some ideas that, eventually, could conduct toward such formalization.

Define *B* is *analogous to A*, if it exists a family K of mappings

$$\sigma : [0, 1]^X \rightarrow [0, 1]^X ,$$

such that  $B = \sigma \circ A$ , for  $\sigma \in K$ . Namely, *B* is K-analogous to *A*. At its turn the set of fuzzy sets that are *analogous or similar* to those in P can be defined by

$$\begin{aligned} K(A_P) &= \{B \in [0, 1]^X ; \\ &B = \sigma \circ A_P, \sigma \in K\} . \end{aligned}$$

Then:

- 1) If  $id \leq \sigma \Rightarrow A_P \leq \sigma \circ A_P \Rightarrow \sigma \circ A_P \in C.(P)$
- 2) If  $\sigma < id \Rightarrow \sigma \circ A_P < A_P \Rightarrow \sigma \circ A_P \in Hyp.(P)$
- 3) If  $id \leq \sigma \Rightarrow \sigma \circ A_P \leq A_P \Rightarrow \sigma \circ A_P \in Sp.(P)$
- 4) If  $id \leq \sigma' \Rightarrow A_P \leq \sigma' \circ A_P = (\sigma \circ A_P)' \Rightarrow (\sigma \circ A_P)' \in Ref.(P)$ .

Depending on the possible ordering of the pairs  $(id, \sigma)$ , and  $(id, \sigma')$ , with  $id$  the identity mapping in  $[0, 1]^X$ , that is,  $id(A) = A$ , for all  $A \in [0, 1]^X$ , the *fuzzy sets analogous to A<sub>P</sub>* are either consequences or hypotheses, speculations, or refutations. Notice that in point [16.4] it is  $id \leq \sigma'$  equivalent to  $\sigma \leq id'$ , that is,  $\sigma \circ A \leq A'$  for all fuzzy set *A*.

Of course, for a further study of analogical types of reasoning it lacks to submit transformations  $\sigma$  to some restricting properties, surely depending on the concrete case under consideration.

## 16.9 Conclusions

The establishment of a general framework for the several types of reasoning comprised in Commonsense Reasoning seems to be of an upmost importance. At least, it should be so for fuzzy researchers in the new field of Computing with Words (**CWW**) that, with a calculus able to simulate reasoning, tries to deal with sentences and arguments in natural language more complex than those considered in today's current fuzzy logic.

In the way toward a full development of **CWW** covering as many scenarios as possible of the people's ways of reasoning, it seems relevant not to forget the big amount of nondeductive reasoning people commonly do. This chapter just offers a wide framework to jointly consider the four modalities of deduction, abduction, speculation, and refutation, typical of both ordinary and also specialized reasoning, where deduction and refutation are *deductive* modalities of reasoning, but where abduction and speculation can be considered its *inductive* modalities [16.35, 36].

There remain some unended questions that concern the proposed model and, among them, can be posed the two following ones:

- The finding of rules in the *Mill's* style [16.37], for obtaining hypotheses and speculations from the premises. These rules could conduct to obtain computer programs or algorithms able, in some cases,

to find either hypotheses or speculations, and can be also useful for clarifying the concept of a *heuristics*.

- The study of what happens with the conjectures once new consistent information supplied by new premises, is added to the initial set P [16.38]. It should not to be forgot that ordinary reasoning is rarely made from a *static* initial set of items of information, but that the information comes in a kind of *flux* under which conjectures can vary of number and of character.

Like speculations facilitate heuristics for finding consequences, hypotheses, and refutations, analogical reasoning could constitute a *good trick* for obtaining conjectures and refutations, on the base of some earlier solved similar problems. It should be pointed out that what is not yet clear enough is how to compute the degree of liability an analogical conclusion could deserve.

What is not addressed in this chapter is the theoretic and practical important problem of which is the best hypothesis or speculation to be selected at each particular case. This question seems linked with the translation into the conclusions of some numerical *weights of confidence* previously attributed to the premises, and that depend on the case into consideration. Because in this chapter such weights are neither considered for premises, nor for conclusions, the presented model can be qualified as a *crisp* one, but not yet as a *fuzzy* one,

since it fails taking into account the level of liability of the sentences represented in fuzzy terms. The semantics of the linguistic terms is here confined, through its most careful possible design [16.15, 16], to the contextual and purpose driven meaning of the involved fuzzy sets and fuzzy connectives, as well as to the possible linguistic interpretation of the accepted conclusions, but what is not yet taken into account is their degree of liability.

By viewing formal theories as abstract constructions that could help us to reach a better understanding of a subject inscribed in some reality, this chapter represents a *formal theory* of reasoning with precise and imprecise linguistic terms represented by fuzzy sets and already presented in [16.28]. It consists in a way of formalizing conjectures and refutations in the wide mathematical setting of **BFA**s whose axioms comprise the particular instances of ortholattices, De Morgan algebras, standard algebras of fuzzy sets, and, of course, Boolean algebras. As is shown by two of the forms allowing to define what weak deduction could be, depending on the kind of consistency chosen, and that, with crisp sets, also collapse in the classical case, this formalization cannot be yet considered as definitive, but open to further study.

Nevertheless, this new theory should not be confused with the actual human reasoning, and only through some work of an experimental character on **CR** it will be possible to clarify which degree of agreement with the reality of reasoning either the selected way for defining weak deduction, or a different one, does show. Provided this kind of work could be done, the observational appearance of some observed regularities in **CR**, or *observed laws* of the actual ordinary reasoning, and that can be *predicted* by some *invariants* in the model, is a very important topic for future research.

Anyway, to advance toward a kind of Experimental Science of **CR**, there are today no answers to some crucial questions like, for instance:

- Which regularities exist in natural language and in **CR** that, reflected by some invariants in the model, can be submitted to experimentation?

- How observation and experiments on **CR** could be systematically projected and programmed?
- Which quantities linked to such realities can exist in the model, and that could show numerical effects, measurable through experiments?

One of the reasons for such ignorance could come from both the small number of axioms the **BFA**-model have, and from the too big number of axioms the standard algebras of fuzzy sets show, for saying nothing on the Boolean and De Morgan algebras. When the number of axioms is too small, it seems difficult to think in a way to find invariants, and if there are too many axioms then the big number of relationships among them seems to show too much theoretical invariants, like it is, for instance, the indistinguishability between contradiction and incompatibility in Boolean algebras.

That ignorance can also come from the lack of numerical quantities associated with some important properties concerning both natural language and **CR**, like it can be, for instance, a degree of associativity in the case the model is just a **BFA**, or a degree of liability of speculations for allowing to reach refutations for some reality described by a set P of premises. It can also be the lack of a standard degree of similarity (like the one studied in [16.11]) to numerically reflect how much analogous to a possible hypothesis for P can be some known statement in order to be taken itself as the hypothesis.

Without some numerical quantities reflecting important characteristics of, for instance, words, it is difficult to think on how to project experiments for detecting some regularities or invariants without which it seems very difficult to conduct a deep scientific study of **CR**. Possible instances of such quantities are the measures of both the specificity [16.39], and the fuzziness [16.40] of imprecise predicates, and a experiment to be projected could be, perhaps, an analysis of how their values jointly vary in some context.

Actually and currently, an Experimental Science of **CR** is just a dream. Would this chapter also serve as a humble bell's peal toward such goal!

# Fuzzy Control

Christian Moewes, Ralf Mikut, Rudolf Kruse

Fuzzy control is by far the most successful field of applied fuzzy logic. This chapter discusses human-inspired concepts of fuzzy control. After a short introduction to classical control engineering, three types of very well known fuzzy control concepts are presented: Mamdani–Assilian, Takagi–Sugeno and fuzzy logic-based controllers. Then three real-world fuzzy control applications are discussed. The chapter ends with a conclusion and a future perspective.

## 17.1 Knowledge-Driven Control

With no doubt, the biggest achievement of fuzzy logic with respect to industrial and commercial applications has been obtained by *fuzzy control*. Since its first practical use for a *simple dynamic plant* by *Mamdani* [17.1], over attention-getting applications such as the automatic train operation in Sendai, Japan [17.2], fuzzy control systems have become indispensable in the industry today (Until today more than 60 000 patents have been filed worldwide using the words *fuzzy* and *control* according to [17.3]). A wide range of real-world applications have also been described by *Hirota* [17.4], *Terano* and *Sugeno* [17.5], *Precup* and *Hellendoorn* [17.6].

Simply speaking, fuzzy control is a kind of defining a nonlinear table-based controller. Every entry in such a table can be seen as partial knowledge about the specified input–output behavior [17.7]. However, knowledge does not have to exist for every input–output combination. Thus, the transition function of a fuzzy controller is a typical nonlinear interpolation between defined regions of this *knowledge*. The knowledge is commonly

stored as *imprecise* rules consisting of imprecise terms such as *small*, *big*, *cold*, or *warm*. Consequently, these rules lead to an *imprecisely defined* transition function that is eventually *defuzzified* if a crisp decision is needed.

This procedure is sometimes advantageous when compared to classical control systems – especially for control problems that are usually solved intuitively by human beings, but not by computing machines, e.g., parking a car, riding the bike, boiling an egg [17.8]. This might be also a reason why fuzzy control did not originate from control engineering researchers. It had rather been inspired by *Zadeh* [17.9] who proposed rule-based systems for handling complex systems using fuzzy sets – a concept which he introduced 8 years before [17.10].

The focus of this chapter is a profound discussion of such human-inspired concepts of fuzzy control. Other fuzzy control approaches based on a fuzzification of well-known methods of the classical control theory (fuzzy PID control, fuzzy adaptive control, stability

of fuzzy systems, fuzzy sliding mode, fuzzy observer, etc.) are only described briefly. For these topics, the reader is referred to other textbooks, e.g., *Tanaka and Wang* [17.11].

But before we formally present the concepts of fuzzy control, let us give a brief introduction of classical control engineering in Sect. 17.2. Then, in detail, we cover fuzzy control in Sect. 17.3, including the

most well-known approaches of Mamdani and Assilian, Takagi and Sugeno, and *truly* fuzzy-logic-based controllers in the Sects. 17.3.1, 17.3.2, and 17.3.3, respectively. We also talk about their advantages and limitations. We discuss some more recent industrial applications in Sect. 17.4 and automatic learning strategies in Sect. 17.5. Finally, we conclude our presentation of fuzzy control in Sect. 17.6.

## 17.2 Classical Control Engineering

To introduce the problem of controlling a process, let us consider a technical system for which we dictate a desired behavior [17.12]. Generally speaking, we wish to reach a desired set value for a time-dependent *output variable* of the process. This output is influenced by a variable that we can influence, i.e., the *control variable*. Last but not least – to deal with unexpected influences – let a time-dependent *disturbance variable* be given that manipulates the output, too.

Then the current control value is typically specified by mainly two components, i.e., the present measurement values of the output variable  $\xi$ , the variation of the output  $\Delta\xi = \frac{d\xi}{dt}$ , and further variables which we do not specify here. We refer to  $n$  input variables  $\xi_1 \in X_1, \dots, \xi_n \in X_n$  of the controller (e.g., computed from the measured output variable of the process and its desired values) and one control variable  $\eta \in Y$ . Formally, the solution of a control problem is a desired control function  $\varphi : X_1 \times \dots \times X_n \rightarrow Y$  which sets a suitable control value  $y = \varphi(\vec{x})$  for every input tuple  $\vec{x} = (x^{(1)}, x^{(2)}, \dots, x^{(n)}) \in X_1 \times \dots \times X_n$ . Controllers with multiple outputs are often handled as independent controllers with one output each.

In classical control, we can determine  $\varphi$  using different techniques. The most popular one for practical applications is the use of simple standard controllers such as the so-called *PID controller*. This controller uses three parameters to compute a weighted sum of proportional, integral, and derivative (*PID*) components of the error between the output variable and desired values to compute the control variable. In many relevant cases, a good control performance of the closed-loop feedback system with controller and process can be

reached by simple tuning heuristics for these parameters. This strategy is successful for many processes that can be described by linear differential equations for the overall behavior or at least near all relevant setpoints. More advanced controllers are used in cases with nonlinear process behavior, time-variant process changes, or complicated process dynamics. They require both a mathematical process model based on a set of differential or difference equations and a fitness function to quantify the performance. Here, many different strategies exist starting from a setpoint-dependent adaptation of the *PID* parameters, additional feedforward components to react to setpoint changes or known disturbances, the estimation of internal process states by observers in state-space controllers, the online estimation of unknown process parameters in adaptive controllers, the use of inverted process models as controllers, or robust controllers that can handle bounded parameter changes. For all these controllers, many elaborate design and analysis techniques exist that guarantee an optimal behavior based on a known process model, see e.g., Åström and Wittenmark [17.13], Goodwin et al. [17.14].

However, it might be mathematically intractable or even impossible to define the exact differential equations for the process and the controller  $\varphi$ . For such cases, classical control theory cannot be applied at all. For instance, consider the decision process of human beings and compare it to formal mathematical equations. Many of us have the great ability to control diverse processes without knowing about higher mathematics at all – just think of a preschool child operating a bike or juggling a European football with its foot or even head.

## 17.3 Using Fuzzy Rules for Control

Probably the simplest way to obtain a human *control* behavior for a given process is to find out – by asking direct questions for instance – how a person would react given a specific situation. One alternative is to observe the process to be controlled, e.g., using sensors, and then discover substantive information in these signals. Both approaches can be seen as *knowledge-based* analysis which eventually provides us with a set of *linguistic rules*. We assume that these if–then rules are able to properly control the given process.

Let us briefly outline the operating principle of a fuzzy controller based on such if–then rules. Each rule consists of an antecedent and consequent part. The former relates to an imprecise description of the crisp measured input, whereas the latter defines a suitable fuzzy output for the input. In order to enable a computing machine to use such linguistic rules, mathematical terms of the linguistic expressions used in the rules need to be properly defined. Once a control input is present, more than one rule might (partly) fulfill the present concepts. Thus, there is a need for suitable accumulation methods for these instantiated rules to eventually compute one fuzzy output value. From this value, a crisp output value can be obtained if necessary.

This knowledge-based model of a fuzzy controller is conceptually shown in Fig. 17.1. The *fuzzification interface* operates on the current input value  $\vec{x}_0$ . Here too,  $\vec{x}_0$  might be mapped to a desired space if it is necessary – one may want to normalize the input to the unit interval first. The fuzzification interface eventually translates  $\vec{x}_0$  into a linguistic term described by a fuzzy set. The *knowledge base* is *head* of the controller, it serves as *database*. Here, every essential piece of information is stored, i.e., the variable ranges, domain transformations, and the definition of the fuzzy sets with their corresponding linguistic terms. Furthermore, it comprises the *rule base* that is required to linguistically describe and control the process. The *decision logic* computes the fuzzy output value of the given measurement value by taking into account the knowledge base. Last but not least, the *defuzzification interface* computes a crisp output value from the fuzzy one.

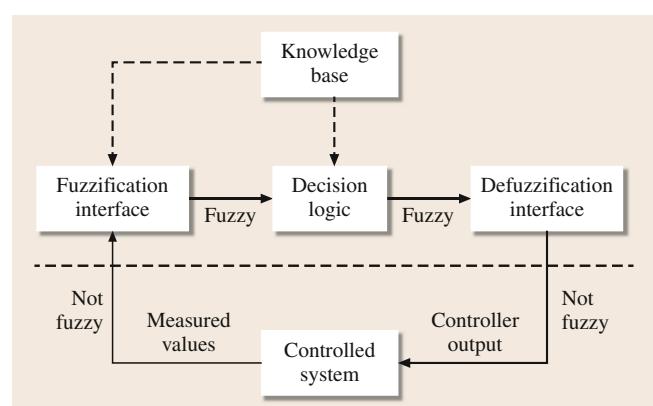

Two well-known and similar approaches have led to the tremendous use and the success of fuzzy control. The Mamdani–Assilian and the Takagi–Sugeno approaches are motivated intuitively in Sects. 17.3.1 and 17.3.2, respectively. They have in common that their interpretation of a linguistic *rule* diverges from

mathematical implications. Both types of controllers rather *associate* an input specified as an antecedent part with the given output given as a consequent part. A mathematically formal approach to fuzzy control as discussed in Sect. 17.3.3 leads to completely different computations. As it turns out in practice, controllers based on any kind of logical implications are usually too restrictive to suitably control a given process.

### 17.3.1 Mamdani–Assilian Control

Just one year after the publication of Zadeh [17.9], Ebrahim Abe Mamdani and his student Sedrak Assilian were the first who successfully controlled a simple process using fuzzy rules [17.1, 15]. They developed a fuzzy algorithm to control a steam engine based on human expert knowledge in an application-driven way. That is why today we refer to their approach as nowadays *Mamdani–Assilian control*.

The expert knowledge of a Mamdani–Assilian controller needs to be expressed by linguistic rules. Therefore, for every set  $X_i$  of given values for an input, we define suitable linguistic terms that summarize or partition this input by fuzzy sets. Let us consider the first set  $X_1$  for which we define  $p_1$  fuzzy sets  $\mu_1^{(1)}, \dots, \mu_{p_1}^{(1)} \in \mathcal{F}(X_\infty)$ . Each of these fuzzy sets is mapped to one preferable linguistic term. Thus,  $X_1$  is partitioned by these fuzzy sets. To ensure a better interpretability of each fuzzy set, we recommend to use just unimodal membership functions. In doing so, every fuzzy set can be seen as imprecisely defined value or interval. We furthermore urge to choose disjoint fuzzy sets for every

**Fig. 17.1** Architecture of a fuzzy controller

partition, i.e., the fuzzy sets shall satisfy

$$i \neq j \Rightarrow \sup_{x \in X_1} \left\{ \min \left\{ \mu_i^{(1)}(x), \mu_j^{(1)}(x) \right\} \right\} \leq 0.5.$$

When  $X_1$  is partitioned into  $p_1$  fuzzy sets  $\mu_1^{(1)}, \dots, \mu_{p_1}^{(1)}$ , we can continue to partition the remaining sets  $X_2, \dots, X_n$  and  $Y$  in the same way. The eventual outcome of this procedure (i.e., the linguistic terms associated with the fuzzy sets for each variable) establishes the database in our knowledge base.

The rule base of any Mamdani–Assilian controller is specified by rules of the form

$$\text{if } \xi_1 \text{ is } A^{(1)} \text{ and } \dots \text{ and } \xi_n \text{ is } A^{(n)} \text{ then } \eta \text{ is } B \quad (17.1)$$

where  $A^{(1)}, \dots, A^{(n)}$  and  $B$  symbolize linguistic terms which correspond to the fuzzy sets  $\mu^{(1)}, \dots, \mu^{(n)}$  and  $\mu$ , respectively, according to the fuzzy partitions of  $X_1 \times \dots \times X_n$  and  $Y$ . Thus, the rule base consists of  $k$  control rules

$$R_r : \text{if } \xi_1 \text{ is } A_{i_{1,r}}^{(1)} \text{ and } \dots \text{ and } \xi_n \text{ is } A_{i_{n,r}}^{(n)} \\ \text{then } \eta \text{ is } B_{i_r}, \quad r = 1, \dots, k.$$

We again underline that these rules are not interpreted logically as mathematical implications. They rather specify the function  $\eta = \varphi(\xi_1, \dots, \xi_n)$  piecewise using the existing associations between the known input–output tuples, i.e.,

$$\eta \approx \begin{cases} B_{i_1} & \text{if } \xi_1 \approx A_{i_{1,1}}^{(1)} \text{ and } \dots \text{ and } \xi_n \approx A_{i_{n,1}}^{(n)}, \\ \vdots & \vdots \\ B_{i_k} & \text{if } \xi_1 \approx A_{i_{1,k}}^{(1)} \text{ and } \dots \text{ and } \xi_n \approx A_{i_{n,k}}^{(n)}. \end{cases}$$

The control function  $\varphi$  is thus composed of partial knowledge that we connect in a *disjunctive* manner. Thus, Mamdani–Assilian control can be referred to knowledge-based interpolation.

Now assume that we observe a measurement  $\vec{x} \in X_1 \times \dots \times X_n$ . Naturally, the decision logic applies each rule  $R_r$  separately to the measured input. It then computes the degree to which the input  $\vec{x}$  fulfills the antecedent of  $R_r$ , i.e., the degree of applicability

$$\alpha_r \stackrel{\text{def}}{=} \min \left\{ \mu_{i_{1,r}}^{(1)}(x^{(1)}), \dots, \mu_{i_{n,r}}^{(n)}(x^{(n)}) \right\}. \quad (17.2)$$

This degree of applicability literally *cuts off* the output fuzzy set  $\mu_{i_r}$  of the rule  $R_r$  at the level  $\alpha_r$  which leads

to the rule's output fuzzy set

$$\mu_{\vec{x}}^{\circ(R_r)}(y) = \min \{ \alpha_r, \mu_{i_r}(y) \}. \quad (17.3)$$

When the decision logic does that for all  $\alpha_r$  for  $r = 1, \dots, k$ , then it unifies all output fuzzy sets  $\mu_{\vec{x}}^{\circ(R_r)}$  by using a  $t$ -conorm. The standard Mamdani–Assilian controller uses the maximum as  $t$ -norm. Thus, the ultimate output fuzzy set

$$\mu_{\vec{x}}^{\circ}(y) = \max_{r=1, \dots, k} \{ \min \{ \alpha_r, \mu_{i_r}(y) \} \}. \quad (17.4)$$

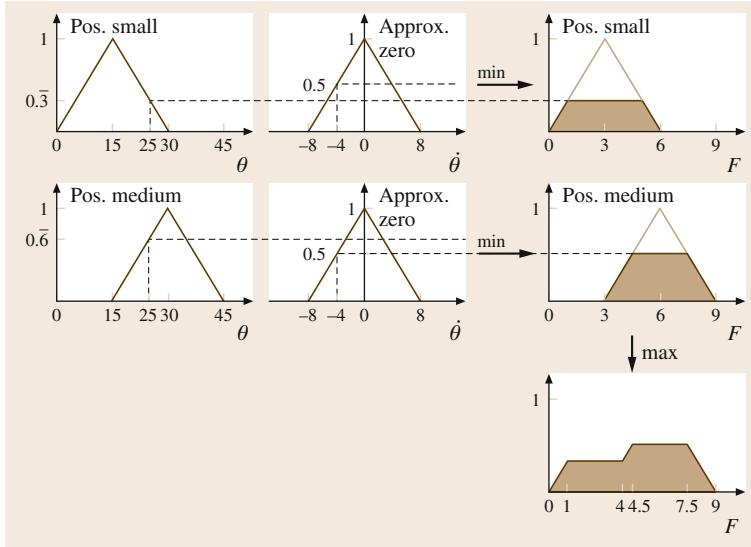

The whole process of evaluating Mamdani–Assilian rules is depicted in Fig. 17.2.

Of course, from a fuzzy set-theoretic and interpretational point of view, it suffices to keep  $\mu_{\vec{x}}^{\circ}(y)$  as the final output *value*. However, fuzzy controllers are used in real-control application where a crisp control value is for sure needed, e.g., to increase the electric current of a hotplate when boiling an egg. That is why the fuzzy control output  $\mu_{\vec{x}}^{\circ}$  is processed in the defuzzification interface. Depending on the implemented method of fuzzifying  $\mu_{\vec{x}}^{\circ}$ , a real value is ultimately obtained. Three methods are used in the literature extensively, i.e., the max criterion method, the mean of maxima (**MOM**) method, and the center of gravity (**COG**) method.

The max criterion method simply returns an arbitrary value  $y \in Y$  such that  $\mu_{\vec{x}}^{\circ}(y)$  obtains a maximum membership degree. However, this arbitrary value picked at random typically results in a nondeterministic control behavior. That is usually undesired as the interpretability and repeatability of already produced outcomes get lost. The **MOM** method returns the mean value of the set of elements  $y \in Y$  that have maximal membership degrees in the output fuzzy set. Using this approach, it might happen that the defuzzified control value  $\eta$  may not even belong to the points leading to maximal membership degrees. Just consider for instance a bimodal normal fuzzy set as a fuzzy output. That is why **MOM** may lead to control actions that you would not await. Finally, the **COG** method returns the value at the center of gravity of the fuzzy output area  $\mu_{\vec{x}}^{\circ}$ , i.e.,

$$\eta = \left( \int_{y \in Y} \mu_{\vec{x}}^{\circ}(y) \cdot y \, dy \right) \Bigg/ \left( \int_{y \in Y} \mu_{\vec{x}}^{\circ}(y) \, dy \right). \quad (17.5)$$

Usually, the **COG** method is taken to defuzzify the fuzzy output as it typically leads to a smooth control

**Fig. 17.2** The Mamdani–Assilian rule evaluation. Here we assume that the control process is described by two input variables  $\theta, \dot{\theta}$  and one output  $F$ . Let the controller be specified by two Mamdani–Assilian rules. Here the input tuple  $(25, -4)$  leads to the fuzzy output shown on the lower right side. If a crisp output is needed, any defuzzification method can eventually be applied

function. Nevertheless, it is possible to obtain an unreasonable output, too. We refer the gentle reader to Kruse et al. [17.16] for a richer treatment of defuzzification methods.

Coming back to the theoretical background of Mamdani–Assilian control, let us analyze its type of linguistic rules. Having a look at (17.3) again, we see that the minimum is used to serve as fuzzy implication. But the minimum does not fulfill all truth value combinations of the propositional logic’s implication. To see this, let us consider  $p \rightarrow q$  and assume that  $p$  is false. Then  $p \rightarrow q$  is true – regardless of the truth value of  $q$ . The minimum of 0 and  $q$ , however, is 0. This logical flaw could be seen as inconsistency of the standard Mamdani–Assilian controller. On the contrary, it actually turns it into a very powerful technique. Created to solve a simple practical problem, we might speak from a heuristic method instead. When we do not see Mamdani–Assilian rules as logical implications but rather as *association* [17.17], then the controller is even theoretically sound: Every rule  $R_r$  associates an output fuzzy set  $B_r$  with  $n$  input fuzzy sets  $A_{j,r}^{(j)}$  for  $j = 1, \dots, n$ . Consequently, we *must* use a fuzzy conjunction, e.g., the minimum *t*-norm.

Mamdani and Assilian’s heuristics can be obtained by the extension principle, too [17.18, 19]. If the fuzzy relation  $R$  that relates to the input  $x^{(j)}$  and the output  $y$  satisfies a couple of extensionality properties, then Mamdani and Assilian’s approach can also be obtained. Therefore, let  $E$  and  $E'$  be two similarity relations defined on the domains  $X$  and  $Y$  of  $x$  and  $y$ ,

respectively. The extensionality of  $R$  on  $X \times Y$  indicates that

$$\begin{aligned} \forall x \in X : \forall y, y' \in Y : R(x, y) \otimes E'(y, y') &\leq R(x, y'), \\ \forall x, x' \in X : \forall y \in Y : R(x, y) \otimes E(x, x') &\leq R(x', y). \end{aligned} \quad (17.6)$$

Thus, if  $(x, y) \in R$ , then  $x$  is related to the neighborhood  $y$ . The same holds for  $y$  in relation to  $x$ . Then  $A_r^{(j)}(x) = E(x, a_r^{(j)})$  and  $B_r(x) = E'(y, b_r)$  can be regarded as fuzzy sets of values in the proximity of  $a_r^{(j)}$  and  $b_r$ , respectively. Hence  $\forall r = 1, \dots, k : R(a_r^{(1)}, \dots, a_r^{(p)}, b_r) = 1$ . Applying this type of control definition to real-world problems, a practitioner must specify sensible similarity relations  $E_j$  and  $E'$  for each input  $\xi_j$  and output  $\eta$ , respectively. Eventually, using the extension principle for  $R$ , we obtain

$$R(x^{(1)}, \dots, x^{(p)}, y) \geq \max_{r=1, \dots, k} \left( \bigotimes \left( A_r^{(1)}(x^{(1)}), \dots, A_r^{(p)}(x^{(p)}), A_r(y) \right) \right).$$

In addition, if we use the minimum *t*-norm for  $\otimes$ , then we get exactly the approach of Mamdani–Assilian. Boixader and Jacas [17.20], Klawonn and Castro [17.21] show that indistinguishability or similarity is the connection between the extensionality property and fuzzy equivalence relations.

In practical applications, different *t*-norms and *t*-conorms as product instead of minimum and bounded

sum instead of maximum play an important role. The reason is a stepwise multilinear interpolation behavior between the rules that cause a smoother function  $y = \varphi(\vec{x})$  compared to minimum and maximum operators.

Depending on the input and output variables, Mamdani–Assilian controllers can intentionally or unintentionally copy concepts from classical control theory. As an example, a controller with inputs as proportional, integral and derivative errors between the output variable and desired values in combination with a symmetrical rule base has a similar behavior to a PID controller. Such a reinvention of established concepts with a more complicated implementation should be avoided though.

### 17.3.2 Takagi–Sugeno Control

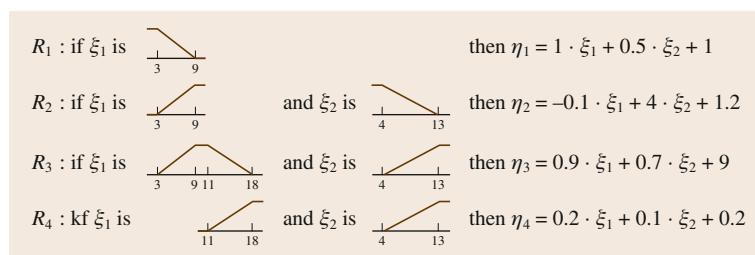

Partitioning both the input and output domains seems to be reasonable from an interpretational point of view. Nevertheless, one might face control applications where a sufficient approximation quality can only be achieved using many linguistic terms for each dimension. This, in turn, will increase the potential number of rules which most probably worsen the ability to interpret the rule base of the fuzzy controller. For such control processes, we recommend to neglect the concept of partitioning the output domain and instead define functions that locally approximate the control behavior.

A controller that uses rules like this is called the Takagi–Sugeno controller [17.22]. The Takagi–Sugeno rules  $R_r$  for  $r = 1, \dots, k$  are typically defined as

$$R_r : \text{if } \xi_1 \text{ is } A_{i_1,r}^{(1)} \text{ and } \dots \text{ and } \xi_n \text{ is } A_{i_n,r}^{(n)} \\ \text{then } \eta = f_r(\xi_1, \dots, \xi_n).$$

Most commonly, linear functions  $f_r$  can be found in many controllers, i. e.,

$$f_r(\vec{x}) = a_r^{(0)} + \sum_{i=1}^n a_r^{(i)} x^{(i)}.$$

The rules of a Takagi–Sugeno controller share the same antecedent parts with the Mamdani–Assilian controller, so does the decision logic computes the same degree of applicability  $\alpha_r$ , i. e., using (17.2). An example of such a controller for two inputs is shown in Fig. 17.3. Eventually, all degrees are used to compute the crisp control value

$$\eta = \frac{\sum_{r=1}^k \alpha_r \cdot f_r(\vec{x})}{\sum_{r=1}^k \alpha_r}$$

which is the weighted sum over all rule outputs. Obviously, a Takagi–Sugeno controller does not need any defuzzification method.

Takagi–Sugeno controllers are not only popular for translating human strategies into formal descriptions, but they can also be combined with many well-known methods from classical control theory. For instance, many locally valid linear models of the process can be aggregated into one nonlinear model in the form of Takagi–Sugeno rules. In a next step, the desired behavior of the resulting closed-loop system is formulated. Stability can be defined in the strictest form as guaranteed convergence to the desired setpoint from any initial state, including robustness against bounded parameter uncertainties of the process model. Mathematical methods as Lyapunov functions in the form of linear matrix equations are now applied to design the Takagi–Sugeno fuzzy controller. For details about these concepts, we refer to Feng [17.23]. The main advantage of this strategy is the guaranteed performance, whereas many disadvantages come into play, too. This approach requires a model and sophisticated mathematical methods. Also it usually leads to a limited performance due to conservative design results and the limited interpretability. That is also why many recent papers propose iterative improvements, e.g., by proposing ways to handle other types of uncertainties such as varying time delays [17.24], and by reducing the conservativeness of the solutions [17.25].

**Fig. 17.3** A Takagi–Sugeno controller for two inputs and one output described by four rules. If a certain clause  $x_j$  is  $A_{j,r}^{(j)}$  in any rule  $R_r$  is missing, then the corresponding membership function  $\mu_{j,r}(x_j) \equiv 1$  for all linguistic values  $i_{j,r}$ . In this example, consider for instance  $x_2$  in rule  $R_1$ . Thus,  $\mu_{i_{2,1}}(x_2) \equiv 1$  for all  $i_{2,1}$ .

### 17.3.3 Fuzzy Logic-Based Controller

Both controllers that have been introduced so far interpret every linguistic rule as an association of an  $n$ -dimensional fuzzy input point with a fuzzy output. Thus, we can interpret the set of fuzzy rules as set-points of the control system. Recall, however, that this has nothing to do with logic inference since not all rules need to be activated by a given input.

When all rules are evaluated in a conjunctive manner, we can regard each fuzzy rule as a fuzzy constrain on a fuzzy input–output relation. The inference operation of such a controller is identical to approximate reasoning. Note that classical reasoning uses inference rules (so-called tautologies) to deductively infer crisp conclusions from *crisp* propositions. A generalization of classical reasoning is approximate reasoning applied to *fuzzy* propositions. Zadeh [17.9] proposed the first approaches to handle fuzzy sets in approximate reasoning. The gentle reader is referred to further details explained in Zadeh [17.26, 27]. The basic idea is to represent incomplete knowledge as possibility distributions.

Possibility theory [17.28] has been proposed to study and model imperfect descriptions of an existing element  $x_0$  in a set  $A \subseteq X$ . It can be seen as a counterpart to probability theory. To formally define a possibility distribution  $\Pi : 2^X \rightarrow [0, 1]$  we need the following axioms that seem to have similarities to the well-known Kolmogorov axioms:

$$\begin{aligned}\Pi(\emptyset) &= 0, \\ \Pi(A) &\leq \Pi(B) \text{ if } A \subseteq B \text{ and} \\ \Pi(A \cup B) &= \max\{\Pi(A), \Pi(B)\} \text{ for all } A, B \subset X.\end{aligned}$$

The expression  $\Pi(A) = 1$  includes that  $x_0 \in A$  is unconditional possible. If  $\Pi(A) = 0$ , then it is impossible that  $x_0 \in A$ . Zadeh [17.29] models uncertainty about  $x_0$  by the possibility measure  $\Pi : 2^{\mathcal{Q}} \rightarrow [0, 1]$ ,  $\Pi(A) = \sup\{\mu(x) \mid x \in A\}$  when a fuzzy set  $\mu : x \rightarrow [0, 1]$  is the only known description of  $x_0$ . Then the possibility measure is given by the possibility degrees of singletons, i.e.,  $\Pi(\{x\}) = \mu(x)$ .

Now, consider only one-dimensional input and output spaces. Then we must specify a suitable two-dimensional possibility distribution. Let the rule

$$R : \text{if } \xi \text{ is } A \text{ then } \eta \text{ is } B$$

associate the input fuzzy set  $\mu_A$  with the output fuzzy set  $\mu_B$ . We can express this rule by a possibility distri-

bution

$$\pi_{X,Y}(x, y) = I(\mu_A(x), \mu_B(y))$$

where  $I$  is an implication of any multivalued logic. So, we can compute the output by the composition of the input and the rule base, i.e.,  $\mu_B = \mu_A \circ \pi_{X,Y}$  where the fuzzy rules are expressed by the fuzzy relation  $\pi_{X,Y}$  defined on  $X \times Y$ . The composition of a fuzzy set  $\mu$  with a fuzzy relation  $\pi$  is defined by

$$\mu \circ \pi : Y \rightarrow [0, 1], \quad y \mapsto \sup_{x \in X} \{\min\{\mu(x), \pi(x, y)\}\}.$$

We can easily see that this is a fuzzification of the standard composition  $\circ$  of two crisp sets  $M \subseteq X$  and  $R \subseteq X \times Y$ , i.e.,

$$M \circ R \stackrel{\text{def}}{=} \{y \in Y \mid \exists x \in X : (x \in M \wedge (x, y) \in R)\} \subseteq Y.$$

The challenge in fuzzy control applications using relational equations is to search for a fuzzy relation  $\pi$  that satisfies all equations  $\mu_{B_r} = \mu_{A_r} \circ \pi$  for every rule  $R_r$  with  $r = 1, \dots, k$ . If multiple inputs  $X_1, \dots, X_n$  are used, then  $\mu_A$  is defined on the product space  $X = X_1 \times \dots \times X_n$  as in (17.2). The fuzzy relation  $\pi$  can be found by determining the *Gödel relation* for every given relational equation, i.e.,

$$(x, y) \in \pi_{X,Y}^G \iff (x \in \mu_A \rightarrow y \in \mu_B).$$

Here the implication arrow  $\rightarrow$  represents the Gödel implication

$$a \rightarrow b = \begin{cases} 1 & \text{if } a \leq b, \\ b & \text{if } a > b. \end{cases}$$

So, actually a linguistic rule expresses the gradual rule in terms of *the more*  $\mu_A$ , *the more*  $\mu_B$ . Hence it constrains the fuzzy relation  $\pi$  by the inequality

$$\min(\mu_A(x), \pi(x, y)) \leq \mu_B(y)$$

for all  $(x, y) \in X \times Y$ . The Gödel implication is theoretically not the only way to represent  $\pi$ . Dubois and Prade [17.30, 31] give a variety of good conclusions, however, not to take another but the Gödel implication.

If the system of relational equations  $\mu_{B_r} = \mu_{A_r} \circ \pi$  for  $r = 1, \dots, k$  is solvable, then the intersection of all rule's Gödel relations

$$\pi^G = \bigcap_{r=1}^k \pi_r^G(\mu_{A_r}(x), \mu_{B_r}(y))$$

is a solution with  $\cap$  being the minimum  $t$ -norm. Due to the mathematical properties of the Gödel implication, the Gödel relation  $\pi^G$  is the greatest solution in terms of elementwise membership degrees.

To conclude this type of controller, we recall that the relation

$$\Pi(\{(x, y)\}) \stackrel{\text{def}}{=} \pi(x, y)$$

approximates if it is *possible* to assign the output value  $y$  to the input tuple  $x$ . Besides the overall *conjunctive*

nature of the rules does *softly constrain* the control function  $\varphi$ . It might thus happen in practical applications that these constraints lead to contradictions if very narrow output fuzzy sets are assigned to overlapping input fuzzy sets. In such a case, the controller's output will be the empty fuzzy set which corresponds to no solution. One way to overcome this problem is to specify both narrow input fuzzy sets and broader output fuzzy sets. This procedure, however, limits the expressiveness and thus applicability of fuzzy logic-based controllers.

## 17.4 A Glance at Some Industrial Applications

Shortly after big success stories in the 1980s, mainly in Japan [17.2], many real-world control applications have been greatly solved using the Mamdani–Assilian approach all around the world. So did the research group of the paper's third author initiate the development of some automobile controllers.

We want to discuss two of these control processes that have been developed with Volkswagen AG

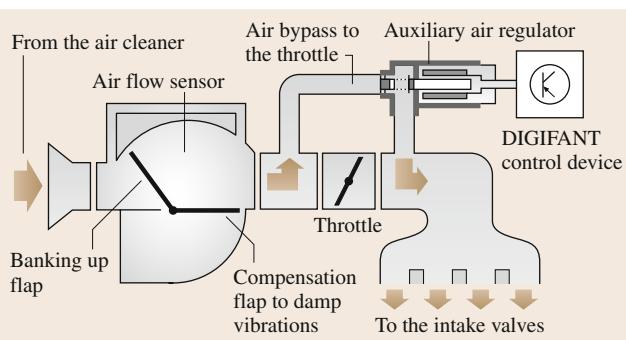

(VW), i.e., the engine idle speed control [17.18] and the shift-point determination of an automatic transmission [17.32]. Both of these very successful Mamdani–Assilian controllers can nowadays be still found in VW automobiles. The idle speed controller is based on similarity relations which facilitates to interpret the control function as interpolation of a point-wise imprecisely known function. The shift-point determination continuously adapts the gearshift schedule between two extremes, i.e., economic and sporting. This controller determines a so-called sport factor and individually adapts the gearshift movements of the driver.

### 17.4.1 Engine Idle Speed Control

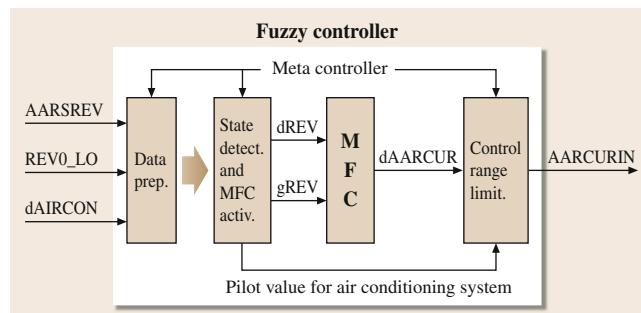

This controller shall adjust the idle speed of a spark ignition engine. Usually, a volumetric control is used to control the spark ignition engine. The principle is shown in Fig. 17.4. Here an auxiliary air regulator differs from the cross-section of a bypass to the throttle.

The controller's task is to adjust the auxiliary air regulator's pulse width. In the case of a rapid fall of the number of revolutions, the controller shall drive the auxiliary air regulator to broaden the bypass cross-section. This increase of the air flow rate is measured by an air flow sensor which serves as controller signal. Then a new amount for the fuel injection has to be determined, and with a higher air flow rate the engine yields more torque. This, in turn, leads to a higher number of revolutions which could be decreased correspondingly by narrowing the bypass cross-section.

The ultimate goal is to reduce both fuel consumption and pollutant emissions. It is straightforward to achieve this goal by slowing down the idle speed. On the contrary, some automobile facilities, e.g., the air-

**Fig. 17.4** Principle of the engine idle speed control

**Fig. 17.5** Structure of the fuzzy controller

conditioning system, are very often switched on and off which forces the number of revolutions to drop. So a very flexible controller is needed to adjust this process properly. Schröder et al. [17.32] even point out other problems of this control application.

As it turned out, the engineers who defined the similarity relations to model indistinguishability/similarity of two control states did not experience any big difficulties. Remember that the control expert must define a set of  $k$  input-output tuples  $((x_r^{(1)}, \dots, x_r^{(p)}), y_r)$ . So, for each  $r = 1, \dots, k$  the output value  $y_r$  seems appropriate for the input  $(x_r^{(1)}, \dots, x_r^{(p)})$ . Like that the control expert specifies a partial control function  $\varphi_0$ . According to (17.6), we directly obtain a Mamdani-Assilian controller by determining the extensional hull of  $\varphi_0$  given the similarity relations. We thus obtain the rules from the partial control function  $\varphi_0$  as

$R_r : \text{if } \xi_1 \text{ is approximately } x_r^{(1)} \text{ and } \dots$   
 $\text{and } \xi_p \text{ is approximately } x_r^{(p)}$   
 $\text{then } \eta \text{ is approximately } y_r$ .

Klawonn et al. [17.18] explain the more detailed theory of this approach.

Eventually, only two input variables are needed to control the engine idle speed controller, i. e.:

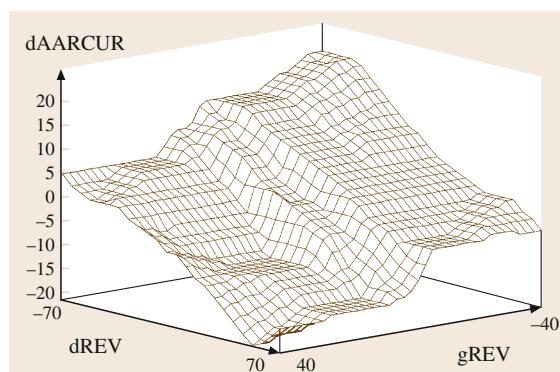

Fig. 17.6 Performance characteristics

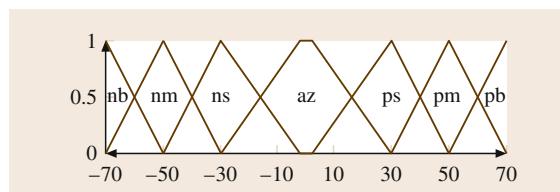

Fig. 17.7 Deviation dREV of the number of revolutions

1. The deviation dREV [rpm] of the number of revolutions to the set value.
2. The gradient gREV [rpm] of the number of revolutions between two ignitions.

There exists just one output variable which is the change of current dAARCUR for the auxiliary air regulator. The final controller is shown in Fig. 17.5.

The control rules of the engine idle speed controller have been found from idle speed experiments. The partial control function  $\varphi_0 : X_{(\text{dREV})} \times X_{(\text{gREV})} \rightarrow Y_{(\text{dAARCUR})}$  is depicted in the upper half of Tab. 17.1.

The fuzzy controller has been defined by a similarity relation and the partial control mapping  $\varphi_0$ . With the center of area (COA) method, it yields a control surface as shown in Fig. 17.6. The function values here are evaluated in a grid of equally sampled input points. The respective Mamdani-Assilian controller has been found by relating each point of  $\varphi_0$  to a linguistic term, e.g., negative big (nb), negative medium (nm), negative small (ns), and approximately zero (az). The resulting fuzzy partitions of dREV, gREV, and dAARCUR are displayed in Figs. 17.7, 17.8, 17.9, respectively. So, we obtain linguistic rules from  $\varphi_0$  like

*if dREV is A and gREV is B then dAARCUR is C.*

The complete set of rules is given in the lower part of Tab. 17.1.

Klawonn et al. [17.18], Schröder et al. [17.32] show that this Mamdani-Assilian controller leads to a very smooth and thus better control behavior when com-

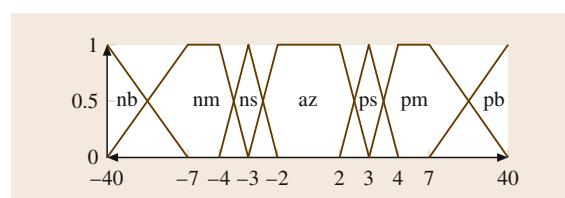

Fig. 17.8 Gradient gREV of the number of revolutions

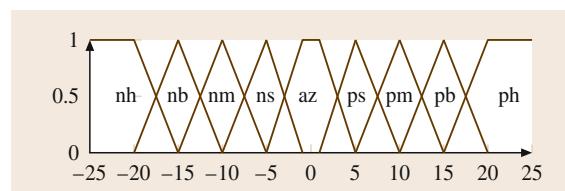

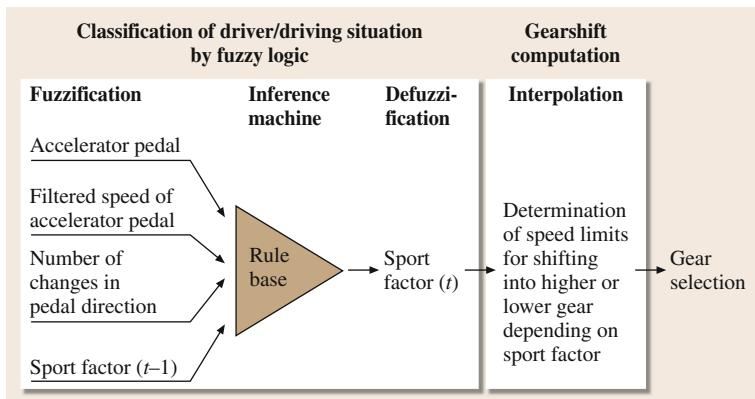

Fig. 17.9 Change of current dAARCUR for the auxiliary air regulator

**Fig. 17.10** Flowing shift-point determination with fuzzy logic

pared to classical controllers. Still, for this application, it has been much simpler to define a fuzzy controller than a one based on higher mathematics. Moreover, they found that this fuzzy controller reaches the desired setpoint precisely and fast. Last but not least, even increasing the load slowly does not change the control behavior significantly. So it is nearly impossible to experience any vibration, even after drastic load changes.

#### 17.4.2 Flowing Shift-Point Determination

Conventional automatic transmissions select gears based on the so-called gearshift diagrams. Here, the gearshift simply depends on the accelerator position

and the velocity. A lagging between the up and down shift avoids oscillating gearshift when the velocity varies slightly, e.g., during stop-and-go traffic. For instance, if the driver kicks gas with half throttle, the gearshift will start with the first gear. For a standardized behavior, a fixed diagram works well. Until 1994, the VW gear box had two different types of gearshift diagrams, i.e., economic *ECO* and sporting *SPORT*. An economic gearshift diagram switches gears at a low number of revolutions to reduce the fuel consumption. A sporting one leads to gearshifts at a higher number of revolutions. Since 1991 it was a research issue at VW to develop an individual adaption of shift-points. No additional sensors should be used to observe the driver.

The idea was that the car *observes* the driver [17.32] and classifies him or her into calm, normal, sportive (assigning a sport factor  $\in [0, 1]$ ), or nervous (to calm down the driver). A test car from VW was operated by many different drivers. These people were classified by a human expert (passenger). Simultaneously, 14 attributes were continuously measured during test drives. Among them were variables such as the velocity of the car, the position of the acceleration pedal, the speed of the acceleration pedal, the kick down, or the steering wheel angle.

The final Mamdani controller was based on four input variables and one output. The basic structure of the controller is shown in Fig. 17.10. In total, seven rules could be identified at which the antecedent consists of up to four clauses. The program was highly optimized: It used 24 byte **RAM** and 702 byte **ROM**, i.e., less than 1 KB. The runtime was 80 ms which means that 12 times per second a new sport factor was assigned. The controller is in series since January 1995. It shows an excellent performance.

## 17.5 Automatic Learning of Fuzzy Controllers

The automatic generation of linguistic rules plays an important role in many applications, e.g., classification [17.33–36], regression [17.37–39], and image processing [17.40, 41]. Since fuzzy controllers are based on linguistic rules, automatic ways to tune and learn them have been developed for control applications as well [17.18, 19, 42–44].

How can a computer learn fuzzy rules from data to explain or support decisions like people do? We think that the fuzzy analysis of data can answer this question sufficiently [17.45]. The easiest and most common way is to use *fuzzy clustering* which automatically determines fuzzy sets from data.

Before we talk about the generation of linguistic rules from fuzzy clustering, however, let us briefly list some of the very diverse methods of fuzzy data analysis. *Grid-based* approaches define fixed fuzzy partitions for every variable. Every cell in that multidimensional grid may correspond to one rule [17.39]. Most well known are *hybrid methods* to induce fuzzy rules. Therefore, a fuzzy system is combined with computational intelligence techniques. For instance, *evolutionary algorithms* are used for guided searching the space of possible rule bases [17.46] or fuzzifying and thus summarizing a crisp set of rules [17.47]. *Neuro-fuzzy systems* use learning methods of artificial neural network (e.g., backpropagation) to tune the parameters of a network that can be directly understood as a fuzzy system [17.48]. Standard rule generation methods have been fuzzified as well (e.g., separate-and-conquer rule learning [17.49], decision trees [17.50], and support vector machines [17.51, 52]).

Using fuzzy clustering to learn fuzzy rules from data, we only refer to the standard fuzzy  $c$ -means algorithm (**FCM**) [17.53, 54]. Consider the input space  $X \subset \mathbb{R}^n$  and the output space  $Y \subset \mathbb{R}$ . We observe  $m$  patterns  $(\vec{x}_j, y_j) \in S \subseteq X \times Y$  where  $j = 1, \dots, m$ . Running **FCM** on that dataset  $S$  leads to  $c$  cluster prototypes

$$\vec{c}_i = (c_i^{(1)}, \dots, c_i^{(n)}, c_i^{(y)})$$

with  $i = 1, \dots, c$  that can be seen as concatenation of both the input values  $c_i^{(j)}, j = 1, \dots, n$  and the output value  $c_i^{(y)}$ . Thus, every prototype represents one linguistic rule

$$R_i : \text{if } x \text{ is close to } (c_i^{(1)}, \dots, c_i^{(n)})$$

then  $y$  is close to  $c_i^{(y)}$ .

Using the membership degrees  $U$ , we can rewrite these rules as

$$R_i : \text{if } \vec{u}_i^x(\vec{x}) \text{ then } u_i^y(y). \quad (17.7)$$

The only problem is that **FCM** returns the membership degrees  $\vec{u}_i(\vec{x}, y)$  of the product space  $X \times Y$ . To obtain rules like (17.7), we must *project*  $\vec{u}_i$  onto  $\vec{u}_i^x$  and  $u_i^y$ . If  $\vec{x}$  and  $y$  are restricted to  $[\vec{x}_{\min}, \vec{x}_{\max}]$  and  $[y_{\min}, y_{\max}]$ , respectively, the projections are given by

$$\begin{aligned} \vec{u}_i^x(\vec{x}) &= \sup_{y \in [y_{\min}, y_{\max}]} \vec{u}_i(\vec{x}, y), \\ u_i^y(y) &= \sup_{x \in [\vec{x}_{\min}, \vec{x}_{\max}]} \vec{u}_i(\vec{x}, y). \end{aligned}$$

We can also project  $\vec{u}_i$  onto each single input variable  $X_1, \dots, X_n$  by

$$u_{ik}(x^{(k)}) = \sup_{\vec{x}^{(-k)} \in [\vec{x}_{\min}^{(-k)}, \vec{x}_{\max}^{(-k)}]} \vec{u}_i^x(\vec{x})$$

for  $k = 1, \dots, n$  where  $\vec{x}^{(-k)} \stackrel{\text{def}}{=} (x^{(1)}, \dots, x^{(k-1)}, x^{(k+1)}, \dots, x^{(n)})$ . We may thus write (17.7) in the form of a *Mamdani-Assilian rule* (17.1) as

$$R_i : \text{if } \bigwedge_{k=1}^n u_{ik}(x^{(k)}) \text{ then } u_i^y(y). \quad (17.8)$$

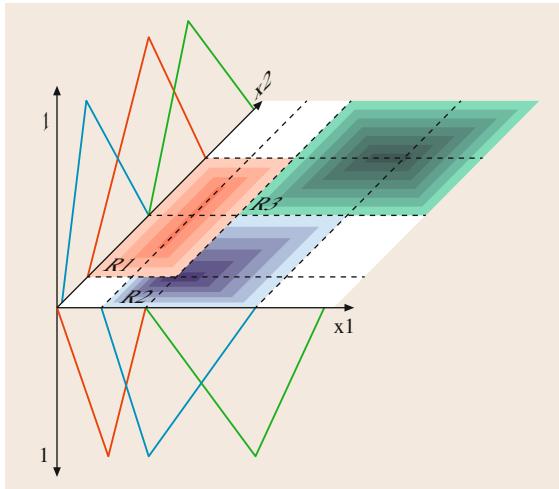

For one rule, the output value of an unseen input  $\vec{x} \in \mathbb{R}^n$  will be equivalent to (17.2) if the minimum  $t$ -norm is used as conjunction  $\wedge$ . The overall output of the complete rule base is given by a disjunction  $\vee$  of all rule outputs (cf. (17.4) if  $\vee$  is the  $t$ -conorm maximum).

A crisp output can then again be computed by defuzzification, e.g., using the **COG** method (17.5). Since this computation is rather costly, the output membership functions  $u_i^y$  are commonly replaced by singletons, i.e.,

$$u_i^y(y) = \begin{cases} 1 & \text{if } y = c_i^{(y)}, \\ 0 & \text{otherwise.} \end{cases}$$

Since each rule consequently comprise the component  $c_i^{(y)}$  of the cluster prototype, we can rewrite (17.8) as the *Sugeno-Yasukawa rule* [17.55]

$$R_i : \text{if } \bigwedge_{k=1}^n u_{ik}(x^{(k)}) \text{ then } y = c_i^{(y)}.$$

**Fig. 17.11** Fuzzy rules and induced imprecise areas

These rules strongly resemble the neurons of an radial basis function (**RB**F) network. This will become clear if every membership function is Gaussian, i. e.,

$$\vec{u}_i(\vec{x}) = \exp\left(\frac{\vec{x} - \mu_i}{\sigma_i}\right)^2,$$

and if there are normalized, i. e.,

$$\sum_{i=1}^c \vec{u}_i(\vec{x}) = 1 \quad \text{for all } \vec{x} \in \mathbb{R}^n.$$

Note that this link is used in neuro-fuzzy systems for both training fuzzy rules with backpropagation and initializing **RB**F networks with fuzzy rules [17.34].

### 17.5.1 Transfer Passenger Analysis Based on **FCM**

In this section, we present another real-world control problem that deals with the control of passenger movements and flows in terminal areas on an airport's land side. Especially during mass events such as world championships, concerts, or in the peak season in touristic areas, the capacities of passenger airports reach their upper limits. The conflict-free allocation, e.g., using intelligent destination boards and signpost, can increase the safety and security of passengers and airport employees. Thus, it is rational to study intelligent control approaches to allocate passengers from their arrival terminal to their departure terminal.

To evaluate different controllers, the German Aerospace Center (**DLR**) implemented a macroscopic

passenger flow model that simulates passenger movements. Here, probabilistic distributions are used to describe passenger movements in terminal areas. The approach of *Keller and Kruse* [17.56] constructs a fuzzy rule base using **FCM** to describe the transfer passenger amount between aircraft. These rules can be used as control feedback for the macroscopic simulation.

The following attributes of passengers are used to for analysis:

- The maximal amount of passengers in a certain aircraft (depending on the type of the aircraft)
- The distance between the airport of departure and the airport of destination (in three categories: short-, medium-, and long-haul)
- The time of departure
- The percentage of transfer passengers in the aircraft.

The number of clusters is determined by validity measures [17.41, 57] evaluating the whole partition of all data. The clustering algorithm is run for a varying number of clusters. The validity of the resulting partitions is then compared by different measures.

An example of resulting fuzzy clusters is given in Fig. 17.11. Here, every fuzzy cluster corresponds to one fuzzy rule. The color intensity indicates the firing strength of a specific rule. The imprecise areas are the fuzzy clusters where the color intensity indicates the membership degree. The tips of the fuzzy partitions are obtained in every domain by projections of the multidimensional cluster centers (as explained before in Sect. 17.5).

The fuzzy rules obtained by **FCM** are simplified through several steps. First, similar fuzzy sets are combined to one fuzzy set. Fuzzy sets similar to the universal fuzzy set are removed. Fuzzy rules with the same input clauses are either combined if they also share the same output clauses or else they are removed from the rule base. Eventually, **FCM** and the rule-simplifying process yield five rules.

Among them are the two following rules. If an aircraft with a relatively small amount of maximal passengers (80–200) has a short- or medium-haul destination departing late at night, then usually this flight has a high amount of transfer passengers (80–90%). If a flight with a medium-haul destination and a small aircraft (about 150 passengers) starts about noon, then it carries a relatively high amount of transfer passengers (ca. 70%). We refer the gentle reader to *Keller and Kruse* [17.56] for further details about this real-world control application.

## 17.6 Conclusions

In this chapter, we introduced fuzzy control – a human-inspired way to control a nonlinear process as an imprecisely defined function. We talked about classical control engineering and its limitations which also motivates the need for a human knowledge-based approach of control. This knowledge is typically represented as either Mamdani–Assilian rules or Takagi–Sugeno rules. We presented both types of fuzzy controllers, and also discussed the shortcomings of logic-based controllers, although they are mathematically well defined. We thoroughly presented two successful industrial applications of fuzzy control. We also stressed the necessity for automatic learning and tuning algorithms. We mentioned the most known approaches briefly and rule induction from fuzzy clustering in de-

tail. We also showed a real-world control application where such rules are used in the feedback loop of a simulation.

How will the future of fuzzy control look alike? Even in university lectures for control engineers, fuzzy control has become part of the curriculum years ago. With the drastically growing number of control systems – becoming more and more complex – a new generation of well-educated engineers and scientists will strengthen the presence of fuzzy controllers for real-world applications. In the far future, the use of data analysis techniques and algorithms will most probably drive evolving fuzzy controllers that are even able to react in nonstationary environments.

# 18. Interval Type-2 Fuzzy PID Controllers

Tufan Kumbasar, Hani Hagras

The aim of this chapter is to present a general overview about interval type-2 fuzzy **PID** (proportional-integral-derivative) controller structures. We will focus on the standard double input direct action type fuzzy **PID** controller structures and their present design methods. It has been shown in various works that the type-1 fuzzy **PID** controllers, using crisp type-1 fuzzy sets, might not be able to fully handle the high levels of uncertainties associated with control applications while the type-2 fuzzy **PID** controller using type-2 fuzzy sets might be able to handle such uncertainties to produce a better control performance. Thus, we will classify and examine the handled fuzzy **PID** controllers within two groups with respect to the fuzzy sets they employ, namely type-1 and interval type-2 fuzzy sets. We will present and examine the controller structures of the direct action type-1 fuzzy **PID** and interval type-2 fuzzy **PID** controllers on

a generic, a symmetrical  $3 \times 3$  rule base. We will present general information about the type-1 fuzzy **PID** and interval type-2 fuzzy **PID** controllers tuning parameters and design strategies. Finally, we will present a simulation study to evaluate the control performance of the type-1 fuzzy **PID** and interval type-2 fuzzy **PID** on a first-order plus time-delay benchmark process.

## 18.1 Fuzzy Control Background

It is a known fact that the conventional **PID** controllers are the most popular controllers used in industry due to their simple structure and cost efficiency [18.1, 2]. However, the **PID** controller being linear is not suited for strongly nonlinear and uncertain systems. Thus, fuzzy logic controllers (**FLCs**) are extensively used as an alternative to **PID** control in processes where the system dynamics is either very complex or exhibit highly nonlinear characteristics. **FLCs** have achieved a huge success in real-world control applications since it does not require the process model and the controller can be constructed based on the human operator's control expertise.

In the fuzzy control literature, fuzzy **PID** controllers (**FPID**) are often mentioned as an alternative to the conventional **PID** controllers since they are analogous to the conventional **PID** controllers from the input–output

relationship point of view [18.3–6]. The **FPID** controllers can be classified into three major categories as direct action type, fuzzy gain scheduling type, and hybrid type fuzzy **PID** controllers [18.6]. The direct action type can also be classified into three categories according to the number of inputs as single input, double input, and triple input direct action **FPID** controllers [18.6]. In the literature, researchers mainly focused on and analyzed double input direct action **FPID** controllers [18.6–10]. Numerous techniques have been developed in the literature for analyzing and designing a wide variety of **FPID** control systems. After the pioneer study by *Qiao* and *Mizumoto* [18.7], the main research was focused on type-1 fuzzy **PID** controllers (**T1-FPID**); however, a growing number of techniques have been developed for interval type-2 fuzzy **PID** controllers (**IT2-FPID**) controllers, recently.

It has been demonstrated that type-2 fuzzy logic systems are much more powerful tools than ordinary (type-1) fuzzy logic systems to represent highly nonlinear and/or uncertain systems. As a consequence, type-2 fuzzy logic systems have been applied in various areas especially in control system design. The internal structure of the interval type-2 fuzzy logic controllers (**IT2-FLC**) is similar to the type-1 counterpart. However, the major difference is that at least one of the input fuzzy sets (**FS**s) is an interval type-2 fuzzy set (**IT2-FS**) [18.11]. Thus, a type reducer is needed to convert type-2 sets into a type-1 fuzzy set before a defuzzification procedure can be performed [18.12]. Generally, interval type-2 fuzzy logic systems achieve better control performance because of the additional degree of freedom provided by the footprint of uncertainty (**FOU**) in their membership functions [18.13]. Consequently, **IT2-FLCs** have attracted much research interest, especially in control applications, since they are a much more pow-

erful to handle uncertainties and nonlinearities [18.14]. Thus, several applications employed successfully **IT2-FLCs** such as pH control [18.13], liquid-level process control [18.15], autonomous mobile robots [18.14, 16, 17], and bioreactor control [18.18].

In this chapter, we will focus on the most commonly used double input direct action type **FPID** controller structures. We will first present the general structure of the **FPID** controller and then classify the **FPID** controllers within two groups with respect to the fuzzy sets they employ, namely type-1 and interval type-2 fuzzy sets. Thus, we will present and examine the structures of the **T1-FPID** and **T2-FPID** controllers on a generic, a symmetrical  $3 \times 3$  rule base. We will present detailed information about their internal structures and design strategies presented in the literature. Finally, we will evaluate the control performance of the **T1-FPID** and **IT2-FPID** on a first-order plus time delay benchmark process.

## 18.2 The General Fuzzy PID Controller Structure

In this section, we present the general structure of the two input direct action type **FPID** controllers formed using a fuzzy PD controller with an integrator and a summation unit at the output [18.7–10]. The standard **FPID** controller is constructed by choosing the inputs to be error ( $e$ ) and derivative of error ( $\Delta e$ ) as shown and the output is the control signal ( $u$ ) as illustrated in Fig. 18.1. The output of the **FPID** is defined as

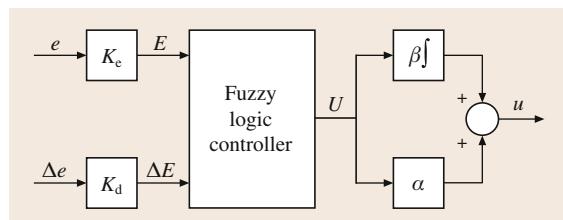

$$u = \alpha U + \beta \int U dt, \quad (18.1)$$

where  $U$  is the output of the fuzzy inference system.

The design parameters of the **FPID** controller structure can be summarized within two groups, structural parameters and tuning parameters [18.6]. The structural parameters include input/output variables to fuzzy in-

ference, fuzzy linguistic sets, type of membership functions, fuzzy rules, and the inference mechanism, i.e., the fuzzy logic controller. In the handled **FPID** structure, the **FLC** is constructed as a set of heuristic control rules, and the control signal is directly deduced from the knowledge base and the fuzzy inference as done in diagonal rule base generation approaches [18.7–10]. More detailed information about the internal structure of the **FPID** will be presented in the following subsections. Usually the structural parameters of the **FPID** controller structure are determined during an off-line design.

The tuning parameters include input/output scaling factors (**SFs**) and parameters of membership functions (**MFs**). As can be seen from Fig. 18.1, the handled **FPID** controller structure has two input and two output scaling factors [18.7–10]. The input **SFs**  $K_e$  (for error ( $e$ )) and  $K_d$  (for the change of error ( $\Delta e$ )) normalize the inputs to the common interval  $[-1, 1]$  in which the membership functions of the inputs are defined (thus  $e(t)$  and  $\Delta e(t)$ )) are converted after normalization into  $E$  and  $\Delta E$ . While the **FLC** output ( $U$ ) is mapped onto the respective actual output ( $u$ ) domain by output **SFs**  $\alpha$  and  $\beta$ . Usually, the tuning parameters can be calculated during offline design process as well as online adjustments of the controller to enhance the process performance [18.9, 10].

**Fig. 18.1** Illustration of the **FPID** controller structure

In the following subsections, we will examine the structures of the **T1-FPID** and **IT2-FPID** controllers. We will present detailed information about the **T1-FPID** and **IT2-FPID** internal structures, design parameters, and tuning strategies. Finally, we will present a comparative simulation results to show the superiority of the interval type-2 fuzzy **PID** controller compared to its type-1 counterparts.

### 18.2.1 Type-1 Fuzzy PID Controllers

In this subsection, we will start by presenting the internal structure of the handled **T1-FPID** controller and then we will present brief information about the design strategies for the **T1-FPID** controller structure in the literature.

#### The Internal Structure of the Type-1 Fuzzy PID Controller

In the handled **T1-FPID** structure, a symmetrical  $3 \times 3$  rule base is used as shown in Table 18.1. The rule structure of the type-1 fuzzy logic controller (**T1-FLC**) is as follows

$$R_m: \text{If } E \text{ is } A_{1k} \text{ and } \Delta E \text{ is } A_{2l} \text{ then } U \text{ is } G_m, \quad (18.2)$$

where  $E$  (normalized error) and  $\Delta E$  (normalized change of error) are the inputs,  $U$  is the output of **FLC**,  $G_n$  is the consequent crisp set ( $f = 1 \dots F = 9$ ), and  $F$  is the number of rules. Here,  $A_{1k}$  and  $A_{2l}$  represent the type-1 membership functions (**T1-MFs**) ( $k = 1, 2, K = 3$ ;  $l = 1, 2, L = 3$ ),  $K$ , and  $L$  are the number of MFs that cover the universe of discourse of the inputs  $E$  and  $\Delta E$ , respectively. In this chapter, we will employ three triangular type **T1-MFs** for each input domain ( $E$  and  $\Delta E$ ) and denote them as N (negative), Z (zero), and P (positive). The **T1-MFs** of the **T1-FLC** are defined with the three parameters ( $l_{ij}, c_{ij}, r_{ij}; i = 1, 2; j = 1, 2, J = 3$ ), as shown in Fig. 18.2a. Here,  $I$  is the total number of the inputs ( $I = 2$ ) and  $J$  ( $J = K = L = 3$ ) is the total number of MFs. The outputs of the **FLC** are

**Table 18.1** The rule base of the **FPID** controller

$E/\Delta E$	N	Z	P
N	N	NM	Z
Z	NM	Z	PM
P	Z	PM	P

defined with five crisp singleton consequents (negative (N) =  $y_N$ , negative medium (NM) =  $y_{NM}$ , zero (Z) =  $y_Z$ , positive medium (PM) =  $y_{PM}$ , positive (P) =  $y_P$ ) as illustrated in Fig. 18.2b. The implemented **T1-FLCs** use the product implication and the center of sets defuzzification method. Thus, the output ( $U$ ) of the **T1-FLC** is defined as

$$U = \frac{\sum_{m=1}^M f_m G_m}{\sum_{m=1}^M f_m}, \quad (18.3)$$

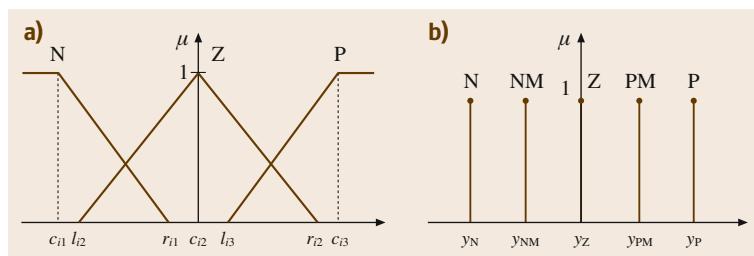

where  $f_m$  is the total firing strength for the  $m$ -th rule is defined as

$$f_m = \mu_{A_{1k}} * \mu_{A_{2l}}. \quad (18.4)$$

Here,  $*$  represents the product implication (the  $t$ -norm) and  $\mu_{A_{1k}}$  and  $\mu_{A_{2l}}$  are the membership grades of the  $A_{1k}$  and  $A_{2l}$  **T1-FMs**, respectively.

#### Type-1 Fuzzy PID Design Strategies

In the design of the handled **T1-FPID** controller structure with a  $3 \times 3$  rule base, the parameters to be determined are the scaling factors and the parameters of the antecedent and consequent membership functions. The antecedent MFs of the **T1-FPID** controller that are labeled as the N and P are defined for each input with two parameters each which are  $c_{i1}, r_{i1}$  (for N) and  $l_{i3}, c_{i3}$  (for P) ( $i = 1, 2$ ), respectively, while the linguistic label Z is defined with three parameters which are  $l_{i2}, c_{i2}, r_{i2}$ , ( $i = 1, 2$ ). Hence for two inputs, the total number of the antecedent membership function parameters to be designed for the **T1-FPID** is then  $2 \times 7 = 14$ . Moreover, five output consequent parameters ( $y_N, y_{NM}, y_Z, y_{PM}, y_P$ ) have to be determined. Thus,

**Fig. 18.2a,b** Illustration of the (a) antecedent MFs (b) consequent MFs of the **T1-FLC**

in total 19 MF parameters have to be tuned. Besides the input and output scaling factors ( $K_e$ ,  $K_d$ ,  $\alpha$  and  $\beta$ ) of the T1-FPID controller must also be determined. Thus, there are 19 MF and four SF parameters ( $19 + 4 = 23$ ) that have to be tuned for the handled T1-FPID controller.

In the fuzzy control literature, one method for the T1-FPID controller design is by employing evolutionary algorithms [18.19, 20]. Besides Ahn and Truong [18.21] used a robust extended Kalman filter to tune the membership functions of the fuzzy controller during the system operation process to improve the control performance in an online manner. Moreover, various heuristic and nonheuristic scaling factor tuning algorithms have been presented in the case of the systems that own nonlinearities, parameter changes, modeling errors, disturbances [18.7, 9, 10, 22–25].

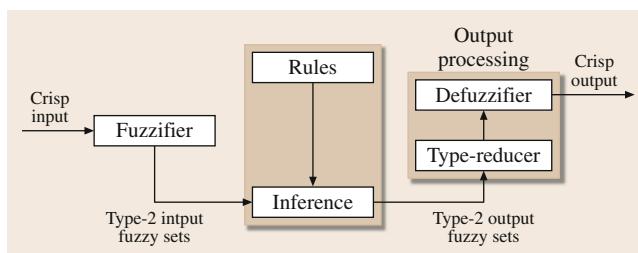

## 18.2.2 Interval Type-2 Fuzzy PID Controllers

In this subsection, we will start by presenting the internal structure of the handled IT2-FPID controller and then we will present brief information about the design strategies for the IT2-FPID controller structure in the literature.

### The Internal Structure of the Interval Type-2 Fuzzy PID Controller

In the handled IT2-FPID structures, the same  $3 \times 3$  rule base presented for T1-FPID controller is used which is presented in Table 18.1. The internal structure of the IT2-FPID is similar to the type-1 counterpart. However, the major differences are that IT2-FLCs employ IT2-FSSs (rather than type-1 fuzzy sets) and the IT2-FLCs process interval type-2 fuzzy sets (IT2-FSSs) and thus the IT2-FLC has the extra type-reduction process [18.12, 14].

Type-2 fuzzy sets are the generalized forms of type-1 fuzzy sets. A type-2 fuzzy set ( $\tilde{A}$ ) is characterized by

**Fig. 18.3** Block diagram of the IT2-FLC

a type-2 membership function  $\mu_{\tilde{A}}(x, u)$ , i.e.,

$$\tilde{A} = \{(x, u), \underline{\mu}_{\tilde{A}}(x, u) \mid \forall x \in X, \forall u \in J_x \subseteq [0, 1]\} \quad (18.5)$$

in which  $0 \leq \mu_{\tilde{A}}(x, u) \leq 1$ .

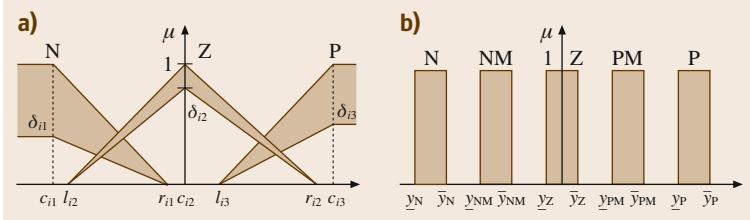

For a continuous universe of discourse,  $\tilde{A}$  can be also expressed as

$$\tilde{A} = \iint_{x \in X, u \in J_x} \mu_{\tilde{A}}(x, u) / (x, u), \quad J_x \subseteq [0, 1], \quad (18.6)$$

where  $\iint$  denotes union over all admissible  $x$  and  $u$  [18.12, 14].  $J_x$  is referred to as the primary membership of  $x$ , while  $\mu_{\tilde{A}}(x, u)$  is a type-1 fuzzy set known as the secondary set. The uncertainty in the primary membership of a type-2 fuzzy set  $\tilde{A}$  is defined by a region named footprint of uncertainty (FOU). The FOU can be described in terms of an upper membership function ( $\overline{\mu}_{\tilde{A}}$ ) and a lower membership function ( $\underline{\mu}_{\tilde{A}}$ ). The primary membership is called  $J_x$ , and its associated possible secondary membership functions can be trapezoidal, interval, etc. When the interval secondary membership function is employed an IT2-FS (such as the ones shown in Fig. 18.4a) is obtained [18.12, 14]. In other words, when  $\mu_{\tilde{A}}(x, u) = 1$  for  $\forall u \in J_x \subseteq [0, 1]$ , an IT2-FS is constructed.

The internal structure of the IT2-FLC is given in Fig. 18.3. Similar to a T1-FLC, an IT2-FLC includes fuzzifier, rule-base, inference engine, and substitutes the defuzzifier by the output processor comprising a type reducer and a defuzzifier. The IT2-FLC uses interval type-2 fuzzy sets (such as the ones shown in Fig. 18.4a) to represent the inputs and/or outputs of the FLC. In the interval type-2 fuzzy sets all the third dimension values are equal to one. The use of IT2-FLC helps to simplify the computation (as opposed to the general type-2 FLC where the third dimension of the type-2 fuzzy sets can take any shape).

The IT2-FLC works as follows: the crisp inputs are first fuzzified into input type-2 fuzzy sets; singleton fuzzification is usually used in IT2-FLC applications due to its simplicity and suitability for embedded processors and real-time applications. The input type-2 fuzzy sets then activate the inference engine and the rule base to produce output type-2 fuzzy sets. The IT2-FLC rule base remains the same as for the T1-FLC but its MFs are represented by interval type-2 fuzzy sets instead of type-1 fuzzy sets. The inference engine combines the fired rules and gives a mapping from input

**Fig. 18.4a,b** Illustration of the (a) antecedent MFs (b) consequent MFs of the IT2-FLC

type-2 fuzzy sets to output type-2 fuzzy sets. The type-2 fuzzy output sets of the inference engine are then processed by the type reducer which combines the output sets and performs a centroid calculation which leads to type-1 fuzzy sets called the type-reduced sets. There are different types of type-reduction methods. In this paper, we will be using the center of sets type reduction as it has reasonable computational complexity that lies between the computationally expensive centroid type-reduction and the simple height and modified height type-reductions which have problems when only one rule fires [18.12]. After the type-reduction process, the type-reduced sets are defuzzified (by taking the average of the type-reduced sets) to obtain crisp outputs. More information about the type-2 fuzzy logic systems and their benefits can be found in [18.11, 12, 14].

The rule structure of the interval type-2 fuzzy logic controller is as follows

$$R_m: \text{If } E \text{ is } \tilde{A}_{1k} \text{ and } \Delta E \text{ is } \tilde{A}_{2l} \text{ then } U \text{ is } \tilde{G}_m, \quad (18.7)$$

where  $E$  (normalized error) and  $\Delta E$  (normalized change of error) are the inputs,  $U$  is the output of **IT2-FLC**,  $\tilde{G}_m$  is the consequent interval set ( $\tilde{G}_m = [\underline{g}_m, \bar{g}_m]$ ,  $m = 1, \dots, M = 9$ ) and  $M$  is the number of rules. The antecedents of the **IT2-FLC** are defined interval type-2 membership functions (**IT2-MFs**) ( $\tilde{A}_{1k}, \tilde{A}_{2l}$ ) for the inputs  $E$  and  $\Delta E$ , respectively, which can be simply obtained by extending/blurring the **T1-MFs** ( $A_{1k}, A_{2l}$ ) of the **T1-FLC**. Here, the **IT2-MF** is defined with four parameters ( $l_{ij}, c_{ij}, r_{ij}, \delta_{ij}; i = 1, 2, j = 1, 2, 3$ ), as shown in Fig. 18.4a. Since the input **IT2-FS** is described in terms of an upper membership function ( $\bar{\mu}_{\tilde{A}}$ ) and a lower membership function ( $\underline{\mu}_{\tilde{A}}$ ), the total firing strength for the  $m$ th rule is

$$\tilde{f}_m = [\bar{f}_m \underline{f}_m], \quad (18.8)$$

where  $\tilde{f}_m$  is the total firing interval and is defined as

$$f_m = \underline{\mu}_{\tilde{A}_{1k}} * \underline{\mu}_{\tilde{A}_{2l}} \quad (18.9)$$

$$\bar{f}_m = \bar{\mu}_{\tilde{A}_{1k}} * \bar{\mu}_{\tilde{A}_{2l}}. \quad (18.10)$$

Here,  $*$  represents the product implication (the  $t$ -norm) and  $\underline{\mu}_{\tilde{A}_{1k}}, \underline{\mu}_{\tilde{A}_{2l}}$  and  $\bar{\mu}_{\tilde{A}_{1k}}, \bar{\mu}_{\tilde{A}_{2l}}$  are the lower and upper membership grades of the  $\tilde{A}_{1k}$  and  $\tilde{A}_{2l}$  **IT2-FMs**, respectively.

The consequent membership functions of the **IT2-FLC** are defined with five interval consequents and label them as negative (N) =  $[\underline{y}_N, \bar{y}_N]$ , negative medium (NM) =  $[\underline{y}_{NM}, \bar{y}_{NM}]$ , zero (Z) =  $[\underline{y}_Z, \bar{y}_Z]$ , positive medium (PM) =  $[\underline{y}_{PM}, \bar{y}_{PM}]$ , and positive (P) =  $[\underline{y}_P, \bar{y}_P]$  as shown in Fig. 18.4b.

The implemented **IT2-FLC** uses the center of sets type reduction method [18.12]. It has been demonstrated that the defuzzified output of an **IT2-FLC** can be calculated as

$$U = \frac{U_l + U_r}{2}, \quad (18.11)$$

where  $U_l$  and  $U_r$  are the left- and right-end points, respectively, of the type reduced set, are defined as follows

$$U_l = \frac{\sum_{m=1}^L \bar{f}_m G_m + \sum_{m=1}^{M=9} \underline{f}_m G_m}{\sum_{m=1}^L \bar{f}_m + \sum_{m=1}^{M=9} \underline{f}_m}, \quad (18.12)$$

$$U_r = \frac{\sum_{m=1}^R \underline{f}_m G_m + \sum_{m=1}^{M=9} \bar{f}_m G_m}{\sum_{m=1}^R \underline{f}_m + \sum_{m=1}^{M=9} \bar{f}_m}. \quad (18.13)$$

The typed reduced set can be calculated by using the iterative Karnik and Mendel method (**KM**), which is given in Table 18.2 [18.26].

#### Interval Type-2 Fuzzy PID Design Strategies

In the interval type-2 fuzzy **PID** control design strategy, the scaling factors, the parameters of the antecedent, and consequent membership functions of the **IT2-FPID**s have to be determined. The antecedent **IT2-FS**s of **IT2-FPID** controller that are labeled as the P and N for each input are defined with three parameters each which are  $(c_{i1}, r_{i1}, \delta_{i1})$ , and  $(l_{i3}, c_{i3}, \delta_{i3}, i = 1, 2)$ , respectively, while the **IT2-FS** labeled as Z is defined with

**Table 18.2** Calculation of the two end points of the type reduced set

Steps	The Karnik Mendel algorithm for computing $U_1$	The Karnik Mendel algorithm for computing $U_r$
1.	Sort $\underline{g}_m$ ( $m = 1, \dots, M$ ) in increasing order such that $\underline{g}_1 \leq \underline{g}_2 \leq \dots \leq \underline{g}_M$ . Match the corresponding weights $\bar{f}_M, f_M$ (with their index corresponds to the renumbered $\underline{g}_m$ )	Sort $\bar{g}_m$ ( $m = 1, 2, \dots, M$ ) in increasing order such that $\bar{g}_1 \leq \bar{g}_2 \leq \dots \leq \bar{g}_M$ . Match the corresponding weights $\bar{f}_m, f_m$ (with their index corresponds to the renumbered $\bar{g}_m$ )
2.	Initialize $f_m$ by setting $f_m = \frac{\bar{f}_m + f_m}{2}, \quad m = 1, 2, \dots, M$ Compute $U = \frac{\sum_{m=1}^M f_m \underline{g}_m}{\sum_{m=1}^M f_m}$	Initialize $f_m$ by setting $f_m = \frac{\bar{f}_m + f_m}{2} \quad m = 1, 2, \dots, M$ Compute $U = \frac{\sum_{m=1}^M f_m \underline{g}_m}{\sum_{m=1}^M f_m}$
3.	Find the switch point $L$ ( $1 \leq L \leq M - 1$ ) such that $\underline{g}_m \leq U \leq \underline{g}_{m+1}$	Find the switch point $R$ ( $1 \leq L \leq M - 1$ ) such that $\bar{g}_m \leq U \leq \bar{g}_{m+1}$
4.	Set $f_m = \begin{cases} \bar{f}_m & m \leq L \\ f_m & m > L \end{cases}$ and compute $U' = \frac{\sum_{m=1}^M f_m \underline{g}_m}{\sum_{m=1}^M f_m}$	Set $f_m = \begin{cases} f_m & m \leq R \\ \bar{f}_m & m > R \end{cases}$ and compute $U' = \frac{\sum_{m=1}^M f_m \bar{g}_m}{\sum_{m=1}^M f_m}$
5.	Check if $U = U'$ . If not go to step 3 and set $U' = U$ . If yes stop and set $U_1 = U'$ .	Check if $U = U'$ . If not go to step 3 and set $U' = U$ . If yes stop and set $U_r = U'$ .

four parameters ( $l_{i2}, c_{i2}, r_{i2}, \delta_{i2}, i = 1, 2$ ). Consequently, for the two inputs the total numbers to be designed is  $2 \times 10 = 20$ . Moreover, 10 output consequent parameters ( $\underline{y}_N, \bar{y}_N, \underline{y}_{NM}, \bar{y}_{NM}, \underline{y}_Z, \bar{y}_Z, \underline{y}_{PM}, \bar{y}_{PM}, \underline{y}_P, \bar{y}_P$ ) have to be determined. Hence, in total 30 MF parameters have to be tuned. Besides, the input and output scaling factors ( $K_e, K_d, \alpha$ , and  $\beta$ ) of the controller must also be determined. Thus, there are 30 MF and four SF parameters ( $30 + 4 = 34$ ) have to be tuned for the handled IT2-FPID controller. It is obvious that, the IT2-FPID has 11 more tuning parameters, i.e., extra degrees of freedom, than the T1-FPID controller structure (23 parameters).

The systematic design of type-2 fuzzy controllers is a challenging problem since the output cannot be presented in a closed form due to the KM-type reduction method. To overcome this bottleneck, alternative type reduction algorithms which are closed-form approximations to the original KM-type reduction algorithm have been proposed and employed in controller design [18.27, 28]. However, the main difficulty is to tune the relatively big number of parameters of the

IT2-FPID controller structure. Thus, several studies have employed various techniques for the design problem including genetic algorithms [18.15, 29], particle swarm optimization [18.30], and ant colony optimization [18.31].

In practical point of view, the IT2-FPID controller design problem can be simply solved by blurring/extending MFs of an existing T1-FPID controller [18.16, 28, 32]. Moreover, each rule consequent can also be chosen as a crisp number ( $\underline{g}_m = \bar{g}_m$ ) to reduce the number of parameters to be determined. It is also common to set the consequent parameters and the scaling factors to the same value of a pre-designed T1-FPID controller. Thus, in the IT2-FPID design only the antecedent membership parameters have to be tuned [18.28]. This design approach will reduce the parameters to be tuned from 34 to 20 since only the parameters of the antecedent membership functions must be designed. The design of the antecedent MFs can be solved by extensively trial and error procedures or employing evolutionary algorithms [18.33].

## 18.3 Simulation Studies

In this section, we will compare the performances of the **IT2-FPID** controller with the **T1-FPID** controller for the following first-order plus-time delay process

$$G(s) = \frac{K}{\tau s + 1} e^{-Ls}, \quad (18.14)$$

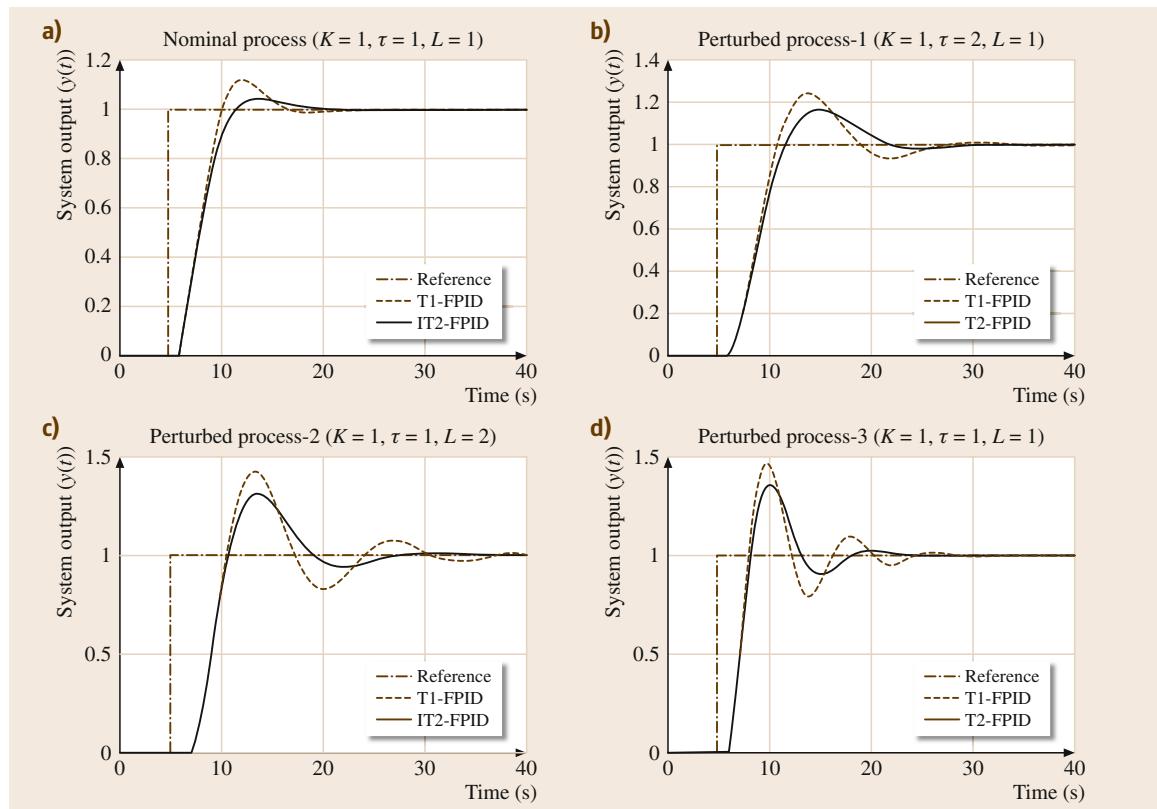

where  $K$  is the gain,  $L$  is the time delay, and  $\tau$  is the time constant of the process. The nominal system parameters are  $K = 1$ ,  $L = 1$  and  $\tau = 1$ .

We will first design a **T1-FPID** controller and then extend the type-1 fuzzy controller to design an **IT2-FPID** controller structure since type-2 fuzzy logic theory is a generalization and extension of type-1 fuzzy logic theory. We will characterize each input domain ( $E$  and  $\Delta E$ ) of the **T1-FPID** controllers with three uniformly distributed symmetrical triangular MFs. The parameters of the MFs are tabulated in Table 18.3. We will

set the consequent parameters as  $y_N = -1.0$  (negative),  $y_{NM} = -0.75$  (negative medium),  $y_Z = 0.0$  (zero),  $y_{PM} = 0.75$  (positive medium),  $y_P = 1.0$  (positive) to obtain a standard diagonal rule base. Then, the scaling factors of the **IT2-FPID** have been chosen such that to obtain a fast and satisfactory output response for

	OS	$T_s$	ITAE	OS	$T_s$	ITAE	OS	$T_s$	ITAE	OS	$T_s$	ITAE
<b>T1-FPID</b>	12	9.8	27.87	25	18.6	53.38	43	23.8	80.83	47	15.5	43.74
<b>IT2-FPID</b>	4	6.0	26.63	16	14.8	47.83	30	18.2	59.13	36	11.9	32.17

a unit step input. The scaling factors are set as  $K_e = 1$ ,  $K_d = 0.1$ ,  $\alpha = 0.1$ , and  $\beta = 0.5$ .

As it has been asserted, the **IT2-FPID** controller design will be accomplished by only blurring/extending antecedent MFs of the **T1-FPID** controller. Thus, we will set the consequent parameters and the scaling factors as the same values of its type-1 counterpart. The antecedent MFs of the **IT2-FPID** parameters are presented in Table 18.3. This setting will give the opportunity to illustrate how the extra degrees of freedom provided by **FOUs** affect the control system performances.

In the simulation studies, both **FPID** controllers are implemented as the discrete-time versions obtained with the bilinear transform with the sampling time  $t_s = 0.1$  s. The simulations were done on a personal computer with an Intel Pentium Dual Core T2370 1.73GHz processor, 2.99GB **RAM**, and software package MATLAB/Simulink 7.4.0. Note that the simulation solver option is chosen as **ode5** (Dormand-prince) and the step size is fixed at a value of 0.1 s.

The unit step response performances of the type-1 and type-2 fuzzy **PID** control systems are investigated for the nominal parameter set  $K = 1, \tau = 1, L = 1$  (nominal process) and for three perturbed parameter sets which are  $K = 1, \tau = 2, L = 1$  (perturbed process-1),  $K = 1, \tau = 1, L = 2$  (perturbed process-2), and  $K = 2, \tau = 1, L = 1$  (perturbed process-3) to examine their

robustness against parameter variations. In this context, we will consider three performance measures namely, the settling time ( $T_s$ ), the overshoot (OS%), and the integral time absolute error (ITAE).

The system performances of the nominal and perturbed systems are illustrated in Fig. 18.5 and the performance measures are given in Table 18.4. As it can be clearly seen in Fig. 18.5, the **IT2-FPID** controller produces superior control performance in comparison to its type-1 controller counterpart. For instance, if we examine the results for nominal process, as compared to **T1-FPID**, the **IT2-FPID** control structure reduces the overshoot by about 66%; it also decreases the settling time by about 39% and the total IAE value by about 8%. Moreover, if we examine the results of perturbed process-2 (the time delay ( $L$ ) has been increased 100%) it can be clearly seen that the **T1-FPID** control system response is oscillating while the **IT2-FPI** was able to reduces the overshoot by about 30%, the settling time by about 24% and the total **ITAE** value by about 27%. Similar comments can be made for presented other two perturbed system performances.

It can be concluded that the transient state performance of the **IT2-FPID** control structure is better than the **T1-FPID** controllers while it appears to be more robust against parameter variations in comparison to the type-1 counterpart.

## 18.4 Conclusion

The aim of this chapter is to present a general overview about **FPID** controller structures in the literature since fuzzy sets are recognized as a powerful tool to handle the faced uncertainties within control applications. We mainly focused on the double input direct action type fuzzy **PID** controller structures and their state-of-the-art design methods. We classified the fuzzy **PID** controllers in the literature within two groups, namely **T1-FPID** and **IT2-FPID** controllers. We examined the internal structures of the **T1-FPID** and **IT2-FPID** on a generic, a diagonal  $3 \times 3$  rule base.

We presented detailed information about their internal structures, design parameters, and tuning strategies presented in the literature. Finally, we evaluated the control performance of the **T1-FPID** and **IT2-FPID** on a first-order plus time delay benchmark process. We illustrated that the **T1-FPID** controller using crisp type-1 fuzzy sets might not be able to fully handle the high levels of uncertainties while **IT2-FPID** using type-2 fuzzy sets might be able to handle such uncertainties to produce a better control performance.

# Soft Computing in Database and Information Management

Guy De Tré, Sławomir Zadrożny

Part B | 19.1

Information is often imperfect. The sources of this imperfection include imprecision, uncertainty, incompleteness, and ambiguity. Soft computing techniques allow for coping more efficiently with such kinds of imperfection when handling data in information systems. In this chapter, we give an overview of selected soft computing techniques for database management. The chapter is subdivided in two parts which deal with the soft computing techniques, respectively, for information modelling and querying. A considerable part of the chapter is related to the issue of bipolarity of preferences and data representation which is among the important recent research trends.

## 19.1 Challenges for Modern Information Systems

Database systems nowadays form a basic component of almost every information system and their role is getting more and more important. Almost every person or company keeps track of a large amount of digital data and this amount is still growing everyday. Many ICT managers declare that *big data* is a point of attention for the coming years. Despite the fact that the concept of *big data* is not clearly defined, one can generally agree that it refers to the increasing need for efficiently storing and handling large amounts of information.

However, it is easy to observe that information is not always available in a perfect form. Just consider the fact that human beings communicate most of the time using vague terms hereby reflecting the fact that they do not know exact, precise values with certainty. In general, imperfection of information might be due to the imprecision, uncertainty, incompleteness, or ambiguity.

Our life and society have changed in such a way that we simply cannot neglect or discard imperfect information anymore. To be competitive, companies need to cope with all information that is available. Efficiently storing and handling imperfect information without introducing errors or causing data loss is therefore considered as one of the main challenges for information management in this century [19.1].

Soft computing offers formalisms and techniques for coping with imperfect data in a mathematically sound way [19.2]. The earliest research activities in this area dates back to the early eighties of the previous century. In this chapter, we present an overview of selected results of the research on soft computing techniques aimed at improving database modelling and database access in the presence of imperfect information. The scope of the chapter is further limited to database access

techniques that are based on querying and specifying and handling user preferences in query formulations. Other techniques, not dealt with in this chapter, include:

- Self-query auto completion systems that help users in formulating queries by exploiting past queries, as used in recommendation systems [19.3].
- Navigational querying systems that allow intelligent navigation through the database [19.4].
- Cooperative querying systems that support *indirect* answers such as summaries, conditional answers, and contextual background information for (empty) results [19.5].

The remainder of the chapter is organized as follows. In Sect. 19.2, we give some preliminaries on (relational) databases, which are used as a basis for illustrating the described techniques. The next two Sects. 19.3 and 19.4 form the core of the chapter. In Sect. 19.3, an overview of soft computing techniques for the modelling and handling of imperfect data in databases is presented. Whereas, in Sect. 19.4 the main trends in soft computing techniques for flexible database querying are discussed. Both, querying of regular databases and querying of databases containing imperfect data are handled. The conclusions of the chapter are stated in Sect. 19.5.

## 19.2 Some Preliminaries

In order to review and discuss main contributions to the research area of soft computing in database and information management, we have to introduce the terminology and notation related to the basics of database management and fuzzy logic.

### 19.2.1 Relational Databases

The techniques presented in this work will be described as general as possible, so that they are in fact applicable to multiple database models. However, due to its popularity and mathematical foundations, the relational database model has been used as the original formal framework for many of these techniques. For that reason, we opt for using the relational model as underlying database model throughout the chapter.

A *relational database* can in an abstract sense be seen as a collection of *relations* or, informally, of *tables* which represent them. Informally speaking, the columns of a table represent its characteristics, whereas its rows reflect its content [19.6]. From a formal point of view, each relation  $R$  is defined via its relation schema [19.7]

$$R(A_1 : D_1, \dots, A_n : D_n), \quad (19.1)$$

where  $A_i : D_i, i = 1, \dots, n$  are the *attributes* (columns) of the relation. Each attribute  $A_i : D_i$  is characterized by its name  $A_i$  and its associated data type (domain)  $D_i$ , to be denoted also as  $\text{dom}_{A_i}$ . The data type  $D_i$  determines the allowed values for the attribute and the basic operators that can be applied on them. Each relation (table) represents a set of real world entities, each of them

being modeled by a *tuple* (row) of the relation. Relations schemas are the basic components of a database schema. In this way, a table contains data describing a part of the real world being modeled by the *database schema*.

The most interesting operation on a database, from this chapter's perspective, is the retrieval of data satisfying certain conditions. Usually, to retrieve data, a user forms a *query* specifying these conditions (criteria). The conditions then reflect the user's preferences with respect to the information he or she is looking for. The retrieval process may be meant as the calculation of a matching degree for each tuple of relevant relation(s). Classically, a row either matches the query or not, i. e., the concept of matching is binary. In the context of soft computing, flexible criteria, soft aggregation, and soft ranking techniques can be used, so that tuple matching becomes a matter of a degree.

Usually two general formal approaches to the querying are assumed: the *relational algebra* and the *relational calculus*. The former has a procedural character: a query consists here of a sequence of operations on relations that finally yield requested data. These operations comprise five basic ones: union ( $\cup$ ), difference ( $\setminus$ ), projection ( $\pi$ ), selection ( $\sigma$ ), and cross product ( $\times$ ) that may be combined to obtain some derived operations such as, e.g., intersection ( $\cap$ ), division ( $\div$ ), and join ( $\bowtie$ ). The latter approach, known in two flavours as the tuple relational calculus (TRC) or the domain relational calculus (DRC), is of a more declarative nature. Here a query just describes what kind of data is requested, but how it is to be retrieved from a database is left to the database management system. The exact

form of queries is not of an utmost importance for our considerations. However, some reported research in this area employs directly the de-facto standard querying language for relational databases, i. e. **SQL** (structured query language) [19.7, 8]. Thus, we will also sometimes refer to the SELECT-FROM-WHERE instruction of this language and more specifically consider its WHERE clause, where query conditions are specified.

### 19.2.2 Fuzzy Set Theory and Possibility Theory

We will use the following concepts and notation concerning fuzzy set theory [19.9]. A *fuzzy set*  $F$  in the universe  $U$  is characterized by a membership function

$$\mu_F : U \rightarrow [0, 1] : u \mapsto \mu_F(u). \quad (19.2)$$

For each element  $u \in U$ ,  $\mu_F(u)$  denotes the membership grade or extent to which  $u$  belongs to  $F$ . The origins of membership functions may be different and depending on that they have different semantics [19.10]. With their traditional interpretation as *degrees of similarity*, membership grades allow it to appropriately represent vague concepts, like *tall man*, *expensive book*, and *large garden*, taking into account the gradual characteristics of such a concept. Membership grades can also express *degrees of preference*, hereby expressing that several values apply to a different extent. For example, the languages one speaks can be expressed by a fuzzy set  $\{(English, 1), (French, 0.7), (Spanish, 0.2)\}$ , and then the membership degrees represent skill levels attained in a given language. A fuzzy set can also be interpreted as a possibility distribution, in which case its membership grades denote *degrees of uncertainty*. Then, it can be used to represent, e.g., the uncertainty about the actual value of a variable, like *the height of a man*, *the price of a book* and *the size of a garden* [19.11, 12]. This interpretation is related to the concept of the *disjunctive fuzzy set*.

*Possibility distributions* are denoted by  $\pi$ . The notation  $\pi_X$  is often used to indicate that the distribution concerns the value of a variable  $X$ ,

$$\pi_X : U \rightarrow [0, 1] : u \mapsto \pi_X(u), \quad (19.3)$$

where  $X$  takes its value from a universe  $U$ .

*Possibility* and *necessity measures* can provide for the quantification of such an uncertainty. These mea-

sures are denoted by  $\Pi$  and  $N$ , respectively, i. e.,

$$\begin{aligned} \Pi : \tilde{\wp}(U) &\rightarrow [0, 1] : A \mapsto \Pi(A) \quad \text{and} \\ N : \tilde{\wp}(U) &\rightarrow [0, 1] : A \mapsto N(A), \end{aligned} \quad (19.4)$$

where the *fuzzy power set*  $\tilde{\wp}(U)$  stands for the family of fuzzy sets defined over  $U$ . Assuming that all we know about the value of a variable  $X$  is a possibility distribution  $\pi_X$ , these measures, for a given fuzzy set  $F$ , assess to what extent, respectively, this set is consistent ( $\Pi$ ) and its complement is inconsistent ( $N$ ) with our knowledge on the value of  $X$ . More precisely, if  $\pi_X$  is the underlying possibility distribution, then

$$\Pi_X(F) = \sup_{u \in U} \min(\pi_X(u), \mu_F(u)), \quad (19.5)$$

$$N_X(F) = \inf_{u \in U} \max(1 - \pi_X(u), \mu_F(u)). \quad (19.6)$$

Sometimes the interval  $[N_X(F), \Pi_X(F)]$  is used as an estimate of the consistency of  $F$  with the actual value of  $X$ . The possibility (necessity) that two variables  $X$  and  $Y$ , whose values are given by possibility distributions,  $\pi_X$  and  $\pi_Y$ , are in relation  $\theta$  – e.g., equality – is computed as follows. The joint possibility distribution,  $\pi_{XY}$ , of  $X$  and  $Y$  on  $U \times U$  (assuming noninteractivity of the variables) is given by

$$\pi_{XY}(u, w) = \min(\pi_X(u), \pi_Y(w)). \quad (19.7)$$

The relation  $\theta$  can be fuzzy and represented by a fuzzy set  $F \in \tilde{\wp}(U \times U)$  such that  $\mu_F(u, w)$  expresses to what extent  $u$  is in relation  $\theta$  with  $w$ . The possibility (resp. necessity) measure associated with  $\pi_{XY}$  will be denoted by  $\Pi_{XY}$  (resp.  $N_{XY}$ ). Then, we calculate the measures of possibility and necessity that the values of the variables are in relation  $\theta$  as follows

$$\begin{aligned} \Pi(X \theta Y) &= \Pi_{XY}(F) \\ &= \sup_{u, w \in U} \min(\pi_X(u), \pi_Y(w), \mu_F(u, w)), \end{aligned} \quad (19.8)$$

$$\begin{aligned} N(X \theta Y) &= N_{XY}(F) = \inf_{u, w \in U} \max(1 - \pi_X(u), \\ &\quad 1 - \pi_Y(w), \mu_F(u, w)). \end{aligned} \quad (19.9)$$

Knowing the possibility distributions of two variables  $X$  and  $Y$ , one may also be interested on how these distributions are similar to each other. Obviously, (19.8)–(19.9) provide some assessment of this similarity, but other indices of similarity are also applicable.

**Table 19.1** Special EPTVs

$\tilde{t}^*(p)$	Interpretation
$(T, 1)$	$p$ is true
$(F, 1)$	$p$ is false
$(T, 1), (F, 1)$	$p$ is unknown
$(\perp, 1)$	$p$ is inapplicable
$(T, 1), (F, 1), (\perp, 1)$	Information about $p$ is not available

This leads to a distinction between representation-based and value-based comparisons of possibility distributions [19.13]. We will discuss this later on in Sect. 19.4.2.

An important class of possibility distributions are *extended probabilistic truth values* (EPTV) [19.14]. An EPTV is defined as a possibility distribution (a disjunctive fuzzy set) in the universe  $I^* = \{T, F, \perp\}$  that consists of the three truth values  $T$  (true),  $F$  (false) and  $\perp$  (undefined). The set of all EPTVs is denoted as  $\tilde{\wp}(I^*)$ . They are meant to represent uncertainty as to the truth value of a proposition  $p \in P$ , where  $P$  denotes the universe of all propositions, in particular in the context of database querying. Thus, a valuation  $\tilde{t}^*$  is assumed such that

$$\tilde{t}^* : P \rightarrow \tilde{\wp}(I^*) : p \mapsto \tilde{t}^*(p). \quad (19.10)$$

In general the EPTV  $\tilde{t}^*(p)$  representing (the knowledge of) the truth of a proposition  $p \in P$  has the following format

$$\begin{aligned} \tilde{t}^*(p) = & [(T, \mu_{\tilde{t}^*(p)}(T)), (F, \mu_{\tilde{t}^*(p)}(F)), \\ & (\perp, \mu_{\tilde{t}^*(p)}(\perp))]. \end{aligned} \quad (19.11)$$

Hereby,  $\mu_{\tilde{t}^*(p)}(T)$ ,  $\mu_{\tilde{t}^*(p)}(F)$  and  $\mu_{\tilde{t}^*(p)}(\perp)$ , respectively denote the possibility that  $p$  is true, false, or undefined. The latter value is also covering cases where  $p$  is not applicable or not supplied. EPTVs extend the approach based on the possibility distributions defined on just the set  $\{T, F\}$  with an explicit facility to deal with the inapplicability of information as can for example occur with the evaluation of query conditions. In Table 19.1, some special cases of EPTVs are presented:

These cases are verified as follows:

- If it is completely possible that the proposition is true and no other truth values are possible, then it means that the proposition is known to be true.
- If it is completely possible that the proposition is false and no other truth values are possible, then it means that the proposition is known to be false.
- If it is completely possible that the proposition is true, it is completely possible that the proposition is false and it is not possible that the proposition is inapplicable, then it means that the proposition is applicable, but its truth value is unknown. This EPTV will be called in short *unknown*.
- If it is completely possible that the proposition is inapplicable and no other truth values are possible, then it means that the proposition is inapplicable.
- If all truth values are completely possible, then this means that no information about the truth of the proposition or its applicability is available. The proposition might be inapplicable, but might also be true or false. This EPTV will be called in short *unavailable*.

## 19.3 Soft Computing in Information Modeling

Soft computing techniques make it possible to grasp imperfect information about a modeled part of the world and represent it directly in a database. If fuzzy set theory [19.9] or possibility theory [19.12] are used to model imperfect data in a database, the database is called a *fuzzy database*. Other approaches include those that are based on rough set theory [19.15] and on probability theory [19.16] and resulting databases are then called *rough databases* and *probabilistic databases*, respectively.

In what follows, we give an overview of the most important soft computing techniques for modeling imperfect information which are based on fuzzy set theory

and possibility theory. Hereby, we distinguish between basic techniques (Sect. 19.3.1) and more advanced techniques (Sect. 19.3.2). As explained in the preliminaries, we use the relational database model [19.6] as the framework for our descriptions. This is also motivated by the fact that initial research in this area has been done on the relational database model and this model is nowadays still the standard for database modeling. Soft-computing-related research on other database models like the (E)ER model, the object-relational model, the XML-model, and object-oriented database models exists. Overviews can, among others, be found in [19.17–22].

### 19.3.1 Modeling of Imperfect Information – Basic Approaches

In view of the correct handling of information, it is of utmost importance that the available information that has to be stored in a database is modeled as adequate as possible so as to avoid the information loss. The most straightforward application of fuzzy logic to the classical relational data model is by assuming that the relations in a database themselves are also fuzzy [19.23]. Each tuple of a relation (table) is associated with a membership degree. This approach is often neglected because the interpretation of the membership degree is unclear. On the other hand, it is worth noticing that fuzzy queries, as will be discussed in Sect. 19.4, in fact produce fuzzy relations. So, we will come back to this issue when discussing fuzzy queries in Sect. 19.4.

Most of the research on modeling imperfect information in databases using soft computing techniques is devoted to a proper representation and processing of an attribute value. Such a value, in general, may not be known perfectly due to many different reasons [19.24]. For example, due to the imprecision, as when the painting is dated to the *beginning of the fourteenth century*; or due to the unreliability, as when the source of information is not fully reliable; or due to the ambiguity, as when the provided value may have different meanings; or due to the inconsistency, as when there are multiple different values provided by different sources; or due to the incompleteness, as when the value is completely missing or given as a set of possible alternatives (e.g., the picture was painted by Rubens or van Dyck). These various forms of information imperfection are not totally unconnected as well as may occur together. From the viewpoint of data representation they may be primarily seen as yielding uncertainty as to the actual value of an attribute and as such may be properly accounted for by a possibility distribution.

It is worth noticing that then the assignment of the value to an attribute may be identified with a Zadeh's [19.25] linguistic expression  $X$  is  $A$ , where  $X$  is a linguistic variable corresponding to the attribute while  $A$  is a (disjunctive) fuzzy set representing imperfect information on its value. Then, various combined forms of information imperfection may be represented by appropriate qualified linguistic expressions such as, e.g.,  $X$  is  $A$  with certainty at least  $\alpha$  [19.26]. Such qualified linguistic expressions may be in turn transformed into a  $X$  is  $B$  expression where a fuzzy set  $B$  is a function of  $A$  and other possible parameters of a qualified

expression, like  $\alpha$  in the previous example. Thus, the basic linguistic expression  $X$  is  $A$  indeed plays a fundamental role in the representation of the imperfect information.

The work of *Prade* and *Testemale* [19.27] is the most representative for the approaches to imperfect information modeling in a database based on the possibility theory. Other works in this vein include [19.27–32]. On the other hand, *Buckles* and *Petry* [19.33] as well as *Anvari* and *Rose* [19.34] assume the representation of attributes' values using sets of alternatives which may be treated as a simple binary possibility distribution. However, their motivation is different as they assume that domain elements are similar/indistinguishable to some extent and due to that it may be difficult to determine a precise value of an attribute. We will first briefly describe the approach of Prade and Testemale and, then, the model of Buckles and Petry.

#### Possibilistic Approach

In the possibilistic approach, disjunctive fuzzy sets are used to represent the *imprecisely* known value of an attribute  $A$ . Hence, such a fuzzy set is interpreted as a possibility distribution  $\pi_A$  and is defined on the domain  $dom_A$  of the attribute. The (degree of) possibility that the actual value of  $A$  is a particular element  $x$  of the domain of this attribute,  $x \in dom_A$ , equals  $\pi_A(x)$ . Every domain value  $x \in dom_A$  with  $\pi_A(x) \neq 0$  is thus a candidate for being the actual value of  $A$ . Together all candidate values and their associated possibility degrees reflect what is actually known about the attribute value. Thus, if the value of an attribute is not known precisely then a set of values may be specified (represented by the support of the fuzzy set used) and, moreover, particular elements of this set may be indicated as a more or less plausible values of the attribute in question.

A typical scenario in which such an imprecise value has to be stored in a database is when the value of an attribute is expressed using a linguistic term. For example, assume that the value of a painting is not known precisely, but the painting is known to be *very valuable*. Then, this information might be represented by the possibility distribution

$$\pi_{\text{value}}(x) = \mu_{\text{very\_valuable}}(x)$$

$$= \begin{cases} 0 & \text{if } x < 10M \\ \frac{x - 10}{10} & \text{if } 10M \leq x \leq 20M \\ 1 & \text{if } x > 20M \end{cases}$$

The term *uncertainty* is often used to refer to situations where one has to cope with several (distinct) candidate attribute values coming from different information sources. For example, one information source can specify that the phone number of a person is  $X$ , while another source can specify that it is  $Y$ . This kind of uncertainty can also be handled with the possibilistic approach as described above. In that case, a possibility distribution  $\pi_A$  over the domain of the attribute is used to model different options for the attribute's actual value. However, in general possibility distributions are less informative than probability distributions. They only inform the user about the relative likeliness of different options. Probability distributions provide more information and led to the so-called probabilistic databases [19.35–39]; cf. also [19.40].

Imprecision at the one hand and uncertainty at the other hand are orthogonal concepts: they can occur at the same time, as already mentioned earlier. For example, it might be uncertain whether the value of a painting is *3M*, *around 2M*, or *much cheaper*, where the latter two options are imprecise descriptions. Using the regular possibilistic modeling approach in such a case would yield in a single possibility distribution over the domain of values and would result in a loss of information on how the original three options were specified. Level-2 fuzzy sets, which are fuzzy sets defined over a domain of fuzzy sets [19.41, 42], can help to avoid this information loss [19.43].

In traditional databases, missing information is mostly handled by means of a pseudovalue, called a *null value* [19.44, 45]. In fact, information may be missing for many different reasons: the data may exist but be unknown (e.g., the salary of an employee may be unknown); the data may not exist nor apply (e.g., an unemployed person earns no salary) [19.46]. For the handling of nonapplicability a special pseudovalue is still required, but the case of unknown information can be adequately handled by using possibility theory. Indeed, as studied in [19.47], in the so-called *extended possibilistic approach*, the domain  $dom_A$  of an attribute  $A$  can be extended with an extra value  $\perp_A$  that is interpreted as *regular value not applicable*. Missing information can then be adequately modeled by considering the following three special possibility distributions  $\pi_{UNK}$ ,  $\pi_{N/A}$ , and  $\pi_{UNA}$ :

- Unknown value

$$\pi_{UNK}(x) = \begin{cases} 1, & \text{if } x \in dom_A \setminus \{\perp_A\} \\ 0, & \text{if } x = \perp_A \end{cases}$$

- Value not applicable

$$\pi_{N/A}(x) = \begin{cases} 0, & \text{if } x \in dom_A \setminus \{\perp_A\} \\ 1, & \text{if } x = \perp_A \end{cases}$$

- No information available

$$\pi_{UNA}(x) = 1, \forall x \in dom_A.$$

### Similarity-Based Approach

The basic idea behind this approach [19.33] is that while specifying the value of a database attribute one may consider similar values as also being applicable. Thus, in general, the value of an attribute  $A$  is assumed to be a subset of its domain  $dom_A$ . Moreover, the domain  $dom_A$  is associated with a similarity relation  $S_A$  quantifying this similarity for each pair of elements  $x, y \in dom_A$ . The values  $S_A(x, y)$  taken by  $S_A$  are in the unit interval  $[0, 1]$ , where 0 corresponds to *totally different* and 1 to *totally similar*. Hence,  $S_A$  is a fuzzy binary relation that associates a membership grade to each pair of domain values. This relation is assumed to be reflexive, symmetric and satisfying some form of transitivity. This requirements have been found too restrictive and some approaches based on a weaker structure have been proposed in [19.48], where the proximity relation is used and all attractive properties of the original approach are preserved. Among these properties, the most important is the proper adaptation of the redundancy concept and of the relational algebra operations.

It has been quickly recognized that the rough sets theory [19.15] offers effective tools to deal with and analyze the indistinguishability/equivalence relation and the similarity-based approaches evolved into the rough-sets-based database model [19.49, 50].

There are also a number of hybrid models proposed in the literature. *Takahashi* [19.51] has proposed a model for a fuzzy relational database assuming possibility distributions as attribute values. Moreover, in his model fuzzy sets are used as tuples' truth values. For example, a tuple  $t$ , accompanied by such a truth qualification, may express that *It is quite true that the paintings origin is the beginning of the fifteenth century*.

*Medina* et al. [19.52] proposed a fuzzy database model called **GEFRED** (generalized fuzzy relational database) in an attempt to integrate both approaches: the possibilistic and similarity based one. The data are stored as generalized fuzzy relations that extend the relations of the relational model by allowing imprecise information and a compatibility degree associated with each attribute value.

### 19.3.2 Modeling of Imperfect Information – Selected Advanced Approaches

In this section, we will focus on some extensions to the possibility-based approach described in Sect. 19.3.1. As argued earlier, a disjunctive fuzzy set may very well represent the situation when an attribute  $A$  of a tuple for sure takes exactly one value from the domain  $\text{dom}_A$  (as it should also due to the classical relational model) but we do not know exactly which one. The complete ignorance is then modeled by the set  $\text{dom}_A$ . However, very often we can distinguish the elements of  $\text{dom}_A$  with respect to their plausibility as the actual value of the attribute. This information, based on some evidence, is represented by the membership function of a disjunctive fuzzy set which is further identified with a possibility distribution. However, the characteristic of the available evidence may be difficult to express using regular fuzzy sets. In the literature dealing with data representation there are first attempts to cover such cases using some extensions to the concept of the fuzzy set. We will now briefly review them.

#### Imprecise Membership Degrees

*Prade and Testemale* in their original approach [19.31] assume that the membership degrees of a mentioned disjunctive fuzzy set are known precisely. On the other hand, one can argue that they may be also known only in an imprecise way. It may be the case, in particular, when the value of an attribute is originally specified using a linguistic term. For example, if a painting is dated to the beginning of the fifteenth century then assigning, e.g., the degree of 0.6 to the year 1440 may be challenging for an expert who is to define the representation of this linguistic term. He or she may be much more comfortable stating that it is something, e.g., between 0.5 and 0.7. Some precision is lost and a *second level* uncertainty is then implied but it may better reflect the evidence actually available.

Type 2 fuzzy sets [19.25] make it possible to model the data in the case described earlier. In particular, their simplest form, the *interval valued fuzzy sets (IFVS)*, may be here of interest. In the case of interval-valued fuzzy sets [19.25] a membership degree is represented as an interval, as in the example given earlier. Thus an interval-valued fuzzy set  $X$  over a universe of discourse  $U$  is defined by two functions

$$\mu_X^l, \mu_X^u : U \rightarrow [0, 1],$$

such that

$$0 \leq \mu_X^l(x) \leq \mu_X^u(x) \leq 1, \quad \forall x \in U, \quad (19.12)$$

and may be denoted by

$$X = [ < x, \mu_X^l(x), \mu_X^u(x) > | (x \in U) \wedge (0 \leq \mu_X^l(x) \leq \mu_X^u(x) \leq 1) ]. \quad (19.13)$$

Constraint (19.12) reflects that  $\mu_X^l(x)$  and  $\mu_X^u(x)$  are, respectively, interpreted as a lower and an upper bound on the actual degree of membership of  $x$  in  $X$ .

Basically, the representation of information using (disjunctive) IVFS is conceptually identical with the original approach of Prade and Testemale while it provides some more flexibility in defining the meaning of linguistic terms. Some preliminary discussion on their use may be found in [19.53].

#### Bipolarity of Information

Bipolarity is related to the existence of the positive and negative information [19.54–58]. It manifests itself, in particular, when people are making judgments about some alternatives and take into account their positive and negative sides. From this point of view, bipolarity of information may play an important role in database querying and is discussed from this perspective in Sect. 19.4.1. Here we will briefly discuss the role of bipolarity in data representation. We will mostly follow in this respect the work of *Dubois and Prade* [19.58].

The value of an attribute may be not known precisely but some information on it may be available in the form of both *positive* and *negative* statements. In some situations positive information is provided, stating what values are possible, satisfactory, permitted, desired, or considered as being acceptable. In other situations, negative statements express what values are impossible, rejected or forbidden.

Different types of bipolarity can be distinguished [19.58, 59]:

- *Type I, symmetric univariate bipolarity:* positive and negative information are considered as being exact complements of each other as in, e.g., the probability theory; for instance, if the probability that a given painting is painted in the eighteenth century is stated to be 0.7 (positive information), then the probability that this painting was not painted in the eighteenth century equals 0.3 (negative information); this simple form of bipolarity is well supported by traditional information systems; this bipolarity is quantified on a *bipolar univariate scale* such as the intervals  $[0, 1]$  or  $[-1, 1]$ ;

- *Type II, symmetric bivariate bipolarity:* another, more flexible approach is to consider positive and negative information as being dual concepts, measured along two different scales but based on the same piece of evidence. The dependency between them is modeled by means of some duality relation. This kind of bipolarity is, among others, used in Atanassov's intuitionistic fuzzy sets [19.60] where each element of a set is assigned both a membership and nonmembership degree which do not have to sum up to 1 but their sum cannot exceed 1. For example, it could be stated that Rubens is a good candidate to be an author of a given painting to a degree 0.6 (due to some positive information) while at the same time he is not a good candidate to a degree 0.2 (due to some negative information); this bipolarity is quantified on a *unipolar bivariate scale* composed of two unipolar scales such as, e.g., two intervals [0, 1];
- *Type III, asymmetric/heterogeneous bipolarity:* in the most general case, positive and negative information is provided by two separate bodies of evidence, which are to some extent independent of each other and are of a different nature. A constraint to guarantee that the information does not contain contradictions can exist but beside of that both statements are independent of each other and hence giving rise to the notion of the heterogeneous bipolarity; this bipolarity is quantified as in the case of Type II bipolarity.

Type III bipolarity is of special interest from the point of view of data representation. Dubois and Prade [19.58] argue that in this context the heterogeneity of bipolarity is related to the different nature of two bodies of evidence available. Namely, the negative information corresponds to the *knowledge* which puts some general constraints on the feasible values of an attribute. On the other hand, the positive information corresponds to *data*, i.e., observed cases which justify plausibility of a given element as the candidate for the value of an attribute.

This type of bipolarity is proposed to be represented for a tuple  $t$  by two separate possibility distributions,  $\delta_{A(t)}$  and  $\pi_{A(t)}$ , defined on the domain of an attribute,  $dom_A$  [19.58] (and earlier works cited therein). A possibility distribution  $\pi_{A(t)}$ , as previously, represents the compatibility of particular elements  $x \in dom_A$  with the available information on the value of the attribute  $A$  for a tuple  $t$ . This compatibility is quantified on a unipolar negative scale identified with the interval [0, 1]. The extreme values of  $\pi_A$ , i.e.,  $\pi_{A(t)}(x) = 1$  and  $\pi_{A(t)}(x) = 0$  are meant to represent, respectively, that  $x$  is *potentially* fully possible to be the value of  $A$  at  $t$  (1 is a *neutral* element on this unipolar scale) and that  $x$  is totally *impossible* to be the value of  $A$  at  $t$  (0 is an extreme negative element on this unipolar scale). On the other hand, a possibility distribution  $\delta_{A(t)}$  expresses the degree of support for an element  $x \in dom_A$  to be the value of  $A$  at  $t$  provided by some evidence. In this case,  $\delta_{A(t)}(x) = 0$  denotes the lack of such a support but is meant as just a neutral assessment while  $\delta_{A(t)}(x) = 1$  denotes full support (1 is an extreme positive element on this scale).

For example, when the exact dating of a painting is unknown, one can be convinced it has been painted in some time range (e.g., related to the time period its author lived in) and also there may be some evidence supporting a particular period of time (e.g., due to the fact that other very similar paintings of a given author are known from this period). Thus, the former is a negative information, excluding some period of time while the latter is a positive information supporting given period.

Thus,  $\delta_{A(t)}$  and  $\pi_{A(t)}$  are said to represent, respectively, the set of *guaranteed/actually possible* and the set of *potentially possible* values of an attribute  $A$  for the tuple  $t$ . These possibility distributions are related by a consistency constraint:  $\pi_{A(t)}(x) \geq \delta_{A(t)}(x)$  as  $x$  have to be first nonexcluded before it may be somehow supported by the evidence.

For a given attribute  $A$  and tuple  $t$ ,  $\pi_{A(t)}$  is based on the set of nonimpossible values  $NI_{A(t)}$  while  $\delta_{A(t)}$  relates to the set of actually possible values  $G_{A(t)}$ . The querying of such a *bipolar database* may be defined in terms of these sets [19.58].

## 19.4 Soft Computing in Querying

The research on soft computing in querying has already a long history. It has been inspired by the success of fuzzy logic in modeling natural language propositions. The use of such propositions in queries, in turn,

seems to be very natural for human users of any information system, notably the database management system. Later on, the interest in fuzzy querying has been reinforced by the omnipresence of network-based

applications, related to buzzwords of modern information technology, such as e-commerce, e-government, etc. These applications evidently call for a flexible querying capability when users are looking for some goods, hotel accommodations, etc., that may be best described using natural language terms such as cheap, large, close to the airport, etc. Another amplification of the interest in fuzzy querying comes from developments in the area of data warehousing and data mining related applications. For example, a combination of fuzzy querying and data mining interfaces [19.61, 62] or fuzzy logic and the **OLAP** (online analytical processing) technology [19.63] may lead to new, effective and more efficient solutions in this area. More recently, *big data* challenges can be seen as driving forces for research in soft querying. Indeed, efficiently querying huge quantities of heterogeneous structured and unstructured data is one of the prerequisites for efficiently handling *big data*.

### 19.4.1 Flexible Querying of Regular Databases

As a starting point, we consider a simplified form of database queries on a classical crisp relational database. Hereby a query is assumed to consist of a combination of conditions that are to be met by the data sought. Introducing flexibility is done by specifying fuzzy preferences. This can be done inside the query conditions via flexible search criterion and allows to express that some values are more desirable than others in a gradual way. Query conditions are allowed to contain natural language terms. Another option is to specify fuzzy preferences at the level of the aggregation. By assigning grades of importance to (groups of) conditions it can be indicated that the satisfaction of some query conditions is more desirable than the satisfaction of others.

#### Basic Approaches

One of the pioneering approaches in recognizing the power of fuzzy set theory for information retrieval purposes in general is [19.64]. The research on the application of soft computing in database querying research proper dates back to an early work of *Tahani* [19.65], proposing the modeling of linguistic terms in queries using elements of fuzzy logic. An important enhancement of this basic approach consisted in considering flexible aggregation operators [19.10, 66–68]. Another line of research focused on embedding fuzzy constructs in the syntax of the standard **SQL** [19.21, 69–74].

#### Fuzzy Preferences Inside Query Conditions.

*Tahani* [19.65] proposed to use imprecise terms typical for natural language such as, e.g., *high*, *young* etc., to form conditions of an **SQL**-like querying language for relational databases. These imprecise linguistic terms are modeled using fuzzy sets defined in attributes domains. The binary satisfaction of a classical query is replaced with the *matching degree* defined in a straightforward way. Namely, a tuple  $t$  matches a simple (elementary) condition  $A = l$ , where  $A$  is an attribute (e.g., *price*) and  $l$  is a linguistic term (e.g., *high*) to a degree  $\gamma(A = l, t)$  such that

$$\gamma(A = l, t) = \mu_l(A(t)), \quad (19.14)$$

where  $A(t)$  is the value of the attribute  $A$  at the tuple  $t$  and  $\mu_l(\cdot)$  is the membership function of the fuzzy set representing the linguistic term  $l$ . The matching degree for compound conditions, e.g., *price = high AND (date = beginning-of-17-century OR origin = south-europe)* is obtained by a proper interpretation of the fuzzy logical connectives. For example

$$\begin{aligned} \gamma[(A_1 = l_1) \text{ AND } (A_2 = l_2), t] \\ = \min[\mu_{l_1}(A_1(t)), \mu_{l_2}(A_2(t))]. \end{aligned} \quad (19.15)$$

The relational algebra has been very early adapted for the purposes of fuzzy flexible querying of regular relational databases. The division operator attracted a special attention and its many *fuzzy* variants has been proposed, among other by *Yager* [19.75], *Dubois* and *Prade* [19.76], *Galindo* et al. [19.77], and *Bosc* et al. [19.78, 79]. *Takahashi* [19.80] was among the first authors to propose a fuzzy version of the relational calculus. His fuzzy query language (**FQL**) was meant as a fuzzy extension of the domain relational calculus (**DRC**).

#### Fuzzy Preferences Between Query Conditions.

Often, a query is composed of several conditions of varying importance for the user. For example, a customer of a real-estate agency may be looking for a cheap apartment in a specific district of a city and located not higher than a given floor. However, for he or she the low price may be much more *important* than the two other features. It may be difficult to express such preferences in a traditional query language. On the other hand, it is very natural for flexible fuzzy querying approaches due to the assumed gradual character of the matching degree as well as due to the existence of sophisticated preference modeling techniques devel-

oped by fuzzy logic community. Thus, most approaches make it possible to assign to a condition an importance weight, usually represented by a number from the  $[0, 1]$  interval.

The impact of a weight can be modeled by first matching the condition as if there is no weight and only then modifying the resulting matching degree in accordance with the weight. A modification function that strengthens the match of more important conditions and weakens the match of less important conditions is used for this purpose.

The evaluation of a whole query against a tuple may be seen as an aggregation of the matching degrees of elementary conditions comprising the query against this tuple. Thus, an aggregation operator is involved which, in the case of a simple conjunction or disjunction of the elementary conditions is usually assumed to take the form of the minimum and maximum operator, respectively. If weights are assigned to the elementary conditions connected using conjunction or disjunction then, first, the matching degrees of these conditions are modified using the weights [19.81] and then they are aggregated as usual.

On the other hand, some special aggregation operators may be explicitly used in the query and then they guide the aggregation process. Kacprzyk et al. [19.66, 67] were first to propose the use in queries of an aggregation operator in the form of a *linguistic quantifier* [19.82]. Thus, the user may require, e.g., *most* of the elementary conditions to be fulfilled instead of all of them (what is required when the conjunction of the conditions is used) or instead of just one of them (what is required in the case of the disjunction. For example, the user may define paintings of his interest as those meeting *most* of the following conditions: *not expensive, painted in Italy, painted not later than in seventeenth century, accompanied by an attractive insurance offer* etc. The overall matching degree of a query involving a linguistic quantifier may be computed using any of the approaches used to model these quantifiers. In [19.66, 67], Zadeh's original approach is used [19.82] while in [19.83] Yager's approach based on the OWA operators is adopted [19.84]. Further studies on modeling sophisticated aggregation operators, notably linguistic quantifiers, in the flexible fuzzy queries include the papers by Bosc et al. [19.85, 86], Galindo et al. [19.21] and Vila et al. [19.87].

A recent book by Bosc and Pivert [19.88] contains a comprehensive survey of the sophisticated flexible database querying techniques.

### Bipolar Queries

An important novel line of research concerning advanced querying of databases addresses the issue of the bipolar nature of users preferences. Some psychological studies (e.g., sources cited by [19.56]) show that while expressing his or her preferences a human being is separately considering *positive* and *negative* aspects of a given option. Thus, to account for this phenomenon, a query should be seen as a combination of two types of conditions: the satisfaction of one of them makes a piece of data desired while the satisfaction of the second makes it to be rejected. Such a query will be referred to as the *bipolar query* and will be denoted as a pair of conditions  $(C, P)$ , where  $C$ , for convenience, denotes the complement of the negative condition and  $P$  denotes the positive condition. The relations between these two types of conditions may be analyzed from different viewpoints, and the conditions itself may be expressed in various ways. In Sect. 19.3.2, we have already introduced the concept of bipolarity in the context of data representation. Now, we will briefly survey different approaches to modeling the *bipolarity* with a special emphasis on the context of database querying.

**Models of Bipolarity.** Various scales may be used to express bipolarity of preferences. Basically, two models based on: a *bipolar univariate* scale and a *unipolar bivariate* scale [19.89] are usually considered. The former assumes one scale with three main levels of negative, neutral, and positive preference degrees, respectively. These degrees are gradually changing from one end of the scale to another accounting for some intermediate levels. In the second model, two scales are used which separately account for the positive and negative preference degrees. Often, the intervals  $[-1, 1]$  and  $[0, 1]$  are used to represent the scales in the respective models of bipolarity.

From the point of view of database querying, the first model may be seen as assuming that the user assesses both positive and negative aspects of a given piece of data (an attribute value or a tuple) and is in a position to come up with an overall scalar evaluation. This is convenient with respect to the ordering of the tuples in the answer to a query.

The second model is more general and makes it possible for the user to separately express his or her evaluation of positive and negative aspects of a given piece of data. This may be convenient if the user cannot, or is not willing to, combine his or her evaluations of positive and negative features of data. Obviously it

requires some special means to order the query answer dataset with respect to a pair of evaluations.

### Levels at Which the Bipolarity May be Expressed.

Bipolar evaluations may concern the domain of an attribute or the whole set of tuples. This is a distinction of a practical importance, in particular if the elicitation of user preferences is considered.

In the former case, the user is supposed to be willing and in a position to partition the domains of selected attributes into (fuzzy) subsets of elements with positive, negative, and neutral evaluations. For example, the domain of the *price* attribute, characterizing paintings offered during an auction at a gallery, may be in the context of a given query subjectively partitioned using fuzzy sets representing the terms *cheap* (positive evaluation), *expensive* (negative evaluation), and some elements with a neutral evaluation.

In the case of bipolar evaluations at the tuples level a similar partitioning is assumed but concerning the whole set of tuples (here, representing the paintings). Usually, this partition will be defined again by (fuzzy) sets, this time defined with reference to possibly many attributes, i.e., defined on the cross product of the domains of several attributes. For example, the user may identify as negative these paintings which satisfy a compound condition *expensive and modern*. Thus, the evaluations in this case have a *comprehensive* character and concern the whole tuples, taking implicitly into account a possibly complex weighting scheme of particular attributes and their interrelations.

Referring to the models of bipolarity, it seems slightly more natural for the bipolar evaluations expressed on the level of the domain of an attribute to use a bipolar univariate scale while the evaluations on the level of the whole set of tuples would rather adopt a unipolar bivariate scale.

**A General Interpretation of Bipolarity in the Context of Database Querying.** In the most general interpretation, we do not assume anything more about the relation between positive and negative conditions. Thus, we have two conditions and each tuple is evaluated against them yielding a pair of matching degrees. Then an important question is how to order data in an answer to such a query. Basically, while doing that we should take into account the very nature of both matching degrees, i.e., the fact that they correspond to the positive and negative conditions. The situation here is somehow similar to that of decision making under risk. Namely, in the latter context a decision

maker who is risk-averse may not accept actions leading with some nonzero probability to a loss. On the other hand, a risk-prone decision maker may ignore the risk of an even serious loss as long as there are prospects for a high gain. Similar considerations may apply in the case of bipolar queries. Some users may be more concerned about negative aspects and will reject a tuple with a nonzero matching degree of the negative condition. Some other users may be more oriented on the satisfaction of the positive conditions and may be ready to accept the fact that given piece of data satisfies to some extent the negative conditions too. Thus, the bipolar query should be evaluated in a database in a way strongly dependent on the attitude of the user. In the extreme cases, the above-mentioned *risk-averse* and *risk-prone* attitudes would be represented by lexicographic orders. In the former case, the lexicographic ordering would be first nondecreasing with respect to the negative condition matching degree and then nonincreasing with respect to the positive condition matching degree. The less extreme attitudes of the users may be represented by various aggregation operators producing a scalar overall matching degree of a bipolar query.

An approach to a comprehensive treatment of so generally meant bipolar queries has been proposed by Matthé and De Tré [19.90], and further developed in [19.91]. In this approach, a pair of matching degrees of the positive and negative conditions is referred to as a *bipolar satisfaction degree* (**BSD**). The respective matching degrees are denoted as  $s$  and  $d$ , and called the *satisfaction degree* and the *dissatisfaction degree*, respectively. The ranking of data retrieved against a bipolar query in this approach may be obtained in various ways. One of the options is based on the difference  $s - d$  of the two matching degrees. In this case, a *risk-neutral* attitude of the user is modeled: he or she does not favor neither positive nor negative evaluation.

**The Required/Desired Semantics.** Most of the research on bipolar queries has been so far focused on a special interpretation of the positive and negative conditions. Namely, the data items sought have to satisfy the complement of the latter condition, i.e., the condition denoted earlier as  $C$ , unconditionally while the former condition, i.e., the condition denoted as  $P$ , is of somehow secondary importance. For example, a painting one is looking for should be from seventeenth century and, *if possible* should be painted by one of the famous Flemish painters. The  $C$  condition is here *painted in the seventeenth century* (the original negative condition is of course *painted not in the seventeenth*

century) while the positive condition  $P$  is *painted by one of the famous Flemish painters*. Thus, the condition  $C$  is *required* to be satisfied condition while the condition  $P$  may be referred to as a *desired* condition. Anyway, we still have two matching degrees, of conditions  $C$  and  $P$ , and the assumed relation between them determines the way the tuples should be ordered in the answer to a query.

The simplest approach is to use the desired condition's matching degree just to order the data items which satisfy the required condition. However, if the required condition is fuzzy, i.e., may be satisfied to a degree, it is not obvious what should it mean that it is *satisfied*. Some authors [19.56, 92] propose to adopt the *risk-averse* model of the user and use the corresponding lexicographic order with the primary account for the satisfaction of the condition  $C$ . This interpretation is predominant in the literature.

Another approach consists in employing an aggregation operator, which combines the degrees of matching of conditions  $C$  and  $P$  in such a way so that the *possibility* of satisfying both conditions  $C$  and  $P$  is explicitly taken into account, i.e., the focus is on a proper interpretation of the following expression which is identified with the bipolar query  $(C, P)$

$$C \text{ and possibly } P. \quad (19.16)$$

Aggregation operators of this type have been studied in the literature under different names and in various contexts. In the framework of database querying it were *Lacroix* and *Lavency* [19.93] who first proposed it. It has been proposed independently in the context of default reasoning by *Yager* [19.94] and by *Dubois* and *Prade* [19.95]. The concept of this operator was also used by *Bordogna* and *Pasi* [19.96] in the context of textual information retrieval. Recently, a more general concept of a *query with preferences* and a corresponding new relational algebra operator, *winnow*, were introduced by *Chomicki* [19.97].

*Zadrożny* and *Kacprzyk* [19.98, 99] proposed a direct *fuzzification* of the concept of the *and possibly* operator, implicit in the work of *Lacroix* and *Lavency* [19.93]. In their approach, the essence of the *and possibly* operator modeling consists in taking into account the whole database (set of tuples) while combining the required and desired conditions matching degrees. Namely:

- If there is a tuple which satisfies both conditions then and only then it is actually *possible* to satisfy

both of them and each tuple have to meet both of them, i.e., the *and possibly* turns into a regular conjunction  $C \wedge P$ ,

- If there is no such tuple then it is *not possible* to satisfy both conditions and the desired one can be disregarded, i.e., the query reduces to  $C$ .

These are however two extreme cases and actually it may be the case that the two conditions may be simultaneously satisfied to a *degree*. Then, the  $(C, P)$  query may be also matched to a degree which is identified with the truth of the following formula

$$\begin{aligned} C(t) \text{ and possibly } P(t) \\ \equiv C(t) \wedge \exists s (C(s) \wedge P(s)) \Rightarrow P(t) \end{aligned} \quad (19.17)$$

This formula has been proposed by *Lacroix* and *Lavency* [19.93] for the crisp case. Its fuzzy counterpart [19.98–100] requires to choose a proper interpretation of the logical connectives, and may take the following form

$$\begin{aligned} C(t) \text{ and possibly } P(t) \\ \equiv \min \left\{ C(t), \max \left[ 1 - \max_{s \in \Gamma} \min(C(s), P(s)), P(t) \right] \right\} \end{aligned} \quad (19.18)$$

where  $\Gamma$  denotes the whole set of tuples being queried.

Formula (19.16) is derived from (19.17) using the classical fuzzy interpretation of the logical connectives via the max and min operators. *Zadrożny* and *Kacprzyk* [19.100–102] studied the properties of the counterparts of (19.18) obtained using a broader class of the operators modeling logical connectives.

It is worth noting that if the *required/preferred* semantics is assumed and the bipolar evaluations are expressed at the level of an attribute domain then it is reasonable to impose some consistency conditions on the form of both fuzzy sets representing condition  $C$  and  $P$ . Namely, it may be argued that a domain element should be first acceptable, i.e., should satisfy the required condition  $C$ , before it may be desired, i.e., satisfy the condition  $P$ . Such consistency conditions between fuzzy sets  $C$  and  $P$  may be conveniently expressed using the concepts of twofold fuzzy sets or *Atanassov* intuitionistic fuzzy sets/interval-valued fuzzy sets, referred to earlier in Sect. 19.3.2. For an in-depth discussion of such consistency conditions the reader is referred to [19.56, 92, 103].

The growing interest in modeling bipolarity of user preferences in queries resulted recently in some further

studies and interpretations of the *and possibly* operator as well as in the concept of new similar operators such as the *or at least* operator. For more details, the reader is referred to [19.104, 105].

## 19.4.2 Flexible Querying of Fuzzy Databases

### Possibilistic Approach

The possibilistic approach to data modeling is based on the sound foundations of a well-developed theory, i.e., the possibility theory. Thus, the standard relational algebra operations have their counterparts in an algebra for retrieving information from a fuzzy possibilistic relational database, proposed by *Prade* and *Testemale* [19.31]. Let us consider the selection operation  $\sigma$ . In the classical relational algebra it is an unary operation which for a given relation  $R$  returns another relation  $\sigma(R)$ , comprising these tuples of  $R$  which satisfy a condition  $c$  (such a condition is a kind of a parameter of the selection operations). In the possibilistic approach, the selection operation has to be redefined so as to make it compatible with the assumed data representation. To this end, two types of elementary conditions are considered:

- (i)  $A \theta a$ , where  $A$  is an attribute,  $\theta$  is a comparison operator (fuzzy or not) and  $a$  is a constant (fuzzy or not);
- (ii)  $A_i \theta A_j$ , where  $A_i$  and  $A_j$  are attributes.

In general, an exact value of an attribute is unknown and, thus, the matching degree is defined as the possibility and necessity of the match between this value and the constant (case (i) above) or the value of another attribute (case (ii) above). Hence, the formulas (19.17)–(19.18) are used to compute the possibility and necessity in the following way.

In case (i), the possibility distribution  $\pi_{A(t)}(\cdot)$  representing the value of the attribute  $A$  at a tuple  $t$  is used to compute the possibility measure of a set  $F$ , crisp or fuzzy, of elements of  $dom_A$  being in the relation  $\theta$  with elements representing the constant  $a$ . The membership function of the set  $F$  is

$$\mu_F(x) = \sup_{y \in dom_A} \min(\mu_\theta(x, y), \mu_a(y)), \quad x \in dom_A, \quad (19.19)$$

where  $\mu_a(\cdot)$  is the membership function of the constant  $a$  and  $\mu_\theta(\cdot)$  represents the fuzzy comparison operator (fuzzy relation)  $\theta$ . Then, the pair  $(\Pi_{A(t)}(F), N_{A(t)}(F))$

represents the membership of a tuple  $t$  to the relation being the result of the selection operator.

In case (ii), the joint possibility distribution  $\pi_{(A_i(t), A_j(t))}(\cdot)$  is used to compute the possibility measure of a subset  $F$  of the Cartesian product of domains of  $A_i$  and  $A_j$  comprising the pairs of elements being in relation  $\theta$ . The membership function of the set  $F$  is defined as follows

$$\mu_F(x, y) = \mu_\theta(x, y), \quad x \in dom_{A_i}, \quad y \in dom_{A_j}. \quad (19.20)$$

Then, the pair  $(\Pi_{(A_i(t), A_j(t))}(F), N_{(A_i(t), A_j(t))}(F))$  represents the membership degree of a tuple  $t$  to the relation being the result of the selection operator. If the attributes  $A_i$  and  $A_j$  are *noninteractive* [19.27] then the computing of the possibility measure is simplified. Namely

$$\pi_{(A_i(t), A_j(t))}(x, y) = \min(\pi_{A_i(t)}(x), \pi_{A_j(t)}(y)). \quad (19.21)$$

It is worth noting that *Prade* and *Testemale* [19.27], in fact, consider the answer to a query as composed of two fuzzy sets of tuples:

- Those which necessarily match the query; the membership function degree for each tuple of this set is defined by  $N_{A(t)}(F)$ ;
- Those which possibly match the query; the membership function degree for each tuple of this set is defined by  $\Pi_{A(t)}(F)$ .

*Prade* and *Testemale* [19.27] consider also the case when the selection operation is used with a compound condition  $C$ , i.e.,  $C = C_1 \wedge C_2$  or  $C = C_1 \vee C_2$  or  $C = \neg C_1$ . Due to the fact that, in general, a calculus of uncertainty, exemplified by the possibility theory, cannot be truth functional [19.106], it is not enough to compute the possibility and necessity measures for elementary conditions using possibility distributions representing values of particular attributes and then combine them using an appropriate operator. In order to secure effective computing of the result of the selection operator it is thus assumed that the attributes referred to in elementary conditions are noninteractive. In such a case, truth-functional combination of the obtained possibility and necessity measures is justified.

*Dubois* and *Prade* [19.58] propose a technique of querying bipolar data using bipolar queries. A tuple may be classified to many categories with respect to an answer to such a query.

In the *extended possibilistic approach* [19.107] the matching degree of an elementary condition against a tuple  $t$  is expressed by an **EPTV** (cf., page 298). This **EPTV** represents the extent to which it is (un)certain that  $t$  belongs to the result of a flexible query. Let us consider a query condition of the form  $A \text{ is } l$ , where  $A$  denotes an attribute and  $l$  denotes a fuzzy set representing a linguistic term used, in a query such as, e.g., *low* in *Price is low* in a query. Then, the **EPTV** representing the matching degree will be computed as

$$\mu_{\tilde{l}^*(A \text{ is } l)}(T) = \sup_{x \in \text{dom}_A} \min(\pi_A(x), \mu_l(x)), \quad (19.22)$$

$$\mu_{\tilde{l}^*(A \text{ is } l)}(F) = \sup_{x \in \text{dom}_A - \{\perp\}} \min(\pi_A(x), 1 - \mu_l(x)), \quad (19.23)$$

$$\mu_{\tilde{l}^*(A \text{ is } l)}(\perp) = \min(\pi_A(\perp), 1 - \mu_l(\perp)), \quad (19.24)$$

where  $\pi_A(\cdot)$  denotes the possibility distribution representing the value of the attribute  $A$  (to simplify the notation we omit here a reference to a tuple  $t$ ). In the case of a compound query condition, the resulting **EPTV** can be obtained by aggregating the **EPTVs** computed for the elementary conditions. Hereby, generalizations of the logical connectives of the conjunction ( $\wedge$ ), disjunction ( $\vee$ ), negation ( $\neg$ ), implication ( $\rightarrow$ ), and equivalence ( $\leftrightarrow$ ) can be applied according to [19.14, 108].

Baldwin et al. [19.109] have implemented a system for querying a possibilistic relational database using semantic unification and the evidential support logic rule to combine matching degrees of the elementary conditions. The queries are composed of one or more conditions, the importance of each condition, a *filtering* function (similar to the notion of quantifier) and a threshold. The particularity of their work is the process, semantic unification, used for matching the fuzzy values of the criteria with the possibility distributions representing the values of the attributes. As a result, one obtains an interval  $[n, p]$ , where, similarly to the previous case,  $n$  (necessity) is the certain degree of matching and  $p$  (possibility) is the maximum possible degree of matching. However, this time the calculations are based on the mass assignments theory developed by Baldwin. In this approach, an interactive iterative process of the querying is postulated.

Bosc and Pivert [19.110] proposed another type of a query against a possibilistic database. Namely, the user may be interested in finding tuples which have a specific features of the possibility distribution representing the value of an attribute. Thus, the condition of such a query does not refer to the value of an attribute

itself but to the characteristics of its possibility distribution. This new type of queries may be illustrated with the following examples:

- I. Find tuples such that all the values  $a_1, a_2, \dots, a_n$  are possible for an attribute  $A$ .
- II. Find tuples such that more than  $n$  values are possible to a degree higher than  $\lambda$  for an attribute  $A$ .
- III. Find tuples where for attribute  $A$  the value  $a_1$  is more possible than the value  $a_2$ .
- IV. Find tuples where for attribute  $A$  only one value is completely possible.

The matching degree for such queries is computed in a fairly straightforward way. For the query of type I. it may be computed as  $\min(\pi_A(a_1), \pi_A(a_2), \dots, \pi_A(a_n))$ .

The reader is referred for more details to the following sources on fuzzy querying in the possibilistic setting [19.28, 29, 32, 111].

### Similarity-Based Approach

The research on querying in similarity-based fuzzy databases is best presented in a series of papers by Petry et al. [19.112–114]. A complete set of operations of the relational algebra has been defined for the similarity relation-based model. These operations result from their classical counterparts by the replacement of the concept of equality of two domain values with the concept of their similarity. The conditions of queries are composed of crisp predicates as in a regular query language. Additionally, a set of level thresholds may be submitted as a part of the query. A threshold may be specified for each attribute appearing in query's condition. Such a threshold indicates what degree of similarity of two values from the domain of a given attribute justifies to consider them equal. The concept of the threshold level also plays a central role in the definition of the redundancy in this database model and thus is important for the relational algebra operations as they are usually assumed to be followed by the reduction of redundant tuples. In this model, two tuples are redundant if the values of all corresponding attributes are similar (to a level higher than a selected degree) rather than equal, as it is the case in the traditional relational data model.

Hybrid models, mentioned earlier, are usually accompanied by their own querying schemes. For example, the **GEFRED** model is equipped with a generalized fuzzy relational algebra. Galindo et al. [19.115] have extended the **GEFRED** model with a fuzzy domain relational calculus (**FDR**) and in [19.116] the fuzzy quantifiers have been included.

## 19.5 Conclusions

In this chapter, we have presented an overview of selected contributions in the areas of data representation and querying. We have focused on approaches rooted in the relational data model. In the literature, many approaches have been also proposed for, e.g., fuzzy object

oriented models or fuzzy spatial information modeling which are not covered here due to the lack of space. We have compiled an extensive list of references which will hopefully help the reader to study particular approaches in detail.

# Application of Fuzzy Techniques to Autonomous Robots

Ismael Rodríguez Fdez, Manuel Mucientes, Alberto Bugarín Díz

The application of fuzzy techniques in robotics has become widespread in the last years and in different fields of robotics, such as behavior design, coordination of behavior, perception, localization, etc. The significance of the contributions was high until the end of the 1990s, where the main aim in robotics was the implementation of basic behaviors. In the last years, the focus in robotics moved to building robots that operate autonomously in real environments; the actual impact of fuzzy techniques in the robotics community is not as deep as it was in the early stages of robotics or as it is in other application areas (e.g., medicine, processes industry ...). In spite of this, new emerging areas in robotics such as human–robot interaction, or well-established ones, such as perception, are good examples of new potential realms of applications where (hybridized) fuzzy approaches will surely be capable of exhibiting their capacity to deal with such complex and dynamic scenarios.

## 20.1 Robotics and Fuzzy Logic

Although many other classical definitions could be stated, an autonomous robot may be defined as a machine that collects data from the environment through sensors, processes these data taking into account its previous knowledge of the world, and acts according to a goal. This definition is general and covers the different types of robots available today: indoor wheeled robots, autonomous cars, unmanned aerial vehicles (**UAVs**), autonomous underwater vehicles, robotic arms, humanoid robots, robotic heads, etc.

Between the early 1990s and today robotics has evolved a lot. From our point of view, it is possible to distinguish three stages in robotics research in the last years. At the beginning, the focus was on endowing robots with a number of simple behaviors to solve basic tasks like wall-following, obstacle avoidance,

entering rooms, etc. Later, the objective in robotics moved to building truly autonomous robots, which required the mapping of the environment, the localization of the robot, and navigation or motion planning. Although these topics are still open, the focus of current robotics is starting to move to a third stage where much higher level and integrated capabilities, such as advanced perception, learning of complex behaviors, or human–robot interaction, are involved.

Within this context, fuzzy logic has been widely used in robotics for several purposes. The main advantage of using fuzzy logic in robotics is its ability to manage the uncertainty due to sensors, actuators, and also in the knowledge about the world. Until the end of the 1990s, the contributions of fuzzy logic were mainly in three fields [20.1]: behaviors, coordination

**Table 20.1** Distribution of the 98 publications considered in the respective rankings: Thomson–Reuters Web of Science (after [20.6]; JCR 2012-WoK) for journals and Microsoft Academic Search (MAS 2013; after [20.5] for conferences

Quartile	Journals no.papers	%papers	Conferences no. papers	%papers

Q2	10	12	1	7
Q3	2	2	1	7
Q4	1	1	0	0
No ranking	3	4	2	14
Total	84	100	14	100

of behaviors, and perception. The design of behaviors for solving specific and simple tasks in robotics has been undoubtedly the most successful application of fuzzy logic in robotics. As examples of these behaviors we have wall-following, navigation, trajectory tracking, moving objects tracking, etc. Also, the selection and/or combination of these basic behaviors has been solved with fuzzy logic [20.2–4]. Finally, fuzzy techniques have contributed to perception in two lines: i) for the preprocessing of sensor data, prior to their use as input to the behavior and ii) for modeling the uncertainty both in occupancy and feature-based maps.

In this chapter we describe and analyze the contributions of fuzzy techniques to robotics in the period 2003–2013. A number of 98 references related to the

topic *fuzzy and robotics* have finally been selected for being categorized and described with the aim to focus on recent papers describing uses of fuzzy-based or hybrid methods in relevant tasks. Both basic behaviors and also high-level tasks of the robotics area as it is understood nowadays were considered. Table 20.1 describes the relevance of the papers considered in terms of their position in the well-known rankings Thomson–Reuters Web of Knowledge for journals and Microsoft Academic Search (MAS 2013) [20.5] for conferences. We decided to consider the MAS 2013 ranking since other conference rankings such as **CORE-ERA** (Computing Research and Education-Excellence in Research for Australia) were not up to date at the moment and do not extensively cover the robotics area. It can be seen that a vast majority of the papers are ranked in the Q1 of the respective lists (81% for journals and 72% for conferences).

All the references were revised and classified according to the robotics area they mainly addressed and were included into one of the 12 categories described in Sects. 20.2–20.13. Also the fuzzy technique they use (together with its hybridization with other soft computing techniques if this is the case) was annotated in order to assess which are the most active areas of soft computing in the field of robotics and also to evaluate their actual impact in the field.

The results of this revision, classification, and analysis are presented in the sections that follow.

## 20.2 Wall-Following

When autonomous robots navigate within indoor environments (e.g., industrial or civil buildings), they have to be endowed with a number of basic capabilities that allow the robot to perform specific tasks during operation. These basic capabilities are usually referred to in the robotics literature as behaviors. Some examples of usual robot behaviors are the ability to move along corridors, to follow walls at a given distance, to turn corners, and to cross open areas in rooms. Wall-following behavior is one of the most relevant ones and has been very widely dealt with in the robotics literature, since it is one of the basic behaviors to be executed when the robot is exploring an unknown area, or when it is moving between two points in a map.

The characteristic that makes a fuzzy controller useful for the implementation of this and other behaviors is

the ability that fuzzy controllers have to cope with noisy inputs. This noise appears when the sensors of the robot detect the surrounding environment and is an inherent feature to the whole field of robotic sensors.

The importance of wall-following behavior for a car-like mobile robot was pointed out in [20.7]. In this work, a fuzzy logic control system was used in order to implement human-like driving skills by an autonomous mobile robot. Four different sensor-based behaviors were merged in order to synthesize the concepts of the maneuvers needed. These behaviors were: wall-following, corner control, garage-parking, and parallel-parking. A description of the design and implementation of a velocity controller for wall-following can be found in [20.8, 9]. In [20.8] fuzzy temporal rules were used in order to filter the sensorial noise of a Nomad

200 mobile robot and to endow the rule base with high expressiveness. The use of these types of rules has noticeably improved the robustness and reliability of the system.

Wall-following behavior has also been used as a testing benchmark for automatic learning of fuzzy controllers. In [20.10] an evolutionary algorithm was used to automatically learn the fuzzy controller, taking into account the tradeoff between complexity and accuracy. Continuing this work, in [20.11] the focus was on reducing the expert knowledge demanded for designing the controller. No restrictions are placed either on the number of linguistic labels or on the values that define the membership functions. Finally, in [20.12] a simple but effective learning methodology was presented. This methodology was proposed in order to not only generate fuzzy controllers with good behavior in simulated experiments but also to use them directly in the real robot, with no further post-processing or implementing a tuning stage.

More recent studies have addressed the use of type-2 fuzzy logic. These proposals are mostly motivated by the claim that type-1 fuzzy sets cannot handle the high levels of uncertainty that are usually present in real-world applications to the same extent that type-2 fuzzy sets can.

As for type-1 fuzzy logic controllers (**FLCs**), this behavior has been used for testing the automatic learning of type-2 **FLCs**. In [20.13] a genetic algorithm was used for tuning the type-2 fuzzy membership functions of a previously defined controller. A more complex learning scheme was presented in [20.14]. The antecedent is learned using a type-2 fuzzy clustering based on examples and without expert knowledge. The actions in the consequent part of rules is selected

from a set of defined control actions through a hybrid method composed of a reinforcement learning algorithm and ant colony optimization. Both works used a real Pioneer robot to demonstrate the viability of the controllers.

In order to show the advantages of using type-2 fuzzy logic, a comparative analysis of type-1 and interval type-2 fuzzy controllers was presented in [20.15]. A particle swarm optimization algorithm was used to optimize a type-1 **FLC**. Next, the interval type-2 fuzzy controller was constructed, blurring the membership functions. The results obtained by a real mobile robot showed that the interval type-2 fuzzy controller can cope better with dynamic uncertainties in the sensory inputs due to the softening and smoothing of the output control surface.

However, these works only focus on interval type-2 fuzzy logic. The high computational complexities associated with general type-2 fuzzy logic systems (**FLSSs**) have, until recently, prevented their application to real-world control problems. In [20.16] this problem was addressed by introducing a complete representation framework, which is referred to as zSlices-based general type-2 fuzzy systems. As a proof-of-concept application, this framework was implemented for a mobile robot, which operates in a real-world outdoor environment using the wall-following behavior. In this case, the proposed approach outperformed type-1 and interval type-2 fuzzy controllers in terms of errors in the distance to the wall. For this behavior, type-2 approaches exhibit a better performance when compared to type-1 approaches. Nevertheless, from a robotics point of view, type-2 proposals still did not outperform in general other fuzzy approaches and have a very limited impact on this area.

## 20.3 Navigation

Robot navigation consists of a series of actions, which are summarized in the ability of the robot to go from a starting point to a goal without a planned route. Navigation is one of the main issues that a mobile robot must solve in order to operate.

In this behavior the ability to work in dynamic environments whose structure is unknown, with great uncertainty, with moving objects or objects that may change their position is of great importance. The capacity to work under these conditions is the best motivation to use fuzzy logic in this particular task.

Some work in this area has been done in simulated environments. In [20.17] a multi-sensor fusion technique was used to integrate all types of sensors and combine them to obtain information about the environment. In this way, the environment can be perceived comprehensively, and the ability of the **FLC** is improved. In [20.18, 19] the navigation behavior was studied for a set of robots that navigate in the same environment. Both works used a Petri net to negotiate the priority of the robots. Also, in [20.19] different **FLCs** were compared. Each controller used a different number of labels for each variable as well as a different

shape of the fuzzy sets. It was concluded that utilizing a Gaussian membership function is better for navigation in environments with a high number of moving objects.

Moreover, there are several works where this behavior has been successfully implemented in a real robot. A hardware implementation of a **FLC** for navigation in mobile robots was presented in [20.20]. The design methodology allows to transform a **FLC** into a system that is suitable for easy implementation on a digital signal processor (**DSP**). This methodology was tested with good results in a ROMEO 4R car-like vehicle for a parking problem. Moreover, in [20.21] the design of a new fuzzy logic-based navigation algorithm for autonomous robots was illustrated. It effectively achieves correct environment modeling, and processes noisy and uncertain sensory data on a low-cost Khepera robot.

The ability to avoid dead-end paths was studied in [20.22, 23]. In these works the minimum risk approach was used to avoid local minima. A novel path-searching behavior was developed to recommend the local direction with minimum risk, where the risk was modeled using fuzzy logic. Another approximation to solve this problem was presented in [20.24]. While the fuzzy logic body of the algorithm performs the main tasks of obstacle avoidance and target seeking, an actual/virtual target switching strategy solves the problem of dead-ends on the way to the target.

In [20.25] a new approach was proposed that employs a fuzzy discrete event system to implement the behavior coordinator mechanism that selects relevant behaviors at a particular moment to produce an appropriate system response. The possible transition from one state to another when an event occurs was modeled using fuzzy sets.

In addition to the use of conventional **FLCs**, different approaches have been used in the last decade. In [20.26] a novel reactive type-2 fuzzy logic architecture was used. Type-2 fuzzy logic was used for both implementing the basic navigation behaviors and also the strategies for their coordination. The proposed architecture was implemented in a robot and successfully tested in indoor and outdoor environments.

In the same way as several learning approaches have been used for wall-following behavior, different works focused on automatically learning navigation skills. In [20.27] a novel fuzzy Q-learning approach was presented, where the weights of the fuzzy rules of the controller were learned through a reinforcement algorithm.

In [20.28] a neuro-fuzzy network that is able to add rules to the rule base was presented. The criteria for adding rules was based on a performance evaluation within a genetic algorithm that explores the new situations to add. A comparison of three different neuro-fuzzy approaches with classical fuzzy controllers can be found in [20.29]. It is shown that neuro-fuzzy approaches perform better and that the best results were obtained by an optimization made by a genetic algorithm for both Mamdani and Takagi–Sugeno approaches.

Although mobile wheeled robots are the most common area of application for navigation, other types of robots also use this behavior. One of the most impressive types of robot that implement the navigation behavior are the unmanned aerial vehicles (**UAVs**). In [20.30] two fuzzy controllers (one for altitude and the other for latitude–longitude) were combined in order to control the navigation of a small **UAV**. In [20.31] the design of a Takagi–Sugeno controller for an unmanned helicopter was presented. The controller proposed is a fuzzy gain-scheduler used for stable and robust altitude, roll, pitch, and yaw control. Testing in both papers was performed in simulated environments to show the results obtained by the controllers and, therefore, real testing on real **UAVs** was not reported.

Another type of robot that demands navigation capabilities are robotic manipulators. Simulated manipulators were used in [20.32, 33]. The strategy followed in [20.32] was to use a fuzzy inference process to tune the gain of a sliding-mode control and the weights of a neural network controller in the presence of disturbance or big tracking errors. It was shown that the combination of these controllers can guarantee stability. In [20.33] a genetic algorithm was presented in order to optimize the controllers of two robotic manipulators working on the same environment.

Other examples of applications of navigation are: a robotic fish motion control algorithm [20.34] endowed with an orientation control system based on a **FLC**; the data transmission latency or data loss considered in [20.35] for internet-based teleoperation of robots (when data transmission fails, the robot automatically moves and protects itself using a fuzzy controller optimized using a co-evolutionary algorithm); and the stabilization of a unicycle mobile robot described in [20.36], where a type-2 **FLC** was used, and computer simulations confirmed its good performance in different navigation problems.

## 20.4 Trajectory Tracking

Tracking refers to the ability of a robot to follow a pre-determined series of movements or a predefined path. Tracking is a relevant behavior in the industrial field, where robots usually have to perform a repeated pattern or trajectory with high precision.

Developing accurate analytical models for such systems and hence reliable controllers based on such models is extremely difficult and in general unfeasible even for not very complex trajectories. Applying fuzzy control strategies for such systems seems appropriate, since with these systems the nonlinear system identification methodologies can be exploited with the help of inherent knowledge. Furthermore, suitable stability conditions for such controllers to guarantee global asymptotic stability can be determined.

In [20.37] a control structure that makes possible the integration of a kinematic controller and an adaptive fuzzy controller was developed for mobile robots. A highly robust and flexible system that automatically follows a sequence of discrete way-points was presented in [20.38]. In [20.39] the combination of a velocity controller with a simple fuzzy system that limits on-line the advancing speed of the vehicle to allow it to follow an assigned path in compliance with the kinematic constraints was presented.

More recent studies in tracking for mobile robots have focused on more advanced and complex systems. The work in [20.40] focused on the design of a dynamic Petri recurrent fuzzy neural network. This network structure was applied to the path-tracking control of a non-holonomic mobile robot for verifying its validity. Also, in [20.41] the tracking control of a mobile robot with uncertainties in the robot kinematics, the robot dynamics, and the wheel actuator dynamics was investigated. A robust adaptive controller was proposed for back-stepping a **FLC**. Finally, [20.42] proposed a complete control law comprising an evolutionary programming-based kinematic control and an adaptive fuzzy sliding-mode dynamic control.

Although mobile robots have a great utility in industry, the robotic manipulators are the most used type of robot in this sector. One main issue is to develop controllers that deal with uncertainties. [20.43] addressed trajectory tracking problems of robotic manipulators using a fuzzy rule controller designed to deal with uncertainty. In [20.44] two adaptive fuzzy systems are employed to approximate the nonlinear and uncertain terms occurring in the robot arm and the joint motor dy-

namics. Other adaptive controllers for motion control of multi-link robot manipulators can be found in [20.45–47].

Other works focused on the ability to adapt the fuzzy control to different demands or requisites over time with different approaches. In [20.48] a fuzzy sliding mode controller was proposed for robotic manipulators. The membership functions of the control gain are updated on-line and, therefore, the controller is not a conventional fuzzy controller but an adaptive one. In [20.49] a design method that constructs the fuzzy rule base from a conventional proportional-integral-derivative (**PID**) controller in an incremental way using recursive feedback was proposed. A direct fuzzy control system for the regulation of robot manipulators was presented in [20.50]. The bounds of the applied torques in this case are adjusted by means of the output membership functions parameters in such a way that the maximum torque demanded by the controller always ranges between the limits given by the manufacturer.

A different perspective of robotic manipulators, but also a very common one, is the scheme of different systems that need to communicate. In [20.51] a new observer-controller structure for robot manipulators with model uncertainty using only the position measurements is proposed. In this method, adaptive fuzzy logic is used to approximate the nonlinear and uncertain robot dynamics in both the observer and the controller.

The effects of network-induced delay and data packet dropout for a class of nonlinear networked control systems for a flexible arm was investigated in [20.52]. The non-linear networked control systems were approximated by linear networked Takagi–Sugeno fuzzy models. An iterative algorithm for constructing the fuzzy model was proposed. Also, in [20.53], the delay transmission of a signal through an internet and wireless module was studied.

As well as for the case of mobile robots, in the recent years of research in robotic manipulators both the automatic design and the learning of different parts of the controllers have been addressed. For example, in [20.54] a novel tracking control design for robotic systems using fuzzy wavelet networks was presented. Fuzzy wavelet networks were used to estimate unknown functions and, therefore, to solve the problem of demanding prior knowledge of the controlled plant.

Intelligent control approaches such as neural networks for the approximation of nonlinear systems have also received considerable attention. They are very effective in coping with structured parametric uncertainty and unstructured disturbance by using their powerful learning capability. Thus, neuro-fuzzy network controllers are the usual choice for robot manipulators.

In [20.55] the position control of modular and reconfigurable robots was addressed. A neuro-fuzzy control architecture was used for tuning the gains inside the **PID** controller. An improvement was achieved with respect to classic controllers in terms of error of the trajectory that is tracked. Another neuro-fuzzy robust tracking control law was implemented in [20.56]. In this work, the controller guaranteed transient and asymptotic performance.

Other different approaches of neuro-fuzzy controllers have also been developed. In [20.57] a stable discrete-time adaptive tracking controller using a neuro-fuzzy dynamic-inversion for a robotic manipulator was presented. The dynamics of the manipulator were approximated by a dynamic Takagi–Sugeno fuzzy model. With the aim of improving the robustness of the controller, in [20.58] a novel parameter adjustment scheme using a neuro-fuzzy inference system architecture was presented.

More real environment applications of neuro-fuzzy networks approaches have also been discussed in the literature [20.59]. In [20.60, 61] a robust neural-fuzzy-network control was investigated for the joint position control of an  $n$ -link robot manipulator for periodic motion, with the aim of achieving high-precision position tracking. In [20.62] an approximate Takagi–

Sugeno type neuro-fuzzy state–space model for a flexible robotic arm was presented. The model was trained using a particle swarm optimization technique.

In the last years, more advanced learning algorithms have been used. In [20.63] an algorithm to learn the path-following behavior for multi-link mobile robots was presented. In this approach the learning complexity of the path-following behavior is reduced, as long paths are divided into a set of small motion primitives that can reach almost every point in the neighborhood. In [20.64], a robot manipulator was controlled by a **FLC**, where the parameters of the Gaussian membership functions were optimized with particle swarm optimization. Also, in [20.65] the authors described the application of ant colony optimization and particle swarm optimization to the optimization of the membership function parameters of a **FLC**. The aim in this case was to find the optimal trajectory tracking controller for an autonomous wheeled mobile robot.

Interval type-2 **FLCs** have been described in several case studies to handle uncertainties. However, one of the main issues in adopting such systems on a larger scale is the lack of a systematic design methodology. [20.66] presented a novel design methodology of interval type-2 Takagi–Sugeno–Kang (**TSK**) **FLCs** for modular and reconfigurable robot manipulators for tracking purposes with uncertain dynamic parameters. Moreover, [20.67] provided a problem-driven design methodology together with a systematic assessment of the performance quality and uncertainty robustness of interval type-2 **FLCs**. The method was evaluated on the problem of position control of a delta parallel robot.

## 20.5 Moving Target Tracking

Service robots have to be endowed with the capacity of working in dynamic environments with high uncertainty. Typical environments with these characteristics are airports, hallways of buildings, corridors of hospitals, domestic environments, etc. One of the most important factors when working in real environments are the moving objects in the surrounding of the robot. The knowledge of the position, speed, and heading of the moving objects is fundamental for the execution of tasks like localization, route planning, interaction with humans, or obstacle avoidance.

In [20.68] a module that allows the mobile robot to localize the target precisely in the environment was pre-

sented. Both direction and distance to the target were measured using infrared sensors. Also, a fuzzy target tracking control unit was proposed. This control unit comprises a behavior network for each action of the tracking control and a gate network for combining the information of the infrared sensors. It was shown that the proposed control scheme is, indeed, effective and feasible through some simulated and real examples of the behavior.

In [20.69, 70] a pattern classifier system for the detection of moving objects using laser range finders data was presented. An evolutionary algorithm was used to learn the classifier system based on the quantified fuzzy

temporal rules model. These quantified fuzzy temporal rules are able to analyze the persistence of the fulfillment of a condition in a temporal reference by using fuzzy quantifiers. Moreover, in [20.71] the authors presented a deep experimental study on the performance of

different evolutionary fuzzy systems for moving object following. Several environments with different degrees of complexity and a real environment were used in order to show the applicability of the methodologies presented.

## 20.6 Perception

Perception is an essential part of any robotic system, since it is the functionality through which the robot incorporates information from the environment. Several sensors have been typically used in mobile robots over the years. Ultrasound, laser range finders, acoustic signals, or cameras are some examples of the most used sensors. The information obtained by these sensors can be used in order to solve various problems such as object recognition, collision avoidance, navigation, or some particular objects.

The perception of landmarks is a very useful and meaningful strategy for helping in localization or navigation. Furthermore, it is a quite common strategy to detect known landmarks that are present in the environments instead of adding artificial landmarks (e.g., visual beacons, radio frequency identification (**RFID**) labels,...) in order to preserve environments with the less possible external intervention or manipulation. Within this context, one of the most commonly used landmarks in indoor environments are doors, since they indicate relevant points of interaction and also for their static nature. In [20.72] fuzzy temporal

rules were used for detecting doors using the information obtained from ultrasound sensors. This paradigm was used to model the temporal variations of the sensor signals together with the model of the necessary knowledge for detection. A different approach for door detection using computer vision was presented in [20.73]. Doors are found in gray-level images by detecting the borders and are distinguished from other similar shapes using a fuzzy system designed using expert knowledge. Also, a tuning mechanism based on a genetic algorithm was used to improve the performance of the system according to the particularities of the environment in which it is going to be employed.

In robotic soccer games perception also plays a principal role. The work presented in [20.74] describes a type-2 **FLC** to accurately track a mobile object, in this case a ball, from a robot agent. Both players and ball positions must be tracked using a low-computational cost image processing algorithm. The fuzzy controller aims to overcome the uncertainty added by this image processing.

## 20.7 Planning

For more complex behaviors in robotics, systems must be able to achieve certain higher-level goals. In order to do that, the robot needs to make choices that maximize the utility or value of the available alternatives. The process by which this objective is solved is called planning. When the robot is not the only actor (as is usual), it must check periodically if the environment matches with the predictions made and change its plan accordingly.

Path planning is a typical task that is needed in most mobile robots that work in unknown environments. The problem consists in determining the path to be followed by the robot in order to reach a goal. In the case when not only the path, but also the movements of the robot at each instant are determined, planning is referred

to as motion planning. In [20.75] a two-layered goal-oriented motion planning strategy using fuzzy logic was developed for a Koala mobile robot navigating in an unknown environment. The information about the global goal and the long-range sensorial data are used by the first layer of the planner to produce an intermediate goal in a favorable direction. The second layer of the planner takes this sub-goal and guides the robot to reach it while avoiding collisions using short-range sensorial data.

Other path planning approaches that use fuzzy logic can be found in more recent years. A cooperative control in a multi-agent architecture was applied in [20.76] in order to implement high cognitive capabilities like planning. The agents provided basic behaviors (such

as moving to a point) sharing the robot resources and negotiating when conflicts arose. A new proposal to solve path planning was also proposed in [20.77]. It was based in an ant colony optimization to find the best route with a fuzzy cost function. In [20.78] fuzzy logic was used in order to discretize the environment in relation to a soccer robot. Then, a multi-objective evolutionary algorithm was designed in order to optimize the actions needed in order to reach the ball.

Some research has also been reported in the field of robot soccer, for high-level planning of team be-

havior. In [20.79] an extensive fuzzy behavior-based architecture was proposed. The behavior-based architecture decomposes the complex multi-robotic system into smaller modules of roles, behaviors, and actions. Each individual behavior was implemented using a **FLC**. The same approach was used for coordinating the various behaviors and select the most appropriate role for each robot. Continuing this work, in [20.80] an evolutionary algorithm approach was used to optimize each **FLC** for each layer of the architecture.

## 20.8 SLAM

Simultaneous localization and mapping (**SLAM**) is a field of robotics that has as its main objective the construction of a map of the environment while at the same time keeping track of the current location of the robot inside the map that is being built. Mapping consists of integrating the information gathered with the robot's sensors into a given representation. In contrast to this, localization is the problem of estimating where the robot is placed on a map. In practice, these two problems cannot be solved independently of each other. Before a robot can answer the question of how the environment looks like given a set of observations, it needs to know from which locations these observations have been made. At the same time, it is hard to estimate the current position of a robot (or any vehicle) without a map.

Different fuzzy approximations have been used in order to help to solve the **SLAM** problem. In [20.81] the development of a new neuro-fuzzy-based adaptive Kalman filtering algorithm was proposed. The neuro-fuzzy-based supervision for the Kalman filtering algorithm is carried out with the aim of reducing the mismatch between the theoretical and the actual covariance of the innovation sequences. To do that, it attempts to estimate the elements of the covariance matrix at

each sampling instant when a measurement update step is carried out. Also, a fuzzy adaptive extended information filtering scheme was used in [20.82] for ultrasonic localization and pose tracking of an autonomous mobile robot. The scheme was presented in order to improve the estimation accuracy and robustness for the proposed localization system with a system having a lack of information and noise.

A novel hybrid method for integrating fuzzy logic and genetic algorithms (genetic fuzzy systems, **GFSs**) to solve the **SLAM** problem was presented in [20.83]. The core of the proposed **SLAM** algorithm searches for the most probable map such that the associated poses provide the robot with the best localization information. Prior knowledge about the problem domain was transferred to the genetic algorithm in order to speed up convergence. Fuzzy logic is employed to serve this purpose and allows the algorithm to conduct the search starting from a potential region of the pose space. The underlying fuzzy mapping rules infer the uncertainty in the location of the robot after executing a motion command and generate a sample-based prediction of its current position. The robustness of the proposed algorithm has been shown in different indoor experiments using a Pioneer 3AT mobile robot.

## 20.9 Cooperation

A multi-agent system is a system composed of multiple interacting intelligent agents within an environment. When the agents are robots, these systems lead to a more challenging task because of their implicit real-world environment, which is presumably difficult to

model. There are two fundamental needs for multi-agent approaches. On one hand, some problems can be naturally too complex or impossible to be accomplished by a single robot. On the other hand, there can be benefits for using several simple robots be-

cause they are cheaper and more fault tolerant than having a single complex robot. Also, multi-agent systems can be helpful for social and life science problems.

An illustrative example of this type of system is shown in [20.84], where a mobile sensor network approach composed by robots that cooperate was presented. The objective of the sensor network was the localization of hazardous contaminants in an unknown large-scale area. The robots have a swarm controller that controls the behavior for the localization for each robot, whose actions are based on a fuzzy logic control system that is identical for all robots.

Control cooperation of robots has been of great interest in the last years. Fuzzy logic controllers have obtained good performance in some simulation experiments. The idea of applying fuzzy controllers comes from the fact that soft computing techniques have

proved to be efficient for poorly defined system optimization and multi-agent coordination. In [20.85] a multi-agent control system was proposed, based on a fuzzy inference system for a group of two wheeled mobile robots executing a common task. An application of this control system is the control of robotic formations moving on the plane such as a group of guard robots taking care of an area and dealing with potential intruders. The use of fuzzy logic in this work allows easy expression of rules, and the multi-agent structure supports separation of team and individual knowledge. Another example can be found in [20.86]. In this work, a collision free target tracking problem of a multi-agent robot system was presented. Game theory provides an effective tool to solve this problem. To enhance robustness, a fuzzy controller tunes the cost function weights directly for the game theoretic solution and helps to achieve a prescribed value of cost function components.

## 20.10 Legged Robots

Wheeled robots have dominated the state of the art of mobile robots. However, in the last decade, there has been an interest to find alternatives for those environments in which wheeled robots are not able to operate. When the terrain is variable and unprepared, adding legs to robots might be a solution. Legged robots can navigate on and adapt to any kind of surfaces (such as rough, rocky, sandy, and steep terrains) and step over obstacles; they can adapt. Moreover, legged robots help the exploration of human and animal locomotion.

One of the main differences between legged and wheeled robots is that legged robots require the system to generate an appropriate gait to move, whereas wheels just need to roll. To clarify this, gait is the movement pattern of limbs in animals and humans used for locomotion over a variety of surfaces. The same concept is used to design the pattern of movement of robots on different surfaces. In [20.87], the learning of a biped gait was solved using reinforcement learning. The aim of this work was to improve the learning rate through the incorporation of expert knowledge using fuzzy logic. This fuzzy logic was incorporated in the reinforcement system through neuro-fuzzy architectures. Moreover, fuzzy rule-based feedback is incorporated instead of numerical reinforcement signals. A different approximation was carried out in [20.88], where two different genetic algorithm approaches were used in order to im-

prove the performance of a **FLC** designed to model the gait generation problem of a biped robot. In both works, computer simulations were done in order to compare the different approaches of the control systems in terms of stability.

The work in [20.89] focused on the design of a leg for a quadrupedal galloping machine. For that, two intelligent strategies, a fuzzy and an heuristic controller, were developed for verification on a one-legged system. The fuzzy controller consists of a fuzzy rule base with an adaptation mechanism that modifies the rule output centers to correct velocity. These techniques were successfully implemented for operating one leg at speeds necessary for a dynamic gallop. It was shown that the fuzzy controller outperformed the heuristic controller without relying on a model of the system.

Finally for the gait problems, in [20.90] a fuzzy logic vertical ground reaction force controller was developed for a robotic cadaveric gait, which altered tendon forces in real time and iteratively adjusted the robotic trajectory in order to track a target reaction. This controller was validated using a novel dynamic cadaveric gait simulator. The fuzzy logic rule-based controller was able to track the target with a very low tracking error, demonstrating its ability to accurately control this type of robot.

Besides the gait problem, the biped robotic system contains a great deal of uncertainties associ-

ated with the mechanism dynamics and environment parameters. In [20.91] it was suggested that type-2 fuzzy logic control systems could be a better way to deal with the uncertainty in a robotic system. A novel type-2 fuzzy switching control system was proposed for biped robots, which includes a type-2 fuzzy modeling algorithm. As in the previous work, simulated experiments were used in order to compare the performance of the controller proposed with other dynamical intelligent control methods.

In [20.92] a fuzzy controller, consisting of a fuzzy prefilter (designed by a genetic algorithm) in the feed-forward loop and a PID-like fuzzy controller in the feed-back loop, was proposed for foot trajectory tracking control of a hydraulically actuated hexapod robot. A COMET-III real robot was used in this work and the experimental results exhibit that the proposed controller manifests better foot trajectory tracking performance compared to an optimal classical controller like the state feedback linear-quadratic regulator (LQR) controller.

## 20.11 Exoskeletons and Rehabilitation Robots

The latest advances in assistive robotics has had a great impact in different fields. For instance, in military applications, these technologies can allow soldiers to carry a higher payload and walk further without requiring more effort or producing fatigue. However, the field where the impact of this type of robotics is the greatest is healthcare. The aging of the population will be one of the main problems in the near future, since more people are going to need some type of assistance on a daily basis. This dependency suffered by the elderly can be partially resolved with the use of robotic systems that help people with a lack of mobility or strength. Robotic systems for assistance can provide total or partial movement to these people. Moreover, rehabilitation using these systems can make regaining movement-related functions easier and faster.

Some studies were developed in recent years that use fuzzy techniques on the rehabilitation of upper-limb motion (shoulder joint motion and elbow joint motion). The principal reason to use fuzzy logic is to deal with complicated, ill-defined, and dynamic processes, which are intrinsically difficult to be modelled mathematically. Moreover, fuzzy logic control incorporates human knowledge and experience directly without relying on a detailed model of the control system.

In [20.93] an exoskeleton and its fuzzy control system to assist the human upper-limb motion of physically weak persons was presented. The proposed robot automatically assists human motion mainly based on electromyogram signals on the skin surface. In a later work [20.94], the authors introduced a hierarchical neuro-fuzzy controller for a robotic exoskeleton where

the angles of the elbow and shoulder are modeled using fuzzy sets. Additionally, fuzzy sets are used in order to set a trigger in the activity of the muscles. In order to solve the same problem, a hybrid position/force fuzzy logic control system was presented in [20.95]. The objective of this work was to assist the subject in performing both passive and active movements along the designed trajectories with specified loads.

More recent studies have been published under the paradigm of fuzzy sliding mode control. In [20.96] a novel adaptive self-organizing fuzzy sliding mode control for the control of a 3-degree-of-freedom (DOF) rehabilitation robot was presented. An interesting characteristic of this approach is the ability to establish and regulate the fuzzy rule base dynamically. Going a step further along that same line, in [20.97] an adaptive self-organizing fuzzy sliding mode control robot was proposed for a 2-DOF rehabilitation robot.

For comparison and performance measurement purposes, one common practice in order to examine the effectiveness of the proposed exoskeleton in motion assistance is to use human subjects who perform different cooperative motions of the elbow and shoulder [20.93]. Different performance measures can be used to show the correctness of the proposed systems. In [20.94] the angles obtained by the exoskeleton were compared, while in [20.95] the results were shown in terms of force and stability. Finally, in [20.96, 97], the performance of the robotic rehabilitation system was measured in terms of response of the system to movements and tracking errors.

## 20.12 Emotional Robots

Future robots need a transparent interface that regular people can interpret, such as an emotional human-like face. Moreover, such robots must exhibit behaviors that are perceived as believable and life like. In general terms, the use of fuzzy techniques in this field did not have a great impact. However, the fuzzy approach can not only simplify the design task, but also enrich the interaction between humans and robots.

An application of fuzzy logic for this type of robot can be found in [20.98]. In this research it was proposed to use fuzzy logic for effectively building the whole behavior system of face emotion expression robots. It was shown how these behaviors could be constructed by a fuzzy architecture that not only seems more realistic but can also be easily implemented.

In [20.73] a fuzzy system that establishes a level of possibility about the degree of interest that the people around the robot may have in interacting with it was presented. Firstly, a method to detect and track persons using stereo vision was proposed. Then, the interest of

each person was computed using fuzzy logic by analyzing its position and its level of attention to the robot. The level of attention is estimated by analyzing whether or not the person is looking at the robot.

A more recent work of video-based emotion recognition was presented in [20.99]. In this work, a fuzzy rule-based approach was used for emotion recognition from facial expressions. The fuzzy classification itself analyzes the deformation of a face separately in each image. In contrast to most existing approaches, also blended emotions with varying intensities as proposed by psychologists can be handled. Other work that was based on physiological measures was presented in [20.100]. In this work, a fuzzy inference engine was developed to estimate human responses. The authors demonstrated in a later work [20.101] that a hidden Markov model is able to achieve better classification results than the previously reported fuzzy inference engine.

## 20.13 Fuzzy Modeling

Some extensions to fuzzy logic have been developed in the last decade in the field of mobile robotics. In [20.102] a probabilistic type-2 FLS was proposed for modeling and control. [20.89] focused on the design of a leg for a quadrupedal galloping machine. For that, two intelligent strategies (fuzzy and heuristic controllers) were developed for verification on a one-legged system. The fuzzy controller consists of a fuzzy rule base with an adaption mechanism that modifies the rule output centers to correct velocity errors. These techniques were successfully implemented for operating one leg at the speeds demanded for a dynamic gallop. It was shown that the fuzzy controller outperformed the heuristic controller without relying on a model of the systems. This proposal aims to solve the lack of capability of FLSs to handle various uncertainties identified by this work in practical applications. Two examples were used to validate the probabilistic fuzzy model: a function approximation and a robotic application. The robotic application was successfully implemented for the control of a simulated biped robot.

A novel representation of robot kinematics was proposed in [20.103, 104] in order to merge qualitative and quantitative reasoning. Fuzzy reasoning is good at communicating with sensing and control level sub-

systems by means of fuzzification and defuzzification methods. It has powerful reasoning strategies utilizing compiled knowledge through conditional statements so as to easily handle mathematical and engineering systems. Fuzzy reasoning also provides a means for handling uncertainty in a natural way, making it robust in significantly noisy environments. However, in this work a lack of ability in fuzzy reasoning alone to deal with qualitative inference about complex systems was pointed out.

It is argued that qualitative reasoning can compensate this drawback. Qualitative reasoning has the advantage of operating at the conceptual modeling level, reasoning symbolically with models that retain the mathematical structure of the problem rather than the input/output representation of rule bases. Moreover, the computational cause–effect relations contained in qualitative models facilitate analyzing and explaining the behavior of a structural model. The kinematics of a PUMA 560 robot is modelled for the trajectory tracking task. Thus demonstrating the ability of fuzzy reasoning. Simulation results demonstrated that the proposed method effectively provides a two-way connection for robot representations used for both numerical and symbolic robotic tasks.

## 20.14 Comments and Conclusions

The significance of the contributions of fuzzy logic to robotics is quite different in the three stages that we have identified. In the first stage, the objective was to endow the robot with a set of simple behaviors to solve basic tasks like wall-following, obstacle avoidance, moving object tracking, trajectory tracking, etc. Fuzzy logic significantly contributed in this stage, not only with the design of behaviors, but also with the coordination or fusion among them (more than 75% of the papers considered in this chapter deal with these topics). In the second stage, the focus moved to implementing autonomous robots that are able to operate in real environments (museums, hospitals, homes, . . .), which should, therefore, be able to generate a map of the environment, localize in the map, and also navigate between different positions (motion planning). The first two tasks were joined under the **SLAM** field, which has been one of the most important topics in robotics in the recent years. Motion planning has been another relevant field, that experimented a great improvement with the use of heuristic search algorithms and the inclusion of kinematic constraints in the planning. The contributions of fuzzy logic to this second wave have been marginal; **SLAM** techniques are dominated by probabilistic and optimization approaches, while the best motion planning proposals rely on heuristic search processes and probabilistic approaches to manage the uncertainty.

We have assessed which is the actual impact of the recently reported research on fuzzy-based approaches to robotics research and applications from a quantitative/qualitative point of view. In order to have an estimation we have considered the two journals with the highest impact factor in the 2012 Thomson-Reuters Web of Knowledge (the *International Journal of Robotics Research* IJRR and *IEEE Transactions on Robotics*, IEEE-TR) and looked for papers that included the term *fuzzy* in the Abstract in the period considered (2003–2013). We found that only one paper fulfilled such conditions in IJRR and only seven papers in IEEE-TR. These results indicate that the actual impact and diffusion of fuzzy approaches in the relevant robotics arena is very limited. A vast majority of research and application results of fuzzy approaches in robotics are, therefore, published and presented in papers and conferences related to soft computing. In fact,

only 22 out of the 98 papers considered in this chapter (i. e., 22%) were published in robotics-related forums. Among these almost all papers (20 out of 22, 91%) described **FLC** of the Mamdani type for different tasks, which suggests that **FLC** is without a doubt the area with the highest impact in papers and conferences of the most genuine robotics area (i. e., out of the soft computing related publications).

Furthermore, **FLC** is the most active area of research and applications, since 66% of the papers considered in this chapter describe Mamdani-based fuzzy controllers for all the behaviors and high-level tasks considered. Other hybrid methodologies such as neuro-fuzzy networks or fuzzy-based ones such as type-2 fuzzy sets and Takagi-Sugeno rules follow at a large distance (12%, 9%, and 7%, respectively), but with almost no impact in robotic-centered publications.

Although these topics are still open, nowadays the focus in robotics is moving to other higher-level fields (third stage), like perception, learning of complex behaviors, or human–robot interaction. Perception requirements are not just the construction of occupancy or feature-based maps, but the recognition of objects, the classification of objects, the identification of actions, etc.; in summary, scene understanding. Moreover, perception has to combine different sources of information, with visual and volumetric data being the two main sources. Contributions from fuzzy techniques are still few in number, but from our point of view, they can contribute to this topic and will surely do so in those cases where high-level reasoning is required, and also in the description of scenes.

From the point of view of human–robot interaction, there are two directions in which fuzzy logic may also contribute significantly. The first one is the interpretation of the emotional state of the people interacting with the robot. This interpretation uses several information sources (visual, acoustic, etc.), requires expert knowledge to build the classification rules, and the kind of uncertainty of the data could be adequately modeled with fuzzy sets. The second direction is the expressiveness of the robot, which will be fundamental for social robotics. Again, and for the same reasons as for the previous topic, fuzzy logic approaches may generate significant contributions in the field.

# Foundations

Andrzej Skowron, Andrzej Jankowski, Roman W. Swiniarski (deceased)

The rough set ([RS](#)) approach was proposed by Pawlak as a tool to deal with imperfect knowledge. Over the years the approach has attracted attention of many researchers and practitioners all over the world, who have contributed essentially to its development and applications. This chapter discusses the [RS](#) foundations from rudiments to challenges.

## 21.1 Rough Sets: Comments on Development

The rough set ([RS](#)) approach was proposed by *Zdzisław Pawlak* in 1982 [21.1, 2] as a tool for dealing with imperfect knowledge, in particular with vague concepts. Many applications of methods based on rough set theory alone or in combination with other approaches have been developed. This chapter discusses the [RS](#) foundations from rudiments to challenges.

In the development of rough set theory and applications, one can distinguish three main stages. While the first period was based on the assumption that objects are perceived by means of partial information represented by attributes, in the second period it was assumed that information about the approximated concepts is also partial. Approximation spaces and searching strategies for relevant approximation spaces were recognized as the basic tools for rough sets. Important achievements both in theory and applications were obtained. Nowadays, a new period for rough sets is emerging, which is also briefly characterized in this chapter.

The rough set approach seems to be of fundamental importance in artificial intelligence [AI](#) and cognitive sciences, especially in machine learning, data mining,

knowledge discovery from databases, pattern recognition, decision support systems, expert systems, intelligent systems, multiagent systems, adaptive systems, autonomous systems, inductive reasoning, common-sense reasoning, adaptive judgment, conflict analysis.

Rough sets have established relationships with many other approaches such as fuzzy set theory, granular computing ([GC](#)), evidence theory, formal concept analysis, (approximate) Boolean reasoning, multicriteria decision analysis, statistical methods, decision theory, and matroids. Despite the overlap with many other theories rough set theory may be considered as an independent discipline in its own right. There are reports on many hybrid methods obtained by combining rough sets with other approaches such as soft computing (fuzzy sets, neural networks, genetic algorithms), statistics, natural computing, mereology, principal component analysis, singular value decomposition, or support vector machines.

The main advantage of rough set theory in data analysis is that it does not necessarily need any preliminary or additional information about data like probability distributions in statistics, basic probability assignments

in evidence theory, a grade of membership, or the value of possibility in fuzzy set theory.

One can observe the following advantages about the rough set approach:

- i) Introduction of efficient algorithms for finding hidden patterns in data.
- ii) Determination of optimal sets of data (data reduction); evaluation of the significance of data.
- iii) Generation of sets of decision rules from data.
- iv) Easy-to-understand formulation.
- v) Straightforward interpretation of results obtained.
- vi) Suitability of many of its algorithms for parallel processing.

Due to space limitations, many important research topics in rough set theory such as various logics related to rough sets and many advanced algebraic properties of rough sets are only mentioned briefly in this chapter.

From the same reason, we herein restrict the references on rough sets to the basic papers by *Zdzisław Pawlak* (such as [21.1, 2]), some survey papers [21.3–5], and some books including long lists of references to papers on rough sets. The basic ideas of rough set theory and its extensions as well as many interesting applications can be found in a number of books, issues

of *Transactions on Rough Sets*, special issues of other journals, numerous proceedings of international conferences, and tutorials [21.3, 6, 7]. The reader is referred to the cited books and papers, references therein, as well as to web pages [21.8, 9].

The chapter is structured as follows. In Sect. 21.2 we discuss some basic issues related to vagueness and vague concepts. The rough set philosophy is outlined in Sect. 21.3. The basic concepts for rough sets such as indiscernibility and approximation are presented in Sect. 21.4. Decision systems and rules are covered in Sect. 21.5. The basic information about dependencies is included in Sect. 21.6. Attribute reduction belonging to one of the basic problems of rough sets is discussed in Sect. 21.7. Rough membership function as a tool for measuring degrees of inclusion of sets is presented in Sect. 21.8. The role of discernibility and Boolean reasoning for solving problems related to rough sets is briefly explained in Sect. 21.9. In Sect. 21.10 a short discussion on rough sets and induction is included. Several generalizations of the approach proposed by Pawlak are discussed in Sect. 21.11. In this section some emerging research directions related to rough sets are also outlined. In Sect. 21.12 some comments about logics based on rough sets are included. The role of adaptive judgment is emphasized.

## 21.2 Vague Concepts

Mathematics requires that all mathematical notions (including sets) must be exact, otherwise precise reasoning would be impossible. However, philosophers [21.10], and recently computer scientists as well as other researchers, have become interested in *vague* (imprecise) concepts. Moreover, in the twentieth century one can observe the drift paradigms in modern science from dealing with precise concepts to vague concepts, especially in the case of complex systems (e.g., in economy, biology, psychology, sociology, and quantum mechanics).

In classical set theory, a set is uniquely determined by its elements. In other words, this means that every element must be uniquely classified as belonging to the set or not. That is to say the notion of a set is a *crisp* (precise) one. For example, the set of odd numbers is crisp because every integer is either odd or even.

In contrast to odd numbers, the notion of a beautiful painting is vague, because we are unable to classify uniquely all paintings into two classes: *beautiful* and

*not beautiful*. With some paintings it cannot be decided whether they are beautiful or not and thus they remain in the doubtful area. Thus, *beauty* is not a precise but a vague concept.

Almost all concepts that we use in natural language are vague. Therefore, common sense reasoning based on natural language must be based on vague concepts and not on classical logic. An interesting discussion of this issue can be found in [21.11]. The idea of vagueness can be traced back to the ancient Greek philosopher Eubulides of Megara (ca. 400 BC) who first formulated the so-called *sorites* (heap) and *falakros* (bald man) paradoxes [21.10]. There is a huge literature on issues related to vagueness and vague concepts in philosophy [21.10].

Vagueness is often associated with the boundary region approach (i.e., existence of objects which cannot be uniquely classified relative to a set or its complement), which was first formulated in 1893 by the father of modern logic, the German logician, *Gottlob Frege* (1848–1925) ([21.12]). According to Frege the concept

must have a sharp boundary. To the concept without a sharp boundary there would correspond an area that would not have any sharp boundary line all around. This means that mathematics must use crisp, not vague concepts, otherwise it would be impossible to reason precisely.

One should also note that vagueness also relates to insufficient specificity, as the result of a lack of feasible searching methods for sets of features adequately

describing concepts. A discussion on vague (imprecise) concepts in philosophy includes their following characteristic features [21.10]: (i) the presence of borderline cases, (ii) boundary regions of vague concepts are not crisp, (iii) vague concepts are susceptible to sorites paradoxes. In the sequel we discuss the first two issues in the RS framework. The reader can find a discussion on the application of the RS approach to the third item in [21.11].

## 21.3 Rough Set Philosophy

Rough set philosophy is founded on the assumption that with every object of the universe of discourse we associate some information (data, knowledge). For example, if objects are patients suffering from a certain disease, symptoms of the disease form information about the patients. Objects characterized by the same information are indiscernible (similar) in view of the available information about them.

The *indiscernibility relation* generated in this way is the mathematical basis of rough set theory. This understanding of indiscernibility is related to the idea of *Gottfried Wilhelm Leibniz* that objects are indiscernible if and only if all available functionals take identical values on them (Leibniz's law of indiscernibility: the identity of indiscernibles) [21.13]. However, in the rough set approach indiscernibility is defined relative to a given set of functionals (attributes).

Any set of all indiscernible (similar) objects is called an elementary set and forms a basic granule (atom) of knowledge about the universe. Any union of some elementary sets is referred to as a *crisp* (precise) set. If a set is not crisp, then it is called *rough* (imprecise, vague). Consequently, each rough set has *borderline cases (boundary-line)*, i.e., objects which cannot be classified with certainty as members of either the set or its complement. Obviously, crisp sets have no borderline elements at all. This means that borderline cases cannot be properly classified by employing available knowledge.

Thus, the assumption that objects can be *seen* only through the information available about them leads to

the view that knowledge has granular structure. Due to the granularity of knowledge, some objects of interest cannot be discerned and appear as the same (or similar). As a consequence, vague concepts in contrast to precise concepts, cannot be characterized in terms of information about their elements. Therefore, in the proposed approach, we assume that any vague concept is replaced by a pair of precise concepts – called the lower and the upper approximation of the vague concept. The lower approximation consists of all objects which definitely belong to the concept and the upper approximation contains all objects which possibly belong to the concept. The difference between the upper and the lower approximation constitutes the boundary region of the vague concept. Approximation operations are the basic operations in rough set theory. Properties of the boundary region (expressed, e.g., by the rough membership function) are important in the rough set methods.

Hence, rough set theory expresses vagueness not by means of membership, but by employing a boundary region of a set. If the boundary region of a set is empty it means that the set is crisp, otherwise the set is rough (inexact). A nonempty boundary region of a set means that our knowledge about the set is not sufficient to define the set precisely.

Rough set theory is not an alternative to classical set theory but it is embedded in it. Rough set theory can be viewed as a specific implementation of Frege's idea of vagueness, i.e., imprecision in this approach is expressed by a boundary region of a set.

## 21.4 Indiscernibility and Approximation

The starting point of rough set theory is the indiscernibility relation, which is generated by information about objects of interest (Sect. 21.1). The indiscernibility rela-

tion expresses the fact that due to a lack of information (or knowledge) we are unable to discern some objects by employing available information (or knowledge).

This means that, in general, we are unable to deal with each particular object but we have to consider granules (clusters) of indiscernible objects as a fundamental basis for our theory.

From a practical point of view, it is better to define basic concepts of this theory in terms of data. Therefore, we will start our considerations from a data set called an *information system*. An information system can be represented by a data table containing rows labeled by objects of interest and columns labeled by attributes and entries of the table are attribute values. For example, a data table can describe a set of patients in a hospital. The patients can be characterized by some attributes, like *age*, *sex*, *blood pressure*, *body temperature*, etc. With every attribute a set of its values is associated, e.g., values of the attribute *age* can be *young*, *middle*, and *old*. Attribute values can also be numerical. In data analysis the basic problem that we are interested in is to find patterns in data, i.e., to find a relationship between some set of attributes, e.g., we might be interested whether *blood pressure* depends on *age* and *sex*.

More formally, suppose we are given a pair  $\mathcal{A} = (U, A)$  of nonempty, finite sets  $U$  and  $A$ , where  $U$  is the *universe of objects*, and an  $A$ - $a$  set consisting of *attributes*, i.e., functions  $a: U \rightarrow V_a$ , where  $V_a$  is the set of values of attribute  $a$ , called the *domain of  $a$* . The pair  $\mathcal{A} = (U, A)$  is called an *information system*. Any information system can be represented by a data table with rows labeled by objects and columns labeled by attributes. Any pair  $(x, a)$ , where  $x \in U$  and  $a \in A$  defines the table entry consisting of the value  $a(x)$ . Note that in statistics or machine learning such a data table is called a sample [21.14].

Any subset  $B$  of  $A$  determines a binary relation  $\text{IND}(B)$  on  $U$ , called an *indiscernibility relation*, defined by

$$\begin{aligned} x\text{IND}(B)y \text{ if and only if } \\ a(x) = a(y) \text{ for every } a \in B, \end{aligned} \quad (21.1)$$

where  $a(x)$  denotes the value of attribute  $a$  for the object  $x$ .

Obviously,  $\text{IND}(B)$  is an equivalence relation. The family of all equivalence classes of  $\text{IND}(B)$ , i.e., the partition determined by  $B$ , will be denoted by  $U/\text{IND}(B)$ , or simply  $U/B$ ; the equivalence class of  $\text{IND}(B)$ , i.e., the block of the partition  $U/B$ , containing  $x$  will be denoted by  $B(x)$  (other notation used:  $[x]_B$  or  $[x]_{\text{IND}(B)}$ ). Thus in view of the data we are unable, in

general, to observe individual objects but we are forced to reason only about the accessible granules of knowledge.

If  $(x, y) \in \text{IND}(B)$  we will say that  $x$  and  $y$  are *B-indiscernible*. Equivalence classes of the relation  $\text{IND}(B)$  (or blocks of the partition  $U/B$ ) are referred to as *B-elementary sets* or *B-elementary granules*. In the rough set approach the elementary sets are the basic building blocks (concepts) of our knowledge about reality. The unions of *B-elementary sets* are called *B-definable sets*. Let us note that in applications we consider only some subsets of the family of definable sets, e.g., defined by conjunction of descriptors only. This is due to the computational complexity of the searching problem for relevant definable sets in the whole family of definable sets.

For  $B \subseteq A$ , we denote by  $\text{Inf}_B(x)$  the *B-signature* of  $x \in U$ , i.e., the set  $\{(a, a(x)): a \in B\}$ . Let  $\text{INF}(B) = \{\text{Inf}_B(x): x \in U\}$ . Then for any objects  $x, y \in U$  the following equivalence holds:  $x\text{IND}(B)y$  if and only if  $\text{Inf}_B(x) = \text{Inf}_B(y)$ .

The indiscernibility relation is used to define the approximations of concepts. We define the following two operations on sets  $X \subseteq U$

$$B_*(X) = \{x \in U: B(x) \subseteq X\}, \quad (21.2)$$

$$B^*(X) = \{x \in U: B(x) \cap X \neq \emptyset\}, \quad (21.3)$$

assigning to every subset  $X$  of the universe  $U$  two sets  $B_*(X)$  and  $B^*(X)$  called the *B-lower* and the *B-upper approximation* of  $X$ , respectively. The set

$$\text{BN}_B(X) = B^*(X) - B_*(X), \quad (21.4)$$

will be referred to as the *B-boundary region* of  $X$ .

From the definition we obtain the following interpretation: (i) the *lower approximation* of a set  $X$  with respect to  $B$  is the set of all objects, which can for *certain* be classified to  $X$  using  $B$  (are *certainly* in  $X$  in view of  $B$ ), (ii) the *upper approximation* of a set  $X$  with respect to  $B$  is the set of all objects which can *possibly* be classified to  $X$  using  $B$  (are *possibly* in  $X$  in view of  $B$ ), (iii) the *boundary region* of a set  $X$  with respect to  $B$  is the set of all objects, which can be classified neither to  $X$  nor to  $\neg X$  using  $B$ .

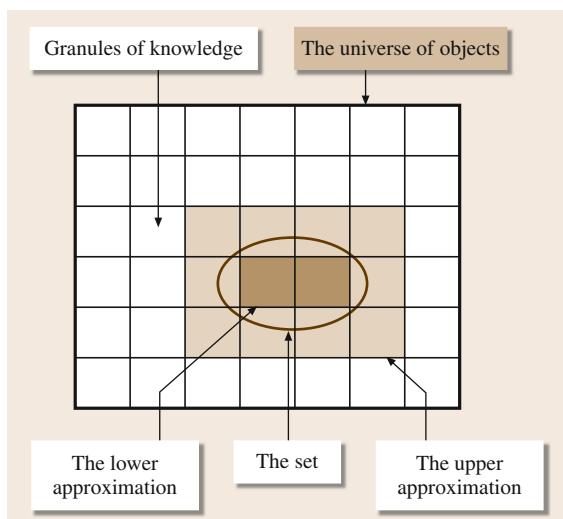

Due to the granularity of knowledge, rough sets cannot be characterized by using available knowledge. The definition of approximations is clearly depicted in Fig. 21.1.

The approximations have the following properties

$$\begin{aligned}
 B_*(X) &\subseteq X \subseteq B^*(X), \\
 B_*(\emptyset) &= B^*(\emptyset) = \emptyset, B_*(U) = B^*(U) = U, \\
 B^*(X \cup Y) &= B^*(X) \cup B^*(Y), \\
 B_*(X \cap Y) &= B_*(X) \cap B_*(Y), \\
 X \subseteq Y \text{ implies } B_*(X) &\subseteq B_*(Y) \\
 \text{and } B^*(X) &\subseteq B^*(Y), \\
 B_*(X \cup Y) &\supseteq B_*(X) \cup B_*(Y), \\
 B^*(X \cap Y) &\subseteq B^*(X) \cap B^*(Y), \\
 B_*(-X) &= -B^*(X), \\
 B^*(-X) &= -B_*(X), \\
 B_*(B_*(X)) &= B^*(B_*(X)) = B_*(X), \\
 B^*(B^*(X)) &= B_*(B^*(X)) = B^*(X). \tag{21.5}
 \end{aligned}$$

Let us note that the inclusions (for union and intersection) in (21.5) cannot, in general, be substituted by the equalities. This has some important algorithmic and logical consequences.

Now we are ready to give the definition of rough sets. If the boundary region of  $X$  is the empty set, i.e.,  $\text{BN}_B(X) = \emptyset$ , then the set  $X$  is *crisp (exact)* with respect to  $B$ ; in the opposite case, i.e., if  $\text{BN}_B(X) \neq \emptyset$ , the set  $X$  is referred to as *rough (inexact)* with respect to  $B$ . Thus any rough set, in contrast to a crisp set, has a nonempty boundary region. This is the idea of vagueness proposed by Frege.

**Fig. 21.1** A rough set

Let us observe that the definition of rough sets refers to data (knowledge), and is *subjective*, in contrast to the definition of classical sets, which is in some sense an *objective* one.

A rough set can also be characterized numerically by the following coefficient

$$\alpha_B(X) = \frac{\text{card}(B_*(X))}{\text{card}(B^*(X))}, \tag{21.6}$$

called the *accuracy of approximation*, where  $X \neq \emptyset$  and  $\text{card}(X)$  denotes the cardinality of  $X$ . Obviously  $0 \leq \alpha_B(X) \leq 1$ . If  $\alpha_B(X) = 1$  then  $X$  is *crisp* with respect to  $B$  ( $X$  is *precise* with respect to  $B$ ), and otherwise, if  $\alpha_B(X) < 1$  then  $X$  is *rough* with respect to  $B$  ( $X$  is *vague* with respect to  $B$ ). The accuracy of approximation can be used to measure the quality of approximation of decision classes on the universe  $U$ . One can use another measure of accuracy defined by  $1 - \alpha_B(X)$  or by

$$1 - \frac{\text{card}(\text{BN}_B(X))}{\text{card}(U)}.$$

Some other measures of approximation accuracy are also used, e.g., based on entropy or some more specific properties of boundary regions. The choice of a relevant accuracy of approximation depends on a particular data set. Observe that the accuracy of approximation of  $X$  can be tuned by  $B$ . Another approach to the accuracy of approximation can be based on the variable precision rough set model (VPRSM).

In [21.10], it is stressed that boundaries of vague concepts are not crisp. In the definition presented in this chapter, the notion of boundary region is defined as a crisp set  $\text{BN}_B(X)$ . However, let us observe that this definition is relative to the subjective knowledge expressed by attributes from  $B$ . Different sources of information may use different sets of attributes for concept approximation. Hence, the boundary region can change when we consider these different views. Another reason for boundary change may be related to incomplete information about concepts. They are known only on samples of objects. Hence, when new objects appear again the boundary region may change. From the discussion in the literature it follows that vague concepts cannot be approximated with satisfactory quality by *static* constructs such as induced membership inclusion functions, approximations, or models derived, e.g., from a sample. An understanding of vague concepts can be only realized in a process in which the induced models adaptively

match the concepts in dynamically changing environments. This conclusion seems to have important consequences for the further development of rough set

theory in combination with fuzzy sets and other soft computing paradigms for adaptive approximate reasoning.

## 21.5 Decision Systems and Decision Rules

In this section, we discuss the decision rules (constructed over a selected set  $B$  of features or a family of sets of features), which are used in inducing classification algorithms (classifiers), making it possible to classify unseen objects to decision classes. Parameters which are tuned in searching for a classifier with high quality are its description size (defined, e.g., by used decision rules) and its quality of classification (measured, e.g., by the number of misclassified objects on a given set of objects). By selecting a proper balance between the accuracy of classification and the description size one can search for classifier with a high quality of classification also on testing objects. This approach is based on the minimum description length principle (**MDL**) [21.15].

In an information system  $\mathcal{A} = (U, A)$  we sometimes distinguish a partition of  $A$  into two disjoint classes  $C, D \subseteq A$  of attributes, called *condition* and *decision (action)* attributes, respectively. The tuple  $\mathcal{A} = (U, C, D)$  is called a *decision system* (or a *decision table*).

Let  $V = \bigcup\{V_a : a \in C\} \cup \bigcup\{V_d : d \in D\}$ . Atomic formulae over  $B \subseteq C \cup D$  and  $V$  are expressions  $a = v$  called *descriptors (selectors) over B and V*, where  $a \in B$  and  $v \in V_a$ . The set of formulae over  $B$  and  $V$ , denoted by  $\mathcal{F}(B, V)$ , is the least set containing all atomic formulae over  $B$  and  $V$  and closed under the propositional connectives  $\wedge$  (conjunction),  $\vee$  (disjunction) and  $\neg$  (negation). By  $\|\varphi\|_{\mathcal{A}}$  we denote the meaning of  $\varphi \in \mathcal{F}(B, V)$  in the decision system  $\mathcal{A}$ , which is the set of all objects in  $U$  with the property  $\varphi$ . These sets are defined by

$$\begin{aligned}\|a = v\|_{\mathcal{A}} &= \{x \in U \mid a(x) = v\}, \\ \|\varphi \wedge \varphi'\|_{\mathcal{A}} &= \|\varphi\|_{\mathcal{A}} \cap \|\varphi'\|_{\mathcal{A}}; \\ \|\varphi \vee \varphi'\|_{\mathcal{A}} &= \|\varphi\|_{\mathcal{A}} \cup \|\varphi'\|_{\mathcal{A}}; \\ \|\neg\varphi\|_{\mathcal{A}} &= U - \|\varphi\|_{\mathcal{A}}.\end{aligned}$$

The formulae from  $\mathcal{F}(C, V)$ ,  $\mathcal{F}(D, V)$  are called *condition formulae of  $\mathcal{A}$*  and *decision formulae of  $\mathcal{A}$* , respectively.

Any object  $x \in U$  belongs to the *decision class*  $\|\bigwedge_{d \in D} d = d(x)\|_{\mathcal{A}}$  of  $\mathcal{A}$ . All decision classes of  $\mathcal{A}$  create a partition  $U/D$  of the universe  $U$ .

A *decision rule* for  $\mathcal{A}$  is any expression of the form  $\varphi \Rightarrow \psi$ , where  $\varphi \in \mathcal{F}(C, V)$ ,  $\psi \in \mathcal{F}(D, V)$ , and  $\|\varphi\|_{\mathcal{A}} \neq \emptyset$ . Formulae  $\varphi$  and  $\psi$  are referred to as the *predecessor* and the *successor* of decision rule  $\varphi \Rightarrow \psi$ . Decision rules are often called *IF ... THEN ...* rules. Such rules are used in machine learning.

Decision rule  $\varphi \Rightarrow \psi$  is *true* in  $\mathcal{A}$  if and only if  $\|\varphi\|_{\mathcal{A}} \subseteq \|\psi\|_{\mathcal{A}}$ . Otherwise, one can measure its *truth degree* by introducing some inclusion measure of  $\|\varphi\|_{\mathcal{A}}$  in  $\|\psi\|_{\mathcal{A}}$ . Let us denote by  $\text{card}_{\mathcal{A}}(\varphi)$  (or  $\text{card}(\varphi)$ , if this does not lead to confusion) the number of objects from  $U$  that satisfies formula  $\varphi$ , i. e., the cardinality of  $\|\varphi\|_{\mathcal{A}}$ . According to Łukasiewicz [21.16], one can assign to formula  $\varphi$  the value

$$\frac{\text{card}(\varphi)}{\text{card}(U)},$$

and to the implication  $\varphi \Rightarrow \psi$  the fractional value

$$\frac{\text{card}(\varphi \wedge \psi)}{\text{card}(\varphi)},$$

under the assumption that  $\|\varphi\|_{\mathcal{A}} \neq \emptyset$ . The fractional part proposed by Łukasiewicz was adapted much later by machine learning and data mining community, e.g., in the definitions of the accuracy of decision rules or confidence of association rules.

For any decision system  $\mathcal{A} = (U, C, D)$  one can consider a *generalized decision* function  $\delta_{\mathcal{A}}: U \rightarrow \text{POW}(\text{INF}(D))$ , where for any  $x \in U$ ,  $\delta_{\mathcal{A}}(x)$  is the set of all  $D$ -signatures of objects from  $U$  which are  $C$ -indiscernible with  $x$ ,  $A = C \cup D$  and  $\text{POW}(\text{INF}(D))$  is the powerset of the set  $\text{INF}(D)$  of all possible decision signatures.

The decision system  $\mathcal{A}$  is called *consistent (deterministic)*, if  $\text{card}(\delta_{\mathcal{A}}(x)) = 1$ , for any  $x \in U$ . Otherwise  $\mathcal{A}$  is said to be *inconsistent (nondeterministic)*. Hence, a decision system is inconsistent if it consists

of some objects with different decisions but that are indiscernible with respect to condition attributes. Any set consisting of all objects with the same generalized decision value is called a *generalized decision class*.

Now, one can consider certain (possible) rules for decision classes defined by the lower (upper) approximations of such generalized decision classes of  $\mathcal{A}$ . This approach can be extended by using the relationships of rough sets with the evidence theory (Dempster–Shafer

theory) by considering rules relative to decision classes defined by the lower approximations of unions of decision classes of  $\mathcal{A}$ .

Numerous methods have been developed for the generation of different types of decision rules, and the reader is referred to the literature on rough sets for details. Usually, one is searching for decision rules that are (semi) optimal with respect to some optimization criteria describing the quality of decision rules in concept approximations.

## 21.6 Dependencies

Another important issue in data analysis is discovering dependencies between attributes in a given decision system  $\mathcal{A} = (U, C, D)$ . Intuitively, a set of attributes  $D$  depends totally on a set of attributes  $C$ , denoted  $C \Rightarrow D$ , if the values of attributes from  $C$  uniquely determine the values of attributes from  $D$ . In other words,  $D$  depends totally on  $C$ , if there exists a functional dependency between values of  $C$  and  $D$ .

$D$  can depend partially on  $C$ . Formally such a dependency can be defined in the following way. We will say that  $D$  depends on  $C$  to a degree  $k$  ( $0 \leq k \leq 1$ ), denoted by  $C \Rightarrow_k D$ , if

$$k = \gamma(C, D) = \frac{\text{card}(\text{POS}_C(D))}{\text{card}(U)}, \quad (21.7)$$

where

$$\text{POS}_C(D) = \bigcup_{X \in U/D} C_*(X), \quad (21.8)$$

which is called a *positive region* of the partition  $U/D$  with respect to  $C$ , is the set of all elements of  $U$  that can

be uniquely classified to blocks of the partition  $U/D$ , by means of  $C$ .

If  $k = 1$ , we say that  $D$  depends totally on  $C$ , and if  $k < 1$ , we say that  $D$  depends partially (to degree  $k$ ) on  $C$ . If  $k = 0$ , then the *positive region* of the partition  $U/D$  with respect to  $C$  is empty.

The coefficient  $k$  expresses the ratio of all elements of the universe, which can be properly classified to blocks of the partition  $U/D$ , employing attributes  $C$  and is called the *degree of the dependency*.

It can be easily seen that if  $D$  depends totally on  $C$ , then  $\text{IND}(C) \subseteq \text{IND}(D)$ . This means that the partition generated by  $C$  is finer than the partition generated by  $D$ .

Summing up:  $D$  is totally (partially) dependent on  $C$ , if all (some) elements of the universe  $U$  can be uniquely classified to blocks of the partition  $U/D$ , employing  $C$ . Observe that (21.7) defines only one of the possible measures of dependency between attributes. Note that one can consider dependencies between arbitrary subsets of attributes in the same way. One also can compare the dependency discussed in this section with dependencies considered in databases.

## 21.7 Reduction of Attributes

We often face the question as to whether we can remove some data from a data table and still preserve its basic properties, that is – whether a table contains some superfluous data. Let us express this idea more precisely.

Let  $C, D \subseteq A$  be sets of condition and decision attributes, respectively. We will say that  $C' \subseteq C$  is a  $D$ -reduct (reduct with respect to  $D$ ) of  $C$ , if  $C'$  is a minimal

subset of  $C$  such that

$$\gamma(C, D) = \gamma(C', D). \quad (21.9)$$

The intersection of all  $D$ -reducts is called a  $D$ -core (core with respect to  $D$ ). Because the core is the intersection of all reducts, it is included in every reduct, i.e., each element of the core belongs to some reduct.

Thus, in a sense, the core is the most important subset of attributes, since none of its elements can be removed without affecting the classification power of attributes. Certainly, the geometry of reducts can be more complex. For example, the core can be empty but there can exist a partition of reducts into a few sets with nonempty intersection.

Many other kinds of reducts and their approximations have been discussed in the literature. They are defined relative to different quality measures. For example, if one changes the condition (21.9) to  $\partial_A(x) = \partial_B(x)$ , (where  $A = C \cup D$  and  $B = C' \cup D$ ), then the defined reducts preserve the generalized decision. Other kinds of reducts preserve, e.g., (i) the distance between attribute value vectors for any two objects, if this distance is greater than a given threshold, (ii) the distance between entropy distributions between any two objects, if this distance exceeds a given. Yet another kind of reducts is defined by the so-called reducts relative to object used for the generation of decision rules.

Reducts are used for building data models. Choosing a particular reduct or a set of reducts has an impact on the model size as well as on its quality in describing a given data set. The model size together with the model quality are two basic components tuned in selecting relevant data models. This is known as the minimum length principle. Selection of relevant kinds of reducts is an important step in building data models. It turns out that the different kinds of reducts can be efficiently computed using heuristics based, e.g., on the Boolean reasoning approach.

Let us note that analogously to the information flow [21.17] one can consider different theories over information or decision systems representing different views on knowledge encoded in the systems. In particular, this approach was used for inducing concurrent models from data tables. For more details the reader is referred to the books cited at the beginning of the chapter.

## 21.8 Rough Membership

Let us observe that rough sets can be also defined employing the rough membership function (21.10) instead of approximation. That is, consider

$$\mu_X^B: U \rightarrow [0, 1],$$

defined by

$$\mu_X^B(x) = \frac{\text{card}(B(x) \cap X)}{\text{card}(B(x))}, \quad (21.10)$$

where  $x \in X \subseteq U$ . The value  $\mu_X^B(x)$  can be interpreted as the degree that  $x$  belongs to  $X$  in view of knowledge about  $x$  expressed by  $B$  or the degree to which the elementary granule  $B(x)$  is included in the set  $X$ . This means that the definition reflects a subjective knowledge about elements of the universe, in contrast to the classical definition of a set related to objective knowledge.

Rough membership function can also be interpreted as the conditional probability that  $x$  belongs to  $X$  given  $B$ . One may refer to Bayes' theorem as the origin of this function. This interpretation was used by several researchers in the rough set community.

One can observe that the rough membership function has the following properties:

- 1)  $\mu_X^B(x) = 1$  iff  $x \in B_*(X)$ ,
- 2)  $\mu_X^B(x) = 0$  iff  $x \in U - B^*(X)$ ,
- 3)  $0 < \mu_X^B(x) < 1$  iff  $x \in \text{BN}_B(X)$ ,
- 4)  $\mu_{U-X}^B(x) = 1 - \mu_X^B(x)$  for any  $x \in U$ ,
- 5)  $\mu_{X \cup Y}^B(x) \geq \max(\mu_X^B(x), \mu_Y^B(x))$  for any  $x \in U$ ,
- 6)  $\mu_{X \cap Y}^B(x) \leq \min(\mu_X^B(x), \mu_Y^B(x))$  for any  $x \in U$ .

From the properties it follows that the rough membership differs essentially from the fuzzy membership [21.18], for properties 5) and 6) show that the membership for union and intersection of sets, in general, cannot be computed – as in the case of fuzzy sets – from their constituents' membership. Thus formally rough membership is different from fuzzy membership. Moreover, the rough membership function depends on available knowledge (represented by attributes from  $B$ ). Besides, the rough membership function, in contrast to the fuzzy membership function, has a probabilistic flavor.

Let us also mention that rough set theory, in contrast to fuzzy set theory, clearly distinguishes two very important concepts, vagueness and uncertainty, very often confused in the AI literature. Vagueness is the property of concepts. Vague concepts can be approximated using the rough set approach. Uncertainty is the property of elements of a set or a set itself (e.g.,

only examples and/or counterexamples of elements of a considered set are given). Uncertainty of elements of a set can be expressed by the rough membership function.

Both fuzzy and rough set theory represent two different approaches to vagueness. Fuzzy set theory addresses *gradualness* of knowledge, expressed by the fuzzy membership, whereas rough set theory addresses *granularity* of knowledge, expressed by the indiscernibility relation. One can also cope with knowledge gradualness using the rough membership. A nice illustration of this difference was given by Dider Dubois and

Henri Prade in their example related to image processing, where fuzzy set theory refers to gradualness of gray level, whereas rough set theory is about the size of pixels.

Consequently, these theories do not compete with each other but are rather complementary. In particular, the rough set approach provides tools for approximate construction of fuzzy membership functions. The rough-fuzzy hybridization approach has proved to be successful in many applications. An interesting discussion of fuzzy and rough set theory in the approach to vagueness can be found in [21.11].

## 21.9 Discernibility and Boolean Reasoning

The discernibility relations are closely related to indiscernibility relations and belong to the most important relations considered in rough set theory. Tools for discovering and classifying patterns are based on *reasoning schemes* rooted in various paradigms. Such patterns can be extracted from data by means of methods based, e.g., on discernibility and Boolean reasoning.

The ability to discern between perceived objects is important for constructing many entities like reducts, decision rules, or decision algorithms. In the standard approach the discernibility relation  $\text{DIS}(B) \subseteq U \times U$  is defined by  $x\text{DIS}(B)y$  if and only if  $\text{non}(x\text{IND}(B)y)$ , i.e.,  $B(x) \cap B(y) = \emptyset$ . However, this is, in general, not the case for generalized approximation spaces.

The idea of Boolean reasoning is based on the construction for a given problem  $P$  of a corresponding Boolean function  $f_P$  with the following property: the solutions for the problem  $P$  can be decoded from prime implicants of the Boolean function  $f_P$  [21.19–21]. Let us mention that to solve real-life problems it is necessary to deal with very large Boolean functions.

A successful methodology based on the discernibility of objects and Boolean reasoning has been developed for computing many important ingredients for applications. These applications include generation of reducts and their approximations, decision rules, association rules, discretization of real-valued attributes, symbolic value grouping, searching for new features defined by oblique hyperplanes or higher-order surfaces, pattern extraction from data, as well as conflict resolution or negotiation [21.4, 6].

Most of the problems related to the generation of the above-mentioned entities are NP-complete or NP-hard. However, it was possible to develop efficient heuris-

tics returning suboptimal solutions of the problems. The results of experiments on many data sets are very promising. They show very good quality of solutions generated by the heuristics in comparison with other methods reported in the literature (e.g., with respect to the classification quality of unseen objects). Moreover, they are very efficient from the point of view of the time necessary to compute the solution. Many of these methods are based on discernibility matrices. However, it is possible to compute the necessary information about these matrices without their explicit construction (i.e., by sorting or hashing original data).

It is important to note that the methodology makes it possible to construct heuristics with a very important *approximation property*, which can be formulated as follows: expressions, called *approximate implicants*, generated by heuristics that are *close* to prime implicants define approximate solutions for the problem.

Mining large data sets is one of the biggest challenges in knowledge discovery and data mining (**KDD**). In many practical applications, there is a need for data mining algorithms running on terminals of a client-server database system where the only access to database (located in the server) is enabled by queries in structured query language (**SQL**).

Let us consider two illustrative examples of problems for large data sets: (i) searching for short reducts, (ii) searching for best partitions defined by cuts on continuous attributes. In both cases, the traditional implementations of rough sets and Boolean reasoning-based methods are characterized by a high computational cost. The critical factor for the time complexity of algorithms solving the discussed problems is the number of data access operations. Fortunately some efficient modifi-

cations of the original algorithms were proposed by relying on concurrent retrieval of higher-level statistics, which are sufficient for the heuristic search of reducts

and partitions [21.4, 6]. The rough set approach was also applied in the development of other scalable big data processing techniques (e.g., [21.22]).

## 21.10 Rough Sets and Induction

The rough set approach is strongly related to inductive reasoning (e.g., in rough set-based methods for inducing classifiers or clusters [21.6]). The general idea for inducing classifiers is as follows. From a given decision table a set of granules in the form of decision rules is induced together with arguments *for* and *against* each decision rule and decision class. For any new object with known signature one can select rules matching this object. Note that the left-hand sides of decision rules are described by formulae that make it possible to check for new objects if they satisfy them assuming that the signatures of these objects are known. In this way, one can consider two semantics of formulae: on a sample of objects  $U$  and on its extension  $U^* \supseteq U$ . Definitely, one should consider a risk related to such generalization, e.g., in the decision rule induction. Next, a conflict resolution should be applied to resolve conflicts between matched rules by new object voting for different decisions. In the rough set approach, the process of inducing classifiers can be considered as the process of inducing approximations of concepts over

extensions of approximation spaces (defined over samples of objects represented by decision systems). The whole procedure can be generalized for the case of approximation of more complex information granules. It is worthwhile mentioning that approaches for inducing approximate reasoning schemes have also been developed.

A typical approach in machine learning is based on inducing classifiers from samples of objects. These classifiers are used for prediction decisions on objects unseen so far, if only the signatures of these objects are available. This approach can be called global, i.e., leading to decision extension from a given sample of objects on the whole universe of objects. This global approach has some drawbacks (see the Epilog in [21.23]). Instead of this one can try to use transduction [21.23], semi-supervised learning, induced local models relative to new objects, or adaptive learning strategies. However, we are still far away from fully understanding the discovery processes behind such generalization strategies [21.24].

## 21.11 Rough Set-Based Generalizations

The original approach by Pawlak was based on indiscernibility defined by equivalence relations. Any such indiscernibility relation defines a partition of the universe of objects. Over the years many generalizations of this approach were introduced, many of which are based on coverings rather than partitions. In particular, one can consider the similarity (tolerance)-based rough set approach, binary relation based rough sets, neighborhood and covering rough sets, the dominance-based rough set approach, hybridization of rough sets and fuzzy sets, and many others.

One should note that dealing with coverings requires solving several new algorithmic problems such as the selection of family of definable sets or resolving problems with the selection of the relevant definition of the approximation of sets among many possible ones. One should also note that for a given problem (e.g.,

classification problem) one should discover the relevant covering for the target classification task. In the literature there are numerous papers dedicated to theoretical aspects of the covering rough set approach. However, still much more work should be done on rather hard algorithmic issues, e.g., for the relevant covering discovery.

Another issue to be solved is related to inclusion measures. Parameters of such measures are tuned in inducing of the high quality approximations. Usually, this is done on the basis of the minimum description length principle. In particular, approximation spaces with rough inclusion measures have been investigated. This approach was further extended to the rough mereological approach. More general cases of approximation spaces with rough inclusion have also been discussed in the literature, including approximation spaces in GC.

Finally, it is worthwhile mentioning the approach for ontology approximation used in hierarchical learning of complex vague concepts [21.6].

In this section, we discuss in more detail some issues related to the above-mentioned generalizations. Several generalizations of the classical rough set approach based on approximation spaces defined as pairs of the form  $(U, R)$ , where  $R$  is the equivalence relation (called indiscernibility relation) on the set  $U$ , have been reported in the literature. They are related to different views on important components used in the definition of rough sets. In the definition of rough sets different kinds of structural sets that are examples of information granules are used. From mathematical point of view, one may treat them as sets defined over the hierarchy of the powerset of objects. Among them are the following ones:

- Elementary granules (neighborhoods) of objects (e.g., similarity, tolerance, dominance neighborhoods, fuzzy neighborhoods, rough-fuzzy neighborhoods, fuzzy rough neighborhoods, families of neighborhoods).
- Granules defined by accessible information about objects (e.g., only partial information on the signature of objects may be accessible).
- Methods for the definition of higher-order information granules (e.g., defined by the left-hand sides of induced decision rules or clusters of similar information granules).
- Inclusion measures making it possible to define the degrees of inclusion and/or closeness between information granules (e.g., the degrees of inclusion granules defined by accessible information about objects into elementary granules).
- Aggregation methods of inclusion or/and closeness degrees.
- Methods for the definition of approximation operations, including strategies for extension of approximations from samples of objects to larger sets of objects.
- Algebraic structures of approximation spaces.

Let us consider some examples of generalizations of the rough set approach proposed by Pawlak in 1982.

A generalized approximation space [21.25] can be defined by a tuple  $\mathcal{AS} = (U, I, \nu)$ , where  $I$  is the *uncertainty function* defined on  $U$  with values in the powerset  $\text{POW}(U)$  of  $U$  ( $I(x)$  is the *neighborhood* of  $x$ ) and  $\nu$  is the *inclusion function* defined on the Cartesian product  $\text{POW}(U) \times \text{POW}(U)$  with values in the interval  $[0, 1]$

measuring the degree of inclusion of sets. The lower and upper approximation operations can be defined in  $\mathcal{AS}$  by

$$\text{LOW}(\mathcal{AS}, X) = \{x \in U : \nu(I(x), X) = 1\}, \quad (21.11)$$

$$\text{UPP}(\mathcal{AS}, X) = \{x \in U : \nu(I(x), X) > 0\}. \quad (21.12)$$

In the case considered by Pawlak [21.2],  $I(x)$  is equal to the equivalence class  $B(x)$  of the indiscernibility relation  $\text{IND}(B)$ ; in the case of the tolerance (or similarity) relation  $T \subseteq U \times U$  we take  $I(x) = [x]_T = \{y \in U : xTy\}$ , i.e.,  $I(x)$  is equal to the tolerance class of  $T$  defined by  $x$ .

The standard rough inclusion relation  $\nu_{\text{SRI}}$  is defined for  $X, Y \subseteq U$  by

$$\nu_{\text{SRI}}(X, Y) = \begin{cases} \frac{\text{card}(X \cap Y)}{\text{card}(X)}, & \text{if } X \neq \emptyset, \\ 1, & \text{otherwise.} \end{cases} \quad (21.13)$$

For applications it is important to have some constructive definitions of  $I$  and  $\nu$ .

One can consider another way to define  $I(x)$ . Usually together with  $\mathcal{AS}$  we consider some set  $\mathcal{F}$  of formulae describing sets of objects in the universe  $U$  of  $\mathcal{AS}$  defined by semantics  $\|\cdot\|_{\mathcal{AS}}$ , i.e.,  $\|\alpha\|_{\mathcal{AS}} \subseteq U$  for any  $\alpha \in \mathcal{F}$ . If  $\mathcal{AS} = (U, A)$  then we will also write  $\|\alpha\|_U$  instead of  $\|\alpha\|_{\mathcal{AS}}$ . Now, one can take the set

$$N_{\mathcal{F}}(x) = \{\alpha \in \mathcal{F} : x \in \|\alpha\|_{\mathcal{AS}}\}, \quad (21.14)$$

and  $I(x) = \{\|\alpha\|_{\mathcal{AS}} : \alpha \in N_{\mathcal{F}}(x)\}$ . Hence, more general uncertainty functions with values in  $\text{POW}(\text{POW}(U))$  can be defined and in consequence different definitions of approximations are considered. For example, one can consider the following definitions of approximation operations in this approximation space  $\mathcal{AS}$

$$\text{LOW}(\mathcal{AS}_o, X)$$

$$= \{x \in U : \nu(Y, X) = 1 \text{ for some } Y \in I(x)\}, \quad (21.15)$$

$$\text{UPP}(\mathcal{AS}_o, X)$$

$$= \{x \in U : \nu(Y, X) > 0 \text{ for any } Y \in I(x)\}. \quad (21.16)$$

There are also different forms of rough inclusion functions. Let us consider two examples. In the first example of a rough inclusion function, a threshold  $t \in (0, 0.5)$  is used to relax the degree of inclusion of sets.

The rough inclusion function  $\nu_t$  is defined by

$$\nu_t(X, Y) = \begin{cases} 1 & \text{if } \nu_{SRI}(X, Y) \geq 1-t, \\ \frac{\nu_{SRI}(X, Y) - t}{1-2t} & \text{if } t \leq \nu_{SRI}(X, Y) < 1-t, \\ 0 & \text{if } \nu_{SRI}(X, Y) \leq t. \end{cases} \quad (21.17)$$

One can obtain approximations considered in the variable precision rough set approach (**VPRSM**) by substituting in (21.12) and (21.13) the rough inclusion function  $\nu_t$  defined by (21.17) instead of  $\nu$ , assuming that  $Y$  is a decision class and  $I(x) = B(x)$  for any object  $x$ , where  $B$  is a given set of attributes. Another example of application of the standard inclusion was developed by using probabilistic decision functions. The rough inclusion relation can be also used for function approximation and relation approximation [21.25].

The approach based on inclusion functions has been generalized to the *rough mereological approach* [21.26]. The inclusion relation  $x\mu_r y$  with the intended meaning  $x$  is a part of  $y$  to a degree at least  $r$  has been taken as the basic notion of the rough mereology being a generalization of the *Leśniewski* mereology [21.27].

Usually families of approximation spaces labeled by some parameters are considered. By tuning such parameters according to chosen criteria (e.g., minimal description length) one can search for the optimal approximation space for concept approximation.

Our knowledge about the approximated concepts is often partial and uncertain. For example, concept approximation should be constructed from examples and counterexamples of objects for the concepts [21.14]. Hence, concept approximations constructed from a given sample of objects are extended, using inductive reasoning, on objects not yet observed. The rough set approach for dealing with concept approximation under such partial knowledge is now well developed.

Searching strategies for relevant approximation spaces are crucial for real-life applications. They include the discovery of uncertainty functions, inclusion measures, as well as selection of methods for approximations of decision classes and strategies for inductive extension of approximations from samples on larger sets of objects.

Approximations of concepts should be constructed under dynamically changing environments. This leads to a more complex situation where the boundary re-

gions are not crisp sets, which is consistent with the postulate of the higher-order vagueness considered by philosophers [21.10]. Different aspects of vagueness in the rough set framework have been discussed.

It is worthwhile mentioning that a rough set approach to the approximation of compound concepts has been developed. For such concepts, it is hardly possible to expect that they can be approximated with the high quality by the traditional methods [21.23, 28]. The approach is based on hierarchical learning and ontology approximation. Approximation methods of concepts in distributed environments have been developed. The reader may find surveys of algorithmic methods for concept approximation based on rough sets and Boolean reasoning in the literature.

In several papers, the problem of ontology approximation was discussed together with possible applications to approximation of compound concepts or to knowledge transfer. In any ontology [21.29] (vague) concepts and local dependencies between them are specified. Global dependencies can be derived from local dependencies. Such derivations can be used as hints in searching for relevant compound patterns (information granules) in approximation of more compound concepts from the ontology. The ontology approximation problem is one of the fundamental problems related to approximate reasoning in distributed environments. One should construct (in a given language that is different from the language in which the ontology is specified) not only approximations of concepts from ontology, but also vague dependencies specified in the ontology. It is worthwhile mentioning that an ontology approximation should be induced on the basis of incomplete information about concepts and dependencies specified in the ontology. Information granule calculi based on rough sets have been proposed as tools making it possible to solve this problem. Vague dependencies have vague concepts in premisses and conclusions.

The approach to approximation of vague dependencies based only on degrees of closeness of concepts from dependencies and their approximations (classifiers) is not satisfactory for approximate reasoning. Hence, more advanced approach should be developed. Approximation of any vague dependency is a method which for any object allows us to compute the arguments *for* and *against* its membership to the dependency conclusion on the basis of analogous arguments relative to the dependency premisses. Any argument is a compound information granule (compound pattern). Arguments are fused by local schemes (production rules) discovered from data. Further fusions are

possible through composition of local schemes, called approximate reasoning schemes (**AR**) [21.30]. To estimate the degree to which (at least) an object belongs to concepts from ontology the arguments *for* and *against* those concepts are collected and next a conflict resolution strategy is applied to them to predict the degree.

Several generalizations of the rough set approach introduced by Pawlak in 1982 are discussed in this handbook in more detail:

- The similarity (tolerance)-based rough set approach (Chap. 25)
- Binary relation based rough sets (Chap. 25)
- Neighborhood and covering rough sets (Chap. 25)
- The dominance-based rough set approach (Chap. 22)
- The probabilistic rough set approach and its probabilistic extension called the variable consistency dominance-based rough set approaches (Chap. 24)
- Parameterized rough sets based on Bayesian confirmation measures (Chap. 22)
- Stochastic rough set approaches (Chap. 22)
- Generalizations of rough set approximation operations (Chap. 25)
- Hybridization of rough sets and fuzzy sets (Chap. 26)
- Rough sets on abstract algebraic structures (e.g., lattices) (Chap. 25).

There are some other well-established or emerging domains not covered in the chapter where some generalizations of rough sets are proposed as the basic tools, often in combination with other existing approaches. Among them are rough sets based on [21.6]:

- i) Incomplete information and/or decision systems
- ii) Nondeterministic information and/or decision systems
- iii) The rough set model on two universes
- iv) Dynamic information and/or decision systems
- v) Dynamic networks of information and/or decision systems.

Moreover, rough sets play a crucial role in the development of granular computing (**GC**) [21.31]. The extension to interactive granular computing (**IGR**) [21.32] requires generalization of basic concepts such as information and decision systems, as well as methods of inducing hierarchical structures of information and decision systems.

Let us note that making progress in understanding interactive computations is one of the key problems in developing high quality intelligent systems working in complex environments [21.33]. The current research projects aim at developing foundations of IGC based on the rough set approach in combination with other soft computing approaches, in particular with fuzzy sets. The approach is called interactive rough granular computing (**IRGC**). In **IRGC** computations are based on interactions of complex granules (**c-granules**, for short). Any **c-granule** consists of a physical part and a mental part that are linked in a special way [21.32]. **IRGC** is treated as the basis for (see [21.6] and references in this book):

- i) Wistech Technology, in particular for approximate reasoning, called adaptive judgment about properties of interactive computations
- ii) Context induction
- iii) Reasoning about changes
- iv) Process mining (this research was inspired by [21.34])
- v) Perception-based computing (**PBC**)
- vi) Risk management in computational systems [21.32].

Interactive computations based on **c-granules** seem to create a good background, e.g., for modeling computations in Active Media Technology (**AMT**) and Wisdom Web of Things (**W2T**). We plan to investigate their role for foundations of natural computing too. Let us also mention that the interactive computations based on **c-granules** are quite different in nature than Turing computations. Hence, we plan to investigate relationships of interactive computability based on **c-granules** and Turing computability.

## 21.12 Rough Sets and Logic

The father of contemporary logic was the German mathematician Gottlob Frege (1848–1925). He thought that mathematics should not be based on the notion

of set but on the notions of logic. He created the first axiomatized logical system but it was not understood by the logicians of those days. During the first three

decades of the twentieth century there was a rapid development in logic, bolstered to a great extent by Polish logicians, in particular by Alfred Tarski, Stanisław Leśniewski, Jan Łukasiewicz, and next by Andrzej Mostowski and Helena Rasiowa. The development of computers and their applications stimulated logical research and widened their scope.

When we speak about logic, we generally mean *deductive logic*. It gives us tools designed for deriving true propositions from other true propositions. Deductive reasoning always leads to true conclusions from true premises. The theory of deduction has well-established, generally accepted theoretical foundations. Deductive reasoning is the main tool used in mathematical reasoning.

Rough set theory has contributed to some extent to various kinds of deductive reasoning. Particularly, various kinds of logics based on the rough set approach have been investigated; rough set methodology has contributed essentially to modal logics, many valued logic, intuitionistic logic, and others (see, e.g., references in the book [21.6] and in articles [21.3, 4]). A summary of this research can be found in [21.35, 36] and the interested reader is advised to consult these volumes.

In natural sciences (e.g., in physics) *inductive reasoning* is of primary importance. The characteristic feature of such reasoning is that it does not begin from axioms (expressing general knowledge about the reality) like in deductive logic, but some partial knowledge (examples) about the universe of interest are the starting point of this type of reasoning, which are generalized next and they constitute the knowledge about a wider reality than the initial one. In contrast to deductive reasoning, inductive reasoning does not lead to true conclusions but only to probable (possible) ones. Also, in contrast to the logic of deduction, the logic of induction does not have uniform, generally accepted, theoretical foundations as yet, although many important and interesting results have been obtained, e.g., concerning statistical and computational learning and others.

Verification of the validity of hypotheses in the logic of induction is based on experiment rather than the formal reasoning of the logic of deduction. Physics is the best illustration of this fact. The research on modern inductive logic has a several centuries' long history. It is worthwhile mentioning here the outstanding English philosophers Francis Bacon (1561–1626) and John Stuart Mill (1806–1873) [21.37].

The creation of computers and their innovative applications essentially contributed to the rapid growth

of interest in inductive reasoning. This domain is developing very dynamically thanks to computer science. Machine learning, knowledge discovery, reasoning from data, expert systems, and others are examples of new directions in inductive reasoning. Rough set theory is very well suited as a theoretical basis for inductive reasoning. Basic concepts of this theory fit very well to represent and analyze knowledge acquired from examples, which can be next used as a starting point for generalization. Besides, in fact, rough set theory has been successfully applied in many domains to find patterns in data (data mining) and acquire knowledge from examples (learning from examples). Thus, rough set theory seems to be another candidate as a mathematical foundation of inductive reasoning.

The most interesting from a computer science point of view is *common sense* reasoning. We use this kind of reasoning in our everyday lives, and we face examples of such kind of reasoning in newspapers, radio, TV, etc., in political, economics, etc., and in debates and discussions.

The starting point for such reasoning is the knowledge possessed by a specific group of people (*common knowledge*) concerning some subject and intuitive methods of deriving conclusions from it. Here we do not have the possibility to resolve the dispute by means of methods given by deductive logic (reasoning) or by inductive logic (experiment). So the best known methods for solving the dilemma are voting, negotiations, or even war. See, e.g., Gulliver's Travels [21.38], where the hatred between Tramecksan (High-Heels) and Slamecksan (Low-Heels) or disputes between Big-Endians and Small-Endians could not be resolved without a war. These methods do not reveal the truth or falsity of the thesis under consideration at all. Of course, such methods are not acceptable in mathematics or physics. Nobody is going to solve the truth of Fermat's theorem or Newton's laws by voting, negotiations, or declare a war.

Reasoning of this kind is the least studied from the theoretical point of view and its structure is not sufficiently understood, in spite of many interesting theoretical research in this domain [21.39]. The meaning of commonsense reasoning, considering its scope and significance for some domains, is fundamental, and rough set theory can also play an important role in it, but more fundamental research must be done to this end. In particular, the rough truth introduced and studied in [21.40] seems to be important for investigating commonsense reasoning in the rough set framework.

Let us consider a simple example. In the decision system considered we assume  $U = \text{Birds}$  is a set of birds that are described by some condition attributes from a set  $A$ . The decision attribute is a binary attribute *Flies* with possible values *yes* if the given bird flies and *no*, otherwise. Then, we define the set of abnormal birds by  $\text{Ab}_A(\text{Birds}) = A^*(\{x \in \text{Birds} : \text{Flies}(x) = \text{no}\})$ . Hence, we have,  $\text{Ab}_A(\text{Birds}) = \text{Birds} - A^*(\{x \in \text{Birds} : \text{Flies}(x) = \text{yes}\})$  and  $\text{Birds} - \text{Ab}_A(\text{Birds}) = A^*(\{x \in \text{Birds} : \text{Flies}(x) = \text{yes}\})$ . This means that for normal birds it is consistent, with knowledge represented by  $A$ , to assume that they can fly, i.e., it is possible that they can fly. One can optimize  $\text{Ab}_A(\text{Birds})$  using  $A$  to obtain minimal boundary region in the approximation of  $\{x \in \text{Birds} : \text{Flies}(x) = \text{no}\}$ .

It is worthwhile mentioning that in [21.41] an approach was presented that combines the rough sets with nonmonotonic reasoning. Some basic concepts are distinguished, which can be approximated on the basis of sensor measurements and more complex concepts that are approximated using so-called transducers defined by first-order theories constructed over approximated concepts. Another approach to commonsense reasoning was developed in a number of papers. The approach is based on an ontological framework for approximation. In this approach, approximations are constructed for concepts and dependencies between the concepts represented in a given ontology, expressed, e.g., in natural language. Still another approach combining rough sets with logic programming has been developed. Let us also note that Pawlak proposed a new approach to conflict analysis [21.42]. The approach was next extended in the rough set framework.

To recapitulate, let us consider the following characteristics of the three above-mentioned kinds of reasoning:

- a) *Deductive*
  - i) *Reasoning methods*: axioms and rules of inference
  - ii) *Applications*: mathematics
  - iii) *Theoretical foundations*: complete theory
  - iv) *Conclusions*: true conclusions from true premises
  - v) *Hypotheses verification*: formal proof
- b) *Inductive*
  - i) *Reasoning methods*: generalization from examples
  - ii) *Applications*: natural sciences (physics)
  - iii) *Theoretical foundations*: lack of generally accepted theory

- iv) *Conclusions*: not true but probable (possible)
- v) *Hypotheses verification*: empirical experiment
- c) *Common sense*
  - i) *Reasoning methods*: reasoning method based on common sense knowledge with intuitive rules of inference expressed in natural language
  - ii) *Applications*: everyday life, humanities
  - iii) *Theoretical foundations*: lack of generally accepted theory
  - iv) *Conclusions*: obtained by mixture of deductive and inductive reasoning based on concepts expressed in natural language, e.g., with application of different inductive strategies for conflict resolution (such as voting, negotiations, cooperation, war) based on human behavioral patterns
  - v) *Hypotheses verification*: human behavior.

There are numerous issues related to approximate reasoning under uncertainty. These issues are discussed in books on granular computing, rough mereology, and the computational complexity of algorithmic problems related to these issues. For more details, the reader is referred to the following books [21.26, 31, 43, 44].

Finally, we would like to stress that still much more work should be done to develop approximate reasoning about complex vague concepts to make progress in the development of intelligent systems. According to *Leslie Valiant* [21.45] (who is the 2011 winner of the ACM Turing Award, for his fundamental contributions to the development of computational learning theory and to the broader theory of computer science):

*A fundamental question for artificial intelligence is to characterize the computational building blocks that are necessary for cognition. A specific challenge is to build on the success of machine learning so as to cover broader issues in intelligence ... This requires, in particular a reconciliation between two contradictory characteristics – the apparent logical nature of reasoning and the statistical nature of learning.*

It is worthwhile presenting two more views. The first one by *Lotfi A. Zadeh*, the founder of fuzzy sets and the computing with words (**CW**) paradigm [21.46]:

*Manipulation of perceptions plays a key role in human recognition, decision and execution processes. As a methodology, computing with words provides a foundation for a computational theory of per-*

*ceptions – a theory which may have an important bearing on how humans make and machines might make – perception-based rational decisions in an environment of imprecision, uncertainty and partial truth. . . . computing with words, or CW for short, is a methodology in which the objects of computation are words and propositions drawn from a natural language.*

The other view is that of Judea Pearl [21.47] (the 2011 winner of the ACM Turing Award, the highest distinction in computer science, for fundamental contributions to artificial intelligence through the development of a calculus for probabilistic and causal reasoning):

*Traditional statistics is strong in devising ways of describing data and inferring distributional parameters from sample. Causal inference requires two additional ingredients: a science-friendly language for articulating causal knowledge, and a mathematical machinery for processing that knowledge, combining it with data and drawing new causal conclusions about a phenomenon.*

The question arises about the logic relevant for the above-mentioned tasks. First, let us observe that the satisfiability relations in the IRGC framework can be treated as tools for constructing new granules. In fact, for a given satisfiability relation one can define the semantics of formulae related to this relation, i. e., which are the candidates for the new relevant granules. We would like to emphasize one a very important feature. The relevant satisfiability relation for the considered problems is not given but it should be induced (discovered) from partial information given by information or decision systems. For real-life problems it is often necessary to discover a hierarchy of satisfiability relations before we obtain the relevant target one. Granules constructed on different levels of this hierarchy finally lead to relevant ones for approximation of complex vague concepts related to complex granules expressed using natural language.

The reasoning making it possible to derive relevant **c-granules** for solutions of the target tasks is called *adaptive judgment*. *Intuitive judgment* and *ra-*

*tional judgment* are distinguished as different kinds of judgment [21.48]. Deduction and induction as well as abduction or analogy-based reasoning are involved in adaptive judgment. Among the tasks for adaptive judgment are the following ones, which support reasoning under uncertainty toward: searching for relevant approximation spaces, discovery of new features, selection of relevant features, rule induction, discovery of inclusion measures, strategies for conflict resolution, adaptation of measures based on the minimum description length principle, reasoning about changes, perception (action and sensory) attributes' selection by agent control, adaptation of quality measures over computations relative to agents, adaptation of object structures, discovery of relevant contexts, strategies for knowledge representation and interaction with knowledge bases, ontology acquisition and approximation, learning in dialog of inclusion measures between granules from different languages (e.g., the formal language of the system and the user's natural language), strategies for adaptation of existing models, strategies for development and evolution of communication language among agents in distributed environments, strategies for risk management in distributed computational systems. Definitely, in the language used by agents for dealing with adaptive judgment (i. e., intuitive and rational) some deductive systems known from logic may be applied for reasoning about knowledge relative to closed worlds. This may happen, e.g., if the agent languages are based on classical mathematical logic. However, if we move to interactions in open worlds, then new specific rules or patterns relative to a given agent or group of agents in such worlds should be discovered. The process of inducing such rules or patterns is influenced by uncertainty because they are induced by agents under uncertain and/or imperfect knowledge about the environment.

The concepts discussed, such as interactive computation and adaptive judgment, are among the basic concepts in Wisdom Technology (**WisTech**) [21.49, 50]. Let us mention here the **WisTech** meta-equation

$$\begin{aligned} \text{WISDOM} &= \text{INTERACTIONS} \\ &+ \text{ADAPTIVE JUDGMENT} \\ &+ \text{KNOWLEDGE} . \end{aligned} \quad (21.18)$$

## 21.13 Conclusions

In the chapter, we have discussed some basic issues and methods related to rough sets together with some generalizations, including those related to relationships of rough sets with inductive reasoning. We have also listed

some current research directions based on interactive rough granular computing. For more details, the reader is referred to the literature cited at the beginning of this chapter (see also [21.9]).

## 22. Rough Set Methodology for Decision Aiding

Roman Słowiński, Salvatore Greco, Benedetto Matarazzo

Part C | 22

Since its conception, the dominance-based rough set approach (DRSA) has been adapted to a large variety of decision problems. In this chapter we outline the rough set methodology designed for multi-attribute decision aiding. DRSA was proposed as an extension of the Pawlak concept of rough sets in order to deal with ordinal data. We focus on decision problems where all attributes describing objects of a decision problem have ordered value sets (scales). Such attributes are called criteria, and thus the problems are called multi-criteria decision problems. Criteria are real-valued functions of gain or cost type, depending on whether a greater value is better or worse, respectively. In these problems, we also assume the presence of a well defined decision maker (DM) (single or group DM) concerned by multi-criteria classification, choice, and ranking.

Ordinal data are typically encountered in multi-attribute decision problems, where a set of objects (also called actions, acts, solutions, etc.) evaluated by a set of attributes (also called criteria, variables, features, etc.) raises one of the following questions: (i) how to assign the objects to some ordered classes (*ordinal classification*), (ii) how to choose the best subset of objects (*choice* or its particular case – *optimization*), or

(iii) how to rank the objects from the best to the worst (*ranking*). The answer to all of these questions involves an aggregation of the multi-attribute evaluation of objects, which takes into account a law relating the evaluation with the classification, or choice, or ranking decision. This law has to be discovered by inductive learning from data describing the considered decision situation. In the case of decision problems that corre-

spond to some physical phenomena, this law is a model of cause–effect relationships, and in the case of human decision making, this law is a decision maker’s preference model. In DRSA, these models have the form of a set of *if ..., then ...* decision rules. In the case of multi-attribute classification the syntax of rules is: *if evaluation of object a is better (or worse) than given values of some attributes, then a belongs to at*

*least (at most) a given class*, and in the case of multi-attribute choice or ranking: *if object a is preferred to object b in at least (at most) given degrees with respect to some attributes, then a is preferred to b in at least (at most) a given degree*. These models are used to work out a recommendation concerning unseen objects in the context of one of the three problem statements.

## 22.1 Data Inconsistency as a Reason for Using Rough Sets

The data describing a given decision situation include either observations of DM’s past decisions in the same decision context, or examples of decisions consciously elicited by the DM on the demand of an analyst. These data hide the value system of the DM, and thus they are called *preference information*. This way of preference information elicitation is called *indirect*, in opposition to *direct* elicitation when the DM is supposed to provide information leading directly to the definition of all preference model parameters, like weights and discrimination thresholds of criteria, trade-off rates, etc. [22.1].

Past decisions or decision examples may, however, be *inconsistent* with the *dominance principle* commonly accepted for multi-criteria decision problems. Decisions are inconsistent with the dominance principle if:

- In case of ordinal classification: object  $a$  has been assigned to a worse decision class than object  $b$ , although  $a$  is at least as good as  $b$  on all the considered criteria, i. e.,  $a$  dominates  $b$ .
- In the case of choice and ranking: a pair of objects  $(a, b)$  has been assigned a degree of preference worse than pair  $(c, d)$ , although differences of evaluations between  $a$  and  $b$  on all the considered criteria is at least as strong as the respective differences of evaluations between  $c$  and  $d$ , i. e., pair  $(a, b)$  dominates pair  $(c, d)$ .

Thus, in order to build a preference model from partly inconsistent preference information, we had the idea to structure this data using the concept of a *rough set* introduced by Pawlak [22.2, 3]. Originally, however, Pawlak’s understanding of inconsistency was different to the above inconsistency with the dominance principle. The original rough set philosophy (Chap. 21) is based on the assumption that with every object of the universe  $U$  there is associated a certain amount of

information (data, knowledge). This information can be expressed by means of a number of attributes that describe the objects. Objects which have the same description are said to be indiscernible (or similar) with respect to the available information. The *indiscernibility relation* thus generated constitutes the mathematical basis of rough set theory. It induces a partition of the universe into blocks of indiscernible objects, called elementary sets, which can be used to build knowledge about a real or abstract world. The use of the indiscernibility relation results in information *granulation*.

Any subset  $X$  of the universe may be expressed in terms of these blocks either precisely (as a union of elementary sets) or approximately. In the latter case, the subset  $X$  may be characterized by two ordinary sets, called the *lower* and *upper approximations*. A rough set is defined by means of these two approximations, which coincide in the case of an ordinary set. The lower approximation of  $X$  is composed of all the elementary sets included in  $X$  (whose elements, therefore, certainly belong to  $X$ ), while the upper approximation of  $X$  consists of all the elementary sets which have a non-empty intersection with  $X$  (whose elements, therefore, may belong to  $X$ ). The difference between the upper and lower approximations constitutes the boundary region of the rough set, whose elements cannot be characterized with certainty as belonging or not to  $X$  (by using the available information). The information about objects from the boundary region is, therefore, inconsistent or ambiguous. The cardinality of the boundary region states, moreover, the extent to which it is possible to express  $X$  in exact terms, on the basis of the available information. For this reason, this cardinality may be used as a measure of vagueness of the information about  $X$ .

Some important characteristics of the rough set approach make it a particularly interesting tool in a variety of problems and concrete applications. For example, it is possible to deal with both quantitative and qualita-

tive input data, and inconsistencies need not be removed prior to the analysis. In terms of the output information, it is possible to acquire *a posteriori* information regarding the relevance of particular attributes and their subsets to the quality of approximation considered within the problem at hand. Moreover, the lower and upper approximations of a partition of  $U$  into decision classes prepare the ground for inducing *certain* and *possible* knowledge patterns in the form of *if... then...* decision rules.

Several attempts have been made to employ rough set theory for decision aiding [22.4, 5]. The Indiscernibility-based Rough Set Approach (IRSA) is not able, however, to handle inconsistencies with respect to the dominance principle.

### 22.1.1 From Indiscernibility-Based Rough Sets to Dominance-Based Rough Sets

An extension of IRSA which deals with inconsistencies with respect to the dominance principle, which are typical for preference data, was proposed by Greco et al. in [22.6–8]. This extension is the dominance-based rough set approach (DRSA), which is mainly based on the substitution of the indiscernibility relation by a dominance relation in the rough approximation of decision classes. An important consequence of this fact is the possibility of inferring (from observations of past decisions or from exemplary decisions) the DM's

preference model in terms of decision rules which are logical statements of the type *if... then...*. The separation of *certain* and *uncertain* knowledge about the DM's preferences is carried out by the distinction of different kinds of decision rules, depending upon whether they are induced from lower approximations of decision classes or from the difference between upper and lower approximations (composed of inconsistent examples). Such a preference model is more general than the classical functional models considered within multi-attribute utility theory or the relational models considered, for example, in outranking methods [22.9–11].

This chapter is based on previous publications of the authors, in particular, on [22.12–14]. In the next section, we explain the need for replacing the indiscernibility relation by the dominance relation in the definition of rough sets when reasoning about ordinal data. This leads us to Sect. 22.3, where DRSA is presented with respect to multi-criteria ordinal classification. This section also includes two special versions of DRSA: variable consistency DRSA (VC DRSA) and stochastic DRSA. Section 22.4 presents DRSA with respect to multi-criteria choice and ranking. Section 22.5 characterizes some relevant extensions of DRSA, and Sect. 22.6 presents applications of DRSA to some operational research problems. Section 22.7 summarizes the features of DRSA applied to multi-criteria decision problems and concludes the chapter.

## 22.2 The Need for Replacing the Indiscernibility Relation by the Dominance Relation when Reasoning About Ordinal Data

When trying to apply the rough set concept based on indiscernibility to reasoning about preference ordered data, it has been noted that IRSA ignores not only the preference order in the value sets of attributes but also the monotonic relationship between evaluations of objects on such attributes (called criteria) and the preference ordered value of decision (classification decision or degree of preference) [22.6, 15–17].

In order to explain the importance of the above monotonic relationship for data describing multi-criteria decision problems, let us consider the example of a data set concerning pupils' achievements in a high school. Suppose that among the criteria used for evaluation of the pupils there are results in *Mathematics* (*Math*) and *Physics* (*Ph*). There is also a *General*

*Achievement* (*GA*) result, which is considered as a classification decision. The value sets of all three criteria are composed of three values: *bad*, *medium*, and *good*. The preference order of these values is obvious: *good* is better than *medium* and *bad*, and *medium* is better than *bad*. The three values *bad*, *medium*, and *good* can be number-coded as 1, 2, and 3, respectively, making a gain-type criterion scale. One can also notice a *semantic correlation* between the two criteria and the classification decision, which means that an improvement in one criterion should not worsen the classification decision, while the other criterion value is unchanged. Precisely, an improvement of a pupil's score in *Math* or *Ph*, with other criterion value unchanged, should not worsen the pupil's general achievement (*GA*), but rather

improve it. In general terms, this requirement is concordant with the dominance principle defined in Sect. 22.1.

This semantic correlation is also called a monotonicity constraint, and thus, an alternative name of the classification problem with semantic correlation between evaluation criteria and classification decision is *ordinal classification with monotonicity constraints*.

Two questions naturally follow the consideration of this example:

- What classification rules can be drawn from the pupils' data set?
- How does the semantic correlation influence the classification rules?

The answer to the first question is: monotonic *if ..., then ...* decision rules. Each decision rule is characterized by a *condition profile* and a *decision profile*, corresponding to vectors of threshold values on evaluation criteria and on classification decision, respectively. The answer to the second question is that condition and decision profiles of a decision rule should observe the dominance principle (monotonicity constraint) if the rule has at least one pair of semantically correlated criteria spanned over the condition and decision part. We say that one profile *dominates* another if the values of criteria of the first profile are not worse than the values of criteria of the second profile.

Let us explain the dominance principle with respect to decision rules on the pupils' example. Suppose that two rules induced from the pupils' data set relate *Math* and *Ph* on the condition side, with *GA* on the decision side:

- rule #1: if *Math* = *medium* and *Ph* = *medium*, then *GA* = *good*,
- rule #2: if *Math* = *good* and *Ph* = *medium*, then *GA* = *medium*.

The two rules do not observe the dominance principle because the condition profile of rule #2 dominates the condition profile of rule #1, while the decision profile of rule #2 is dominated by the decision profile of rule #1. Thus, in the sense of the dominance principle, the two rules are inconsistent, i.e., they are wrong.

One could say that the above rules are true because they are supported by examples of pupils from the analyzed data set, but this would mean that the examples are also inconsistent. The *inconsistency* may come from many sources. Examples include:

- Missing attributes (regular ones or criteria) in the description of objects. Maybe the data set does not

include such attributes as the *opinion of the pupil's tutor* expressed only verbally during an assessment of the pupil's *GA* by a school assessment committee.

- Unstable preferences of decision makers. Maybe the members of the school assessment committee changed their view on the influence of *Math* on *GA* during the assessment.

Handling these inconsistencies is of crucial importance for data structuring prior to induction of decision rules. They cannot be simply considered as noise or error to be eliminated from data, or amalgamated with consistent data by some averaging operators. They should be identified and presented as uncertain rules.

If the semantic correlation was ignored in prior knowledge, then the handling of the above-mentioned inconsistencies would be impossible. Indeed, there would be nothing wrong with rules #1 and #2. They would be supported by different examples discerned by the attributes considered.

It has been acknowledged by many authors that *rough set theory* provides an excellent framework for dealing with inconsistencies in knowledge discovery [22.3, 18–24]. These authors show that the paradigm of rough set theory is that of *granular computing*, because the main concept of the theory (rough approximation of a set) is built up of blocks of objects which are indiscernible by a given set of attributes, called *granules of knowledge*. In the space of regular attributes, the indiscernibility granules are bounded sets. Decision rules induced from indiscernibility-based rough approximations are also built up of such granules.

It appears, however, as demonstrated by the above pupils' example, that rough sets and decision rules built up of indiscernibility granules are not able to handle inconsistency with respect to the dominance principle. For this reason, we have proposed an extension of the granular computing paradigm that enables us to take into account prior knowledge about multi-criteria evaluation with monotonicity constraints. The combination of the new granules with the idea of rough approximation is the *DRSA* approach [22.6, 8, 12–16, 25–27].

In the following, we present the concept of granules, which permit us to handle prior knowledge about multi-criteria evaluation with monotonicity constraints when inducing decision rules.

Let  $U$  be a finite set of objects (universe) and let  $Q$  be a finite set of attributes divided into a set  $C$  of *condition attributes* and a set  $D$  of *decision attributes*, where  $C \cap D = \emptyset$ . Also, let  $X_q$  be the set of possible

evaluations of considered objects with respect to attribute  $q \in Q$ , so that

$$X_C = \prod_{q=1}^{|C|} X_q \quad \text{and} \quad X_D = \prod_{q=1}^{|D|} X_q$$

are attribute spaces corresponding to sets of condition and decision attributes, respectively. The elements of  $X_C$  and  $X_D$  can be interpreted as possible evaluations of objects on attributes from set  $C = \{1, \dots, |C|\}$  and from set  $D = \{1, \dots, |D|\}$ , respectively. In the following, with a slight abuse of notation, we shall denote the value of object  $x \in U$  on attribute  $q \in Q$  by  $x_q$ .

Suppose, for simplicity, that all condition attributes in  $C$  and all decision attributes in  $D$  are criteria, and that  $C$  and  $D$  are semantically correlated.

Let  $\succeq_q$  be a weak preference relation on  $U$ , representing a preference on the set of objects with respect to criterion  $q \in C \cup D$ . Now,  $x_q \succeq y_q$  means  $x_q$  is at least as good as  $y_q$  with respect to criterion  $q$ . On the one hand, we say that  $x$  dominates  $y$  with respect to  $P \subseteq C$  (shortly,  $x$   $P$ -dominates  $y$ ) in the condition attribute space  $X_P$  (denoted by  $xD_Py$ ) if  $x_q \succeq y_q$  for all  $q \in P$ . Assuming, without loss of generality, that the domains of the criteria are number-coded (i.e.,  $X_q \subseteq \mathbb{R}$  for any  $q \in C$ ) and that they are ordered so that the preference increases with the value (gain-type), we can say that  $xD_Py$  is equivalent to  $x_q \geq y_q$  for all  $q \in P$ ,  $P \subseteq C$ . Observe that for each  $x \in X_P$ ,  $xD_Px$ , i.e.,  $P$ -dominance  $D_P$  is reflexive. Moreover, for any  $x, y, z \in X_P$ ,  $xD_Py$  and  $yD_Pz$  imply  $xD_Pz$ , i.e.,  $P$ -dominance  $D_P$  is a transitive relation. Being a reflexive and transitive relation,  $P$ -dominance  $D_P$  is a partial preorder. On the other hand, the analogous definition holds in the decision attribute space  $X_R$ ,  $R \subseteq D$ , where  $x_q \geq y_q$  for all  $q \in R$  will be denoted by  $xD_Ry$ .

The dominance relations  $xD_Py$  and  $xD_Ry$  ( $P \subseteq C$  and  $R \subseteq D$ ) are directional statements where  $x$  is a subject and  $y$  is a referent.

If  $x \in X_P$  is the referent, then one can define a set of objects  $y \in X_P$  dominating  $x$ , called the  $P$ -dominating set (denoted by  $D_P^+(x)$ ) and defined as  $D_P^+(x) = \{y \in U: yD_Px\}$ . If  $x \in X_P$  is the subject, then one can define a set of objects  $y \in X_P$  dominated by  $x$ , called the  $P$ -dominated set (denoted by  $D_P^-(x)$ ) and defined as  $D_P^-(x) = \{y \in U: xD_Py\}$ .

$P$ -dominating sets  $D_P^+(x)$  and  $P$ -dominated sets  $D_P^-(x)$  correspond to *positive* and *negative dominance cones* in  $X_P$ , with the origin  $x$ .

With respect to the decision attribute space  $X_R$  (where  $R \subseteq D$ ), the  $R$ -dominance relation enables us to define the following sets

$$Cl_R^{\geq x} = \{y \in U: yD_Rx\}, \quad Cl_R^{\leq x} = \{y \in U: xD_Ry\}.$$

$Cl_{t_q} = \{x \in X_D: x_q = t_q\}$  is a decision class with respect to  $q \in D$ .  $Cl_R^{\geq x}$  is called the *upward union* of classes, and  $Cl_R^{\leq x}$  is the *downward union* of classes. If  $y \in Cl_R^{\geq x}$ , then  $y$  belongs to class  $Cl_{t_q}$ ,  $x_q = t_q$ , or better, on each decision attribute  $q \in R$ . On the other hand, if  $y \in Cl_R^{\leq x}$ , then  $y$  belongs to class  $Cl_{t_q}$ ,  $x_q = t_q$ , or worse, on each decision attribute  $q \in R$ . The downward and upward unions of classes correspond to the *positive* and *negative dominance cones* in  $X_R$ , respectively.

In this case, the granules of knowledge are open sets in  $X_P$  and  $X_R$  defined by dominance cones  $D_P^+(x)$ ,  $D_P^-(x)$  ( $P \subseteq C$ ) and  $Cl_R^{\geq x}$ ,  $Cl_R^{\leq x}$  ( $R \subseteq D$ ), respectively. Then, classification rules to be induced from data are functions representing granules  $Cl_R^{\geq x}$ ,  $Cl_R^{\leq x}$  by granules  $D_P^+(x)$ ,  $D_P^-(x)$ , respectively, in the condition attribute space  $X_P$ , for any  $P \subseteq C$  and  $R \subseteq D$  and for any  $x \in X_P$ .

## 22.3 The Dominance-based Rough Set Approach to Multi-Criteria Classification

### 22.3.1 Granular Computing with Dominance Cones

When inducing classification rules, a set  $D$  of decision attributes is, usually, a singleton,  $D = \{d\}$ . Let us make this assumption for further presentation, although it is not necessary for DRSA. The decision attribute  $d$  makes a partition of  $U$  into a finite number of classes,  $Cl = \{Cl_t, t = 1, \dots, n\}$ . Each object  $x \in U$

belongs to one and only one class,  $Cl_t \in Cl$ . The upward and downward unions of classes boil down to, respectively,

$$Cl_I^{\geq} = \bigcup_{s \geq t} Cl_s,$$

$$Cl_I^{\leq} = \bigcup_{s \leq t} Cl_s,$$

where  $t = 1, \dots, n$ . Notice that for  $t = 2, \dots, n$  we have  $Cl_t^{\geq} = U - Cl_{t-1}^{\leq}$ , i.e., all the objects not belonging to class  $Cl_t$  or better, belong to class  $Cl_{t-1}$  or worse.

Let us explain how the rough set concept has been generalized in DRSA, so as to enable granular computing with dominance cones.

Given a set of criteria,  $P \subseteq C$ , the inclusion of an object  $x \in U$  to the upward union of classes  $Cl_t^{\geq}$ ,  $t = 2, \dots, n$ , is *inconsistent with the dominance principle* if one of the following conditions holds:

- $x$  belongs to class  $Cl_t$  or better but it is  $P$ -dominated by an object  $y$  belonging to a class worse than  $Cl_t$ , i.e.,  $x \in Cl_t^{\geq}$  but  $D_P^+(x) \cap Cl_{t-1}^{\leq} \neq \emptyset$ ;
- $x$  belongs to a worse class than  $Cl_t$  but it  $P$ -dominates an object  $y$  belonging to class  $Cl_t$  or better, i.e.,  $x \notin Cl_t^{\geq}$  but  $D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset$ .

If, given a set of criteria  $P \subseteq C$ , the inclusion of  $x \in U$  to  $Cl_t^{\geq}$ , where  $t = 2, \dots, n$ , is inconsistent with the dominance principle, we say that  $x$  belongs to  $Cl_t^{\geq}$  with *some ambiguity*. Thus,  $x$  belongs to  $Cl_t^{\geq}$  without any ambiguity with respect to  $P \subseteq C$ , if  $x \in Cl_t^{\geq}$  and there is no inconsistency with the dominance principle. This means that all objects  $P$ -dominating  $x$  belong to  $Cl_t^{\geq}$ , i.e.,  $D_P^+(x) \subseteq Cl_t^{\geq}$ . Geometrically, this corresponds to the inclusion of the complete set of objects contained in the positive dominance cone originating in  $x$ , in the positive dominance cone  $Cl_t^{\geq}$  originating in  $Cl_t$ .

Furthermore,  $x$  possibly belongs to  $Cl_t^{\geq}$  with respect to  $P \subseteq C$  if one of the following conditions holds:

- According to decision attribute  $d$ ,  $x$  belongs to  $Cl_t^{\geq}$ .
- According to decision attribute  $d$ ,  $x$  does not belong to  $Cl_t^{\geq}$ , but it is inconsistent in the sense of the dominance principle with an object  $y$  belonging to  $Cl_t^{\geq}$ .

In terms of ambiguity,  $x$  possibly belongs to  $Cl_t^{\geq}$  with respect to  $P \subseteq C$ , if  $x$  belongs to  $Cl_t^{\geq}$  with or without any ambiguity. Due to the reflexivity of the  $P$ -dominance relation  $D_P$ , the above conditions can be summarized as follows:  $x$  possibly belongs to class  $Cl_t$  or better, with respect to  $P \subseteq C$ , if among the objects  $P$ -dominated by  $x$  there is an object  $y$  belonging to class  $Cl_t$  or better, i.e.,

$$D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset.$$

Geometrically, this corresponds to the non-empty intersection of the set of objects contained in the negative dominance cone originating in  $x$ , with the positive dominance cone  $Cl_t^{\geq}$  originating in  $Cl_t$ .

For  $P \subseteq C$ , the set of all objects belonging to  $Cl_t^{\leq}$  without any ambiguity constitutes the  *$P$ -lower approximation* of  $Cl_t^{\geq}$ , denoted by  $\underline{P}(Cl_t^{\geq})$ , and the set of all objects that possibly belong to  $Cl_t^{\geq}$  constitutes the  *$P$ -upper approximation* of  $Cl_t^{\geq}$ , denoted by  $\overline{P}(Cl_t^{\geq})$ . More formally

$$\begin{aligned}\underline{P}(Cl_t^{\geq}) &= \{x \in U : D_P^+(x) \subseteq Cl_t^{\geq}\}, \\ \overline{P}(Cl_t^{\geq}) &= \{x \in U : D_P^-(x) \cap Cl_t^{\geq} \neq \emptyset\},\end{aligned}$$

where  $t = 1, \dots, n$ . Analogously, one can define the  *$P$ -lower approximation* and the  *$P$ -upper approximation* of  $Cl_t^{\leq}$

$$\begin{aligned}\underline{P}(Cl_t^{\leq}) &= \{x \in U : D_P^-(x) \subseteq Cl_t^{\leq}\}, \\ \overline{P}(Cl_t^{\leq}) &= \{x \in U : D_P^+(x) \cap Cl_t^{\leq} \neq \emptyset\},\end{aligned}$$

where  $t = 1, \dots, n$ .

The  $P$ -lower and  $P$ -upper approximations of  $Cl_t^{\geq}$ ,  $t = 1, \dots, n$ , can also be expressed in terms of unions of positive dominance cones as follows

$$\begin{aligned}\underline{P}(Cl_t^{\geq}) &= \bigcup_{D_P^+(x) \subseteq Cl_t^{\geq}} D_P^+(x), \\ \overline{P}(Cl_t^{\geq}) &= \bigcup_{x \in Cl_t^{\geq}} D_P^+(x).\end{aligned}$$

Analogously, the  $P$ -lower and  $P$ -upper approximations of  $Cl_t^{\leq}$ ,  $t = 1, \dots, n$ , can be expressed in terms of unions of negative dominance cones as follows

$$\begin{aligned}\underline{P}(Cl_t^{\leq}) &= \bigcup_{D_P^-(x) \subseteq Cl_t^{\leq}} D_P^-(x), \\ \overline{P}(Cl_t^{\leq}) &= \bigcup_{x \in Cl_t^{\leq}} D_P^-(x).\end{aligned}$$

The  $P$ -lower and  $P$ -upper approximations so defined satisfy the following *inclusion properties* for each  $t \in \{1, \dots, n\}$  and for all  $P \subseteq C$

$$\begin{aligned}\underline{P}(Cl_t^{\geq}) \subseteq Cl_t^{\geq} &\subseteq \overline{P}(Cl_t^{\geq}), \\ \underline{P}(Cl_t^{\leq}) \subseteq Cl_t^{\leq} &\subseteq \overline{P}(Cl_t^{\leq}).\end{aligned}$$

All the objects belonging to  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$  with some ambiguity constitute the  *$P$ -boundary* of  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$ , denoted by  $Bn_P(Cl_t^{\geq})$  and  $Bn_P(Cl_t^{\leq})$ , respectively. They

can be represented, in terms of upper and lower approximations, as follows

$$\begin{aligned}B_{n_P}(Cl_t^{\geq}) &= \overline{P}(Cl_t^{\geq}) - \underline{P}(Cl_t^{\geq}), \\B_{n_P}(Cl_t^{\leq}) &= \overline{P}(Cl_t^{\leq}) - \underline{P}(Cl_t^{\leq}),\end{aligned}$$

where  $t = 1, \dots, n$ . The  $P$ -lower and  $P$ -upper approximations of the unions of classes  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$  have an important *complementarity property*. It says that if object  $x$  belongs without any ambiguity to class  $Cl_t$  or better, then it is impossible that it could belong to class  $Cl_{t-1}$  or worse, i.e.,

$$\underline{P}(Cl_t^{\geq}) = U - \overline{P}(Cl_{t-1}^{\leq}), \quad t = 2, \dots, n.$$

Due to the complementarity property,  $B_{n_P}(Cl_t^{\geq}) = B_{n_P}(Cl_{t-1}^{\leq})$ , for  $t = 2, \dots, n$ , which means that if  $x$  belongs with ambiguity to class  $Cl_t$  or better, then it also belongs with ambiguity to class  $Cl_{t-1}$  or worse.

Considering application of the lower and the upper approximations based on dominance  $D_P$ ,  $P \subseteq C$ , to any set  $X \subseteq U$ , instead of the unions of classes  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$ , one obtains upward lower and upper approximations  $\underline{P}^{\geq}(X)$  and  $\overline{P}^{\geq}(X)$ , as well as downward lower and upper approximations  $\underline{P}^{\leq}(X)$  and  $\overline{P}^{\leq}(X)$ , as follows

$$\begin{aligned}\underline{P}^{\geq}(X) &= \{x \in U : D_P^+(x) \subseteq X\}, \\ \overline{P}^{\geq}(X) &= \{x \in U : D_P^-(x) \cap X \neq \emptyset\}, \\ \underline{P}^{\leq}(X) &= \{x \in U : D_P^-(x) \subseteq X\}, \\ \overline{P}^{\leq}(X) &= \{x \in U : D_P^+(x) \cap X \neq \emptyset\}.\end{aligned}$$

From the definition of rough approximations  $\underline{P}^{\geq}(X)$ ,  $\overline{P}^{\geq}(X)$ ,  $\underline{P}^{\leq}(X)$  and  $\overline{P}^{\leq}(X)$ , we can also obtain the following properties of the  $P$ -lower and  $P$ -upper approximations [22.28, 29]:

1.  $\underline{P}^{\geq}(\emptyset) = \overline{P}^{\geq}(\emptyset) = \underline{P}^{\leq}(\emptyset) = \overline{P}^{\leq}(\emptyset) = \emptyset$ ,  
 $\underline{P}^{\geq}(U) = \overline{P}^{\geq}(U) = \underline{P}^{\leq}(U) = \overline{P}^{\leq}(U) = U$ ,
2.  $\overline{P}^{\geq}(X \cup Y) = \overline{P}^{\geq}(X) \cup \overline{P}^{\geq}(Y)$ ,  
 $\overline{P}^{\leq}(X \cup Y) = \overline{P}^{\leq}(X) \cup \overline{P}^{\leq}(Y)$ ,
3.  $\underline{P}^{\geq}(X \cap Y) = \underline{P}^{\geq}(X) \cap \underline{P}^{\geq}(Y)$ ,  
 $\underline{P}^{\leq}(X \cap Y) = \underline{P}^{\leq}(X) \cap \underline{P}^{\leq}(Y)$ ,
4.  $X \subseteq Y \Rightarrow \overline{P}^{\geq}(X) \subseteq \overline{P}^{\geq}(Y)$ ,  
 $X \subseteq Y \Rightarrow \overline{P}^{\leq}(X) \subseteq \overline{P}^{\leq}(Y)$ ,
5.  $X \subseteq Y \Rightarrow \underline{P}^{\geq}(X) \subseteq \underline{P}^{\geq}(Y)$ ,  
 $X \subseteq Y \Rightarrow \underline{P}^{\leq}(X) \subseteq \underline{P}^{\leq}(Y)$ ,

6.  $\underline{P}^{\geq}(X \cup Y) \supseteq \underline{P}^{\geq}(X) \cup \underline{P}^{\geq}(Y)$ ,  
 $\overline{P}^{\leq}(X \cup Y) \supseteq \overline{P}^{\leq}(X) \cup \overline{P}^{\leq}(Y)$ ,
7.  $\overline{P}^{\geq}(X \cap Y) \subseteq \overline{P}^{\geq}(X) \cap \overline{P}^{\geq}(Y)$ ,  
 $\overline{P}^{\leq}(X \cap Y) \subseteq \overline{P}^{\leq}(X) \cap \overline{P}^{\leq}(Y)$ ,
8.  $\underline{P}^{\geq}(\underline{P}^{\geq}(X)) = \overline{P}^{\geq}(\underline{P}^{\geq}(X)) = \underline{P}^{\geq}(X)$ ,  
 $\underline{P}^{\leq}(\underline{P}^{\leq}(X)) = \overline{P}^{\leq}(\underline{P}^{\leq}(X)) = \underline{P}^{\leq}(X)$ ,
9.  $\overline{P}^{\geq}(\overline{P}^{\geq}(X)) = \underline{P}^{\geq}(\overline{P}^{\geq}(X)) = \overline{P}^{\geq}(X)$ ,  
 $\overline{P}^{\leq}(\overline{P}^{\leq}(X)) = \underline{P}^{\leq}(\overline{P}^{\leq}(X)) = \overline{P}^{\leq}(X)$ .

From the knowledge discovery point of view,  $P$ -lower approximations of unions of classes represent *certain knowledge* provided by criteria from  $P \subseteq C$ , while  $P$ -upper approximations represent *possible knowledge* and the  $P$ -boundaries contain *doubtful knowledge* provided by the criteria from  $P \subseteq C$ .

### 22.3.2 Variable Consistency Dominance-Based Rough Set Approach (VC-DRSA)

The above definitions of rough approximations are based on a strict application of the dominance principle. However, when defining non-ambiguous objects, it is reasonable to accept a limited proportion of negative examples, particularly for large data tables. This relaxed version of DRSA is called the variable consistency dominance-based rough set approach (VC-DRSA) model [22.30].

For any  $P \subseteq C$ , we say that  $x \in U$  belongs to  $Cl_t^{\geq}$  with no ambiguity at consistency level  $l \in (0, 1]$ , if  $x \in Cl_t^{\geq}$  and at least  $l * 100\%$  of all objects  $y \in U$  dominating  $x$  with respect to  $P$  also belong to  $Cl_t^{\geq}$ , i.e.,

$$\frac{|D_P^+(x) \cap Cl_t^{\geq}|}{|D_P^+(x)|} \geq l.$$

The term  $|D_P^+(x) \cap Cl_t^{\geq}| / |D_P^+(x)|$  is called *rough membership* and can be interpreted as conditional probability  $\text{Pr}(y \in Cl_t^{\geq} | y \in D_P^+(x))$ . The level  $l$  is called the *consistency level* because it controls the degree of consistency between objects qualified as belonging to  $Cl_t^{\geq}$  without any ambiguity. In other words, if  $l < 1$ , then at most  $(1-l) * 100\%$  of all objects  $y \in U$  dominating  $x$  with respect to  $P$  do not belong to  $Cl_t^{\geq}$  and thus contradict the inclusion of  $x$  in  $Cl_t^{\geq}$ .

Analogously, for any  $P \subseteq C$  we say that  $x \in U$  belongs to  $Cl_t^{\leq}$  with no ambiguity at consistency level  $l \in (0, 1]$ , if  $x \in Cl_t^{\leq}$  and at least  $l * 100\%$  of all the objects  $y \in U$  dominated by  $x$  with respect to  $P$  also belong

to  $Cl_t^{\leq}$ , i.e.,

$$\frac{|D_P^-(x) \cap Cl_t^{\leq}|}{|D_P^-(x)|} \geq l.$$

The rough membership  $|D_P^-(x) \cap Cl_t^{\leq}| / |D_P^-(x)|$  can be interpreted as conditional probability  $\Pr(y \in Cl_t^{\leq} | y \in D_P^-(x))$ . Thus, for any  $P \subseteq C$ , each object  $x \in U$  is either ambiguous or non-ambiguous at consistency level  $l$  with respect to the upward union  $Cl_t^{\geq}$  ( $t = 2, \dots, n$ ) or with respect to the downward union  $Cl_t^{\leq}$  ( $t = 1, \dots, n-1$ ).

The concept of non-ambiguous objects at some consistency level  $l$  naturally leads to the definition of  $P$ -lower approximations of the unions of classes  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$ , which can be formally presented as follows

$$\begin{aligned}\underline{P}^l(Cl_t^{\geq}) &= \left\{ x \in Cl_t^{\geq} : \frac{|D_P^+(x) \cap Cl_t^{\geq}|}{|D_P^+(x)|} \geq l \right\}, \\ \underline{P}^l(Cl_t^{\leq}) &= \left\{ x \in Cl_t^{\leq} : \frac{|D_P^-(x) \cap Cl_t^{\leq}|}{|D_P^-(x)|} \geq l \right\}.\end{aligned}$$

Given  $P \subseteq C$  and consistency level  $l$ , we can define the  $P$ -upper approximations of  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$ , denoted by  $\overline{P}^l(Cl_t^{\geq})$  and  $\overline{P}^l(Cl_t^{\leq})$ , respectively, by complementation of  $\underline{P}^l(Cl_{t-1}^{\leq})$  and  $\underline{P}^l(Cl_{t+1}^{\geq})$  with respect to  $U$  as follows

$$\begin{aligned}\overline{P}^l(Cl_t^{\geq}) &= U - \underline{P}^l(Cl_{t-1}^{\leq}), \quad t = 2, \dots, n, \\ \overline{P}^l(Cl_t^{\leq}) &= U - \underline{P}^l(Cl_{t+1}^{\geq}), \quad t = 1, \dots, n-1.\end{aligned}$$

$\overline{P}^l(Cl_t^{\geq})$  can be interpreted as the set of all the objects belonging to  $Cl_t^{\geq}$ , which are *possibly ambiguous* at consistency level  $l$ . Analogously,  $\overline{P}^l(Cl_t^{\leq})$  can be interpreted as the set of all the objects belonging to  $Cl_t^{\leq}$ , which are *possibly ambiguous* at consistency level  $l$ . The  $P$ -boundaries ( $P$ -doubtful regions) of  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$  are defined as

$$\begin{aligned}Bn_P(Cl_t^{\geq}) &= \overline{P}^l(Cl_t^{\geq}) - \underline{P}^l(Cl_t^{\geq}), \\ Bn_P(Cl_t^{\leq}) &= \overline{P}^l(Cl_t^{\leq}) - \underline{P}^l(Cl_t^{\leq}),\end{aligned}$$

where  $t = 1, \dots, n$ . The **VC-DRSA** model provides some degree of flexibility in assigning objects to lower and upper approximations of the unions of decision

classes. It can easily be demonstrated that for  $0 < l' < l \leq 1$  and  $t = 2, \dots, n$ ,

$$\underline{P}^l(Cl_t^{\geq}) \subseteq \underline{P}^{l'}(Cl_t^{\geq}) \quad \text{and} \quad \overline{P}^l(Cl_t^{\geq}) \subseteq \overline{P}^{l'}(Cl_t^{\geq}).$$

The **VC-DRSA** model was inspired by Ziarko's model of the *variable precision* rough set approach [22.31]. However, there is a significant difference in the definition of rough approximations because  $\underline{P}^l(Cl_t^{\geq})$  and  $\overline{P}^l(Cl_t^{\geq})$  are composed of non-ambiguous and ambiguous objects at the consistency level  $l$ , respectively, while Ziarko's  $\underline{P}^l(Cl_t)$  and  $\overline{P}^l(Cl_t)$  are composed of  $P$ -indiscernibility sets such that at least  $l * 100\%$  of these sets are included in  $Cl_t$  or have a non-empty intersection with  $Cl_t$ , respectively. If one would like to use Ziarko's definition of variable precision rough approximations in the context of multiple-criteria classification, then the  $P$ -indiscernibility sets should be substituted by  $P$ -dominating sets  $D_P^+(x)$ . However, then the notion of ambiguity that naturally leads to the general definition of rough approximations [22.21] loses its meaning. Moreover, a bad side effect of the direct use of Ziarko's definition is that a lower approximation  $\underline{P}^l(Cl_t^{\geq})$  may include objects  $y$  assigned to  $Cl_h$ , where  $h$  is much less than  $t$ , if  $y$  belongs to  $D_P^+(x)$ , which was included in  $\underline{P}^l(Cl_t^{\geq})$ . When the decision classes are preference ordered, it is reasonable to expect that objects assigned to far worse classes than the considered union are not counted to the lower approximation of this union.

The **VC-DRSA** model presented above has been generalized in [22.32, 33]. The generalized model applies two types of consistency measures in the definition of lower approximations:

- Gain-type consistency measures  $f_{\geq t}^P(x), f_{\leq t}^P(x)$
- $$\begin{aligned}\underline{P}^{\alpha_{\geq t}}(Cl_t^{\geq}) &= \{x \in Cl_t^{\geq} : f_{\geq t}^P(x) \geq \alpha_{\geq t}\}, \\ \underline{P}^{\alpha_{\leq t}}(Cl_t^{\leq}) &= \{x \in Cl_t^{\leq} : f_{\leq t}^P(x) \geq \alpha_{\leq t}\},\end{aligned}$$
- Cost-type consistency measures  $g_{\geq t}^P(x), g_{\leq t}^P(x)$

$$\begin{aligned}\underline{P}^{\beta_{\geq t}}(Cl_t^{\geq}) &= \{x \in Cl_t^{\geq} : g_{\geq t}^P(x) \geq \beta_{\geq t}\}, \\ \underline{P}^{\beta_{\leq t}}(Cl_t^{\leq}) &= \{x \in Cl_t^{\leq} : g_{\leq t}^P(x) \geq \beta_{\leq t}\},\end{aligned}$$

where  $\alpha_{\geq t}, \alpha_{\leq t}, \beta_{\geq t}, \beta_{\leq t}$ , are threshold values on the consistency measures that condition the inclusion of object  $x$  in the  $P$ -lower approximation of  $Cl_t^{\geq}$ , or

$Cl_t^{\leq}$ . Here are the consistency measures considered in [22.33]: for all  $x \in U$  and  $P \subseteq C$

$$\begin{aligned}\mu_{\geq t}^P(x) &= \frac{|D_P^+(x) \cap Cl_t^{\geq}|}{|D_P^+(x)|}, \\ \mu_{\leq t}^P(x) &= \frac{|D_P^-(x) \cap Cl_t^{\leq}|}{|D_P^-(x)|}, \\ \overline{\mu}_{\geq t}^P(x) &= \max_{\substack{R \subseteq P, \\ z \in D_R^+(x) \cap Cl_t^{\geq}}} \frac{|D_R^+(z) \cap Cl_t^{\geq}|}{|D_R^+(z)|}, \\ \overline{\mu}_{\leq t}^P(x) &= \max_{\substack{R \subseteq P, \\ z \in D_R^-(x) \cap Cl_t^{\leq}}} \frac{|D_R^-(z) \cap Cl_t^{\leq}|}{|D_R^-(z)|}, \\ B_{\geq t}^P(x) &= \frac{|D_P^+(x) \cap Cl_t^{\geq}| |Cl_{t-1}^{\leq}|}{|D_P^+(x) \cap Cl_{t-1}^{\leq}| |Cl_t^{\geq}|}, \quad t = 2, \dots, m, \\ B_{\leq t}^P(x) &= \frac{|D_P^-(x) \cap Cl_t^{\leq}| |Cl_{t+1}^{\geq}|}{|D_P^-(x) \cap Cl_{t+1}^{\geq}| |Cl_t^{\leq}|}, \\ \varepsilon_{\geq t}^P(x) &= \frac{|D_P^+(x) \cap Cl_{t-1}^{\leq}|}{|Cl_{t-1}^{\leq}|}, \quad t = 2, \dots, m, \\ \varepsilon_{\leq t}^P(x) &= \frac{|D_P^-(x) \cap Cl_{t+1}^{\geq}|}{|Cl_{t+1}^{\geq}|}, \quad t = 1, \dots, m-1, \\ \varepsilon'_{\geq t}^P(x) &= \frac{|D_P^+(x) \cap Cl_{t-1}^{\leq}|}{|Cl_t^{\geq}|}, \quad t = 2, \dots, m, \\ \varepsilon'_{\leq t}^P(x) &= \frac{|D_P^-(x) \cap Cl_{t+1}^{\geq}|}{|Cl_t^{\leq}|}, \quad t = 1, \dots, m-1, \\ \varepsilon_{\geq t}^{*P}(x) &= \max_{r \leq t} \varepsilon_{\geq r}^P(x), \\ \varepsilon_{\leq t}^{*P}(x) &= \max_{r \geq t} \varepsilon_{\leq r}^P(x),\end{aligned}$$

with

$$\begin{aligned}\mu_{\geq t}^P(x), \mu_{\leq t}^P(x), \overline{\mu}_{\geq t}^P(x), \\ \overline{\mu}_{\leq t}^P(x), B_{\geq t}^P(x), B_{\leq t}^P(x)\end{aligned}$$

being gain-type consistency measures and

$$\varepsilon_{\geq t}^P(x), \varepsilon_{\leq t}^P(x), \varepsilon'_{\geq t}^P(x), \varepsilon'_{\leq t}^P(x), \varepsilon_{\geq t}^{*P}(x), \varepsilon_{\leq t}^{*P}(x)$$

being cost-type consistency measures.

To be concordant with the rough set philosophy, consistency measures should enjoy some monotonicity properties (Table 22.1). A consistency measure is monotonic if it does not decrease (or does not increase) when:

**Table 22.1** Monotonicity properties of consistency measures (after [22.33])

Consistency measure	(m1)	(m2)	(m3)	(m4)
$\mu_{\geq t}^P(x), \mu_{\leq t}^P(x)$ (rough membership)	no	yes	yes	no
$\overline{\mu}_{\geq t}^P(x), \overline{\mu}_{\leq t}^P(x)$	yes	yes	yes	yes
$B_{\geq t}^P(x), B_{\leq t}^P(x)$ (Bayesian)	no	no	no	no
$\varepsilon_{\geq t}^P(x), \varepsilon_{\leq t}^P(x)$	yes	yes	no	yes
$\varepsilon_{\geq t}^{*P}(x), \varepsilon_{\leq t}^{*P}(x)$	yes	yes	yes	yes
$\varepsilon'_{\geq t}^P(x), \varepsilon'_{\leq t}^P(x)$	yes	yes	yes	yes

(m1) The set of attributes is growing.

(m2) The set of objects is growing.

(m3) The union of ordered classes is growing.

(m4)  $x$  improves its evaluation, so that it dominates more objects.

For every  $P \subseteq C$ , the objects being consistent in the sense of the dominance principle with all upward and downward unions of classes are called *P-correctly classified*. For every  $P \subseteq C$ , the *quality of approximation of classification Cl* by the set of criteria  $P$  is defined as the ratio between the number of  $P$ -correctly classified objects and the number of all the objects in the decision table. Since the objects which are  $P$ -correctly classified are those that do not belong to any  $P$ -boundary of unions  $Cl_t^{\geq}$  and  $Cl_t^{\leq}$ ,  $t = 1, \dots, n$ , the quality of approximation of classification  $Cl$  by the set of criteria  $P$ , can be written as

$$\begin{aligned}\gamma_P(Cl) &= \frac{|(U - (\bigcup_{t \in \{1, \dots, n\}} Bn_P(Cl_t^{\geq})))|}{|U|} \\ &\quad \cup \frac{|(\bigcup_{t \in \{1, \dots, n\}} Bn_P(Cl_t^{\leq}))|}{|U|} \\ &= \frac{|(U - (\bigcup_{t \in \{1, \dots, n\}} Bn_P(Cl_t^{\geq})))|}{|U|}.\end{aligned}$$

$\gamma_P(Cl)$  can be seen as a measure of the quality of knowledge that can be extracted from the decision table, where  $P$  is the set of criteria and  $Cl$  is the classification considered.

Each minimal subset  $P \subseteq C$ , such that  $\gamma_P(Cl) = \gamma_C(Cl)$ , is called a *reduct* of  $Cl$  and is denoted by  $RED_{Cl}$ . Note that a decision table can have more than one reduct. The intersection of all reducts is called the *core* and is denoted by  $CORE_{Cl}$ . Criteria from  $CORE_{Cl}$  cannot be removed from the decision table without deteriorating the knowledge to be discovered. This means that in set  $C$  there are three categories of criteria:

- *Indispensable* criteria included in the core.
- *Exchangeable* criteria included in some reducts but not in the core.
- *Redundant* criteria that are neither indispensable nor exchangeable, thus not included in any reduct.

Note that reducts are minimal subsets of criteria conveying the relevant knowledge contained in the decision table. This knowledge is relevant for the explanation of patterns in a given decision table but not necessarily for prediction.

It has been shown in [22.34] that the quality of classification satisfies properties of set functions called *fuzzy measures*. For this reason, we can use the quality of classification for the calculation of indices that measure the relevance of particular attributes and/or criteria, in addition to the strength of interactions between them. The useful indices are: the value index and interaction indices of Shapley and Banzhaf; the interaction indices of Murofushi-Soneda and Roubens; and the Möbius representation [22.15]. All these indices can help to assess the interaction between the criteria considered and can help us to choose the best reduct.

### 22.3.3 Stochastic Dominance-based Rough Set Approach

From a probabilistic point of view, the assignment of object  $x_i$  to *at least* class  $t$  can be made with probability  $\Pr(y_i \geq t | x_i)$ , where  $y_i$  is the classification decision for  $x_i$ ,  $t = 1, \dots, n$ . This probability is supposed to satisfy the usual axioms of probability

$$\begin{aligned}\Pr(y_i \geq 1 | x_i) &= 1, \\ \Pr(y_i \leq t | x_i) &= 1 - \Pr(y_i \geq t + 1 | x_i), \text{ and} \\ \Pr(y_i \geq t | x_i) &\leq \Pr(y_i \geq t' | x_i) \quad \text{for } t \geq t'.\end{aligned}$$

These probabilities are unknown but can be estimated from data.

For each class  $t = 2, \dots, n$ , we have a binary problem of estimating the conditional probabilities  $\Pr(y_i \geq t | x_i) = 1$ ,  $\Pr(y_i < t | x_i)$ . It can be solved by *isotonic regression* [22.35]. Let  $y_{it} = 1$  if  $y_i \geq t$ , otherwise  $y_{it} = 0$ . Let also  $p_{it}$  be the estimate of the probability  $\Pr(y_i \geq t | x_i)$ . Then, choose estimates  $p_{it}^*$  which minimize the squared distance to the class assignment  $y_{it}$ , subject to the monotonicity constraints

$$\begin{aligned}\text{Minimize} \quad & \sum_{i=1}^{|U|} (y_{it} - p_{it})^2 \\ \text{subject to} \quad & p_{it} \geq p_{jt} \quad \text{for all } x_i, x_j \in U \text{ such that } x_i \succeq x_j,\end{aligned}$$

where  $x_i \succeq x_j$  means that  $x_i$  dominates  $x_j$ .

Then, stochastic  $\alpha$ -lower approximations for classes *at least*  $t$  and *at most*  $t - 1$  can be defined as

$$\begin{aligned}\underline{P}^\alpha(Cl_t^{\geq}) &= \{x_i \in U : \Pr(y_i \geq t | x_i) \geq \alpha\}, \\ \underline{P}^\alpha(Cl_{t-1}^{\leq}) &= \{x_i \in U : \Pr(y_i < t | x_i) \geq \alpha\}.\end{aligned}$$

Replacing the unknown probabilities  $\Pr(y_i \geq t | x_i)$  and  $\Pr(y_i < t | x_i)$  by their estimates  $p_{it}^*$  and  $1 - p_{it}^*$  obtained from isotonic regression, we obtain

$$\begin{aligned}\underline{P}^\alpha(Cl_t^{\geq}) &= \{x_i \in U : p_{it}^* \geq \alpha\}, \\ \underline{P}^\alpha(Cl_{t-1}^{\leq}) &= \{x_i \in U : p_{it}^* \leq 1 - \alpha\},\end{aligned}$$

where parameter  $\alpha \in [0.5, 1]$  controls the allowed amount of inconsistency.

Solving isotonic regression requires  $O(|U|^4)$  time, but a good heuristic needs only  $O(|U|^2)$ . In fact, as shown in [22.35], we do not really need to know the probability estimates to obtain stochastic lower approximations. We only need to know for which object  $x_i$ ,  $p_{it}^* \geq \alpha$  and for which  $x_i$ ,  $p_{it}^* \leq 1 - \alpha$ . This can be found by solving a linear programming (reassignment) problem.

As before,  $y_{it} = 1$  if  $y_i \geq t$ , otherwise  $y_{it} = 0$ . Let  $d_{it}$  be the decision variable which determines a new class assignment for object  $x_i$ . Then, reassign objects from union of classes indicated by  $y_{it}$  to the union of classes indicated by  $d_{it}^*$ , such that the new class assignments are consistent with the dominance principle, where  $d_{it}^*$  results from solving the following linear programming problem

$$\begin{aligned}\text{Minimize} \quad & \sum_{i=1}^{|U|} w_{y_{it}} |y_{it} - d_{it}| \\ \text{subject to} \quad & d_{it} \geq d_{jt} \quad \text{for all } x_i, x_j \in U \\ & \text{such that } x_i \succeq x_j,\end{aligned}$$

where  $w_{y_{it}}$  are some positive weights and  $x_i \succeq x_j$  means that  $x_i$  dominates  $x_j$ .

Due to unimodularity of the constraint matrix, the optimal solution of this linear programming problem is always integer, i.e.,  $d_{it}^* \in \{0, 1\}$ . For all objects consistent with the dominance principle,  $d_{it}^* = y_{it}$ . If we set  $w_0 = \alpha$  and  $w_1 = \alpha - 1$ , then the optimal solution  $d_{it}^*$  satisfies:  $d_{it}^* = 1 \Leftrightarrow p_{it}^* \geq \alpha$ . If we set  $w_0 = 1 - \alpha$  and  $w_1 = \alpha$ , then the optimal solution  $d_{it}^*$  satisfies:  $d_{it}^* = 0 \Leftrightarrow p_{it}^* \leq 1 - \alpha$ .

For each  $t = 2, \dots, n$ , solving the reassignment problem twice, we can obtain the lower approximations  $\underline{P}^\alpha(Cl_t^{\geq})$ ,  $\underline{P}^\alpha(Cl_{t-1}^{\leq})$ , without knowing the probability estimates!

### 22.3.4 Induction of Decision Rules

Using the terms of knowledge discovery, the dominance-based rough approximations of upward and downward unions of classes are applied on the data set in the pre-processing stage. In result of this stage, the data are structured in a way that facilitates induction of *if ... , then ...* decision rules with a guaranteed consistency level. For a given upward or downward union of classes,  $Cl_t^{\geq}$  or  $Cl_s^{\leq}$ , the decision rules induced under the hypothesis that objects belonging to  $P(Cl_t^{\geq})$  or  $P(Cl_s^{\leq})$  are positive and all the others are negative, suggests an assignment to *class  $Cl_t$  or better*, or to *class  $Cl_s$  or worse*, respectively. On the other hand, the decision rules induced under a hypothesis that objects belonging to the intersection  $\overline{P}(Cl_s^{\leq}) \cap \overline{P}(Cl_t^{\geq})$  are positive and all the others are negative, suggest an assignment to some classes between  $Cl_s$  and  $Cl_t$  ( $s < t$ ).

In the case of preference ordered data it is meaningful to consider the following five types of decision rules:

1. *Certain  $D_{\geq}$ -decision rules.* These provide lower profile descriptions for objects belonging to  $Cl_t^{\geq}$  without ambiguity:  
if  $x_{q1} \succeq_{q1} r_{q1}$  and  $x_{q2} \succeq_{q2} r_{q2}$  and ...  $x_{qp} \succeq_{qp} r_{qp}$ , then  $x \in Cl_t^{\geq}$ , where for each  $w_q, z_q \in X_q$ ,  $w_q \succeq_q z_q$  means  $w_q$  is at least as good as  $z_q$ .
2. *Possible  $D_{\geq}$ -decision rules.* Such rules provide lower profile descriptions for objects belonging to  $Cl_t^{\geq}$  with or without any ambiguity:  
if  $x_{q1} \succeq_{q1} r_{q1}$  and  $x_{q2} \succeq_{q2} r_{q2}$  and ...  $x_{qp} \succeq_{qp} r_{qp}$ , then  $x$  possibly belongs to  $Cl_t^{\geq}$ .
3. *Certain  $D_{\leq}$ -decision rules.* These give upper profile descriptions for objects belonging to  $Cl_t^{\leq}$  without ambiguity:  
if  $x_{q1} \preceq_{q1} r_{q1}$  and  $x_{q2} \preceq_{q2} r_{q2}$  and ...  $x_{qp} \preceq_{qp} r_{qp}$ , then  $x \in Cl_t^{\leq}$ , where for each  $w_q, z_q \in X_q$ ,  $w_q \preceq_q z_q$  means  $w_q$  is at most as good as  $z_q$ .
4. *Possible  $D_{\leq}$ -decision rules.* These provide upper profile descriptions for objects belonging to  $Cl_t^{\leq}$  with or without any ambiguity:  
if  $x_{q1} \preceq_{q1} r_{q1}$  and  $x_{q2} \preceq_{q2} r_{q2}$  and ...  $x_{qp} \preceq_{qp} r_{qp}$ , then  $x$  possibly belongs to  $Cl_t^{\leq}$ .
5. *Approximate  $D_{\geq\leq}$ -decision rules.* These represent simultaneously lower and upper profile descriptions for objects belonging to  $Cl_s \cup Cl_{s+1} \cup \dots \cup Cl_t$  without the possibility of discerning the actual class:  
if  $x_{q1} \succeq_{q1} r_{q1}$  and ...  $x_{qk} \succeq_{qk} r_{qk}$  and  $x_{qk+1} \preceq_{qk+1} r_{qk+1}$  and ...  $x_{qp} \preceq_{qp} r_{qp}$ , then  $x \in Cl_s \cup Cl_{s+1} \cup \dots \cup Cl_t$ .

In the left-hand side of a  $D_{\geq\leq}$ -decision rule we can have  $x_q \succeq_q r_q$  and  $x_q \preceq_q r'_q$ , where  $r_q \leq r'_q$ , for the same  $q \in C$ . Moreover, if  $r_q = r'_q$ , the two conditions boil down to  $x_q \sim_q r_q$ , where for each  $w_q, z_q \in X_q$ ,  $w_q \sim_q z_q$  means  $w_q$  is *indifferent* to  $z_q$ .

A rule is *minimal* if there is no other rule with a left-hand side that has at least the same weakness (which means that it uses a subset of elementary conditions and/or weaker elementary conditions) and which has a right-hand side that has at least the same strength (which means a  $D_{\geq}$ - or a  $D_{\leq}$ -decision rule assigning objects to the same union or sub-union of classes, or a  $D_{\geq\leq}$ -decision rule assigning objects to the same or larger set of classes).

Rules of type 1) and 3) represent certain knowledge extracted from the decision table, while the rules of type 2) and 4) represent possible knowledge. Rules of type 5) represent doubtful knowledge.

Rules of type 1) and 3) are *exact* if they do not cover negative examples; they are *probabilistic*, otherwise. In the latter case, each rule is characterized by a confidence ratio, representing the probability that an object matching the left-hand side of the rule also matches its right-hand side.

A set of decision rules is *complete* if it is able to cover all objects from the decision table in such a way that consistent objects are re-classified to their original classes and inconsistent objects are classified to clusters of classes that refer to this inconsistency. Each set of decision rules that is complete and non-redundant is called *minimal*. Note that an exclusion of any rule from this set makes it non-complete.

In the case of **VC-DRSA**, the decision rules are probabilistic because they are induced from the  $P$ -lower approximations whose composition is controlled by the user-specified consistency level  $l$ . Consequently, the value of confidence  $\alpha$  for the rule should be constrained from the bottom. It is reasonable to require that the smallest accepted confidence level of the rule should not be lower than the currently used consistency level  $l$ . Indeed, in the worst case, some objects from the  $P$ -lower approximation may create a rule using all the criteria from  $P$ , thus giving a confidence  $\alpha \geq l$ .

Observe that the syntax of decision rules induced from dominance-based rough approximations uses the concept of dominance cones: each condition profile is a dominance cone in  $X_C$ , and each decision profile is a dominance cone in  $X_D$ . In both cases the cone is positive for  $D_{\geq}$ -rules and negative for  $D_{\leq}$ -rules.

Also note that dominance cones that correspond to condition profiles can originate in any point of  $X_C$ , without the risk of being too specific. Thus, in contrast to granular computing based on the indiscernibility (or similarity) relation, in the case of granular computing based on dominance, the condition attribute space  $X_C$  need not be discretized [22.28, 36, 37].

Procedures for induction of rules from dominance-based rough approximations have been proposed in [22.38, 39]. A publicly available computer implementation of one of these procedures is called **JMAF** (java multi-criteria and multi-attribute analysis framework) [22.40, 41].

The utility of decision rules is threefold: they *explain* (summarize) decisions made on objects from the dataset, they can be used to *make decisions* with respect to new (unseen) objects which are matching conditions of some rules, and they permit to *build up a strategy of intervention* [22.42]. The attractiveness of particular decision rules can be measured in many different ways; however, the most convincing measures are Bayesian confirmation measures enjoying a special monotonicity property, as reported in [22.43, 44].

In [22.45], a new methodology for the induction of monotonic decision trees from dominance-based rough approximations of preference ordered decision classes was proposed.

It is finally worth noting that several algebraic models have been proposed for **DRSA** [22.29, 46, 47] – the algebraic structures are based on bipolar disjoint representation (positive and negative) of the interior and the exterior of a concept. These algebra models give elegant representations of the basic properties of dominance-based rough sets. Moreover, a topology for **DRSA** in a bitopological space was proposed in [22.48].

### 22.3.5 Rule-based Classification Algorithms

We will now comment upon the application of decision rules to some objects described by criteria from  $C$ . When applying  $D_{\geq}$ -decision rules to an object  $x$ , it is possible that  $x$  either matches the left hand side of at least one decision rule or it does not. In the case of at least one such match, it is reasonable to conclude that  $x$  belongs to class  $Cl_t$ , because it is the lowest class of the upward union  $Cl_t^{\geq}$  which results from intersection of all the right hand sides of the rules covering  $x$ . More precisely, if  $x$  matches the left-hand side of rules  $\rho_1, \rho_2, \dots, \rho_m$ , having right-hand sides  $x \in C_{t1}^{\geq}, x \in Cl_{t2}^{\geq}, \dots, x \in Cl_{tm}^{\geq}$ , then  $x$  is assigned to

class  $Cl_t$ , where  $t = \max\{t1, t2, \dots, tm\}$ . In the case of no matching, we can conclude that  $x$  belongs to  $Cl_1$ , i.e., to the worst class, since no rule with a right-hand side suggesting a better classification of  $x$  covers this object.

Analogously, when applying  $D_{\leq}$ -decision rules to the object  $x$ , we can conclude that  $x$  belongs either to class  $Cl_z$  (because it is the highest class of the downward union  $Cl_t^{\leq}$  resulting from the intersection of all the right-hand sides of the rules covering  $x$ ), or to class  $Cl_n$ , i.e., to the best class, when  $x$  is not covered by any rule. More precisely, if  $x$  matches the left-hand side of rules  $\rho_1, \rho_2, \dots, \rho_m$ , having right-hand sides  $x \in C_{t1}^{\leq}, x \in Cl_{t2}^{\leq}, \dots, x \in Cl_{tm}^{\leq}$ , then  $x$  is assigned to class  $Cl_t$ , where  $t = \min\{t1, t2, \dots, tm\}$ . In the case of no matching, it is concluded that  $x$  belongs to the best class  $Cl_n$  because no rule with a right-hand side suggesting a worse classification of  $x$  covers this object. Finally, when applying  $D_{\geq\leq}$ -decision rules to  $x$ , it is possible to conclude that  $x$  belongs to the union of all the classes suggested in the right-hand side of the rules covering  $x$ .

A new classification algorithm was proposed in [22.49]. Let  $\varphi_1 \rightarrow \psi_1, \dots, \varphi_k \rightarrow \psi_k$ , be the rules matching object  $x$ . Then,  $R_t(x) = \{j: Cl_j \in \psi_j, j = 1, \dots, k\}$  denotes the set of rules matching  $x$ , which recommend assignment of object  $x$  to a union including class  $Cl_t$ , and  $R_{\neg t}(x) = \{j: Cl_j \notin \psi_j, j = 1, \dots, k\}$  denotes the set of rules matching  $x$ , which do not recommend assignment of object  $x$  to a union including class  $Cl_t$ .  $||\varphi_j||, ||\psi_j||$  are sets of objects with property  $\varphi_j$  and  $\psi_j$ , respectively,  $j = 1, \dots, k$ . For a classified object  $x$ , one has to calculate the score for each candidate class

$$score(Cl_t, x) = score^+(Cl_t, x) - score^-(Cl_t, x),$$

where

$$score^+(Cl_t, x) = \frac{\left| \bigcup_{j \in R_t(x)} (||\varphi_j|| \cap Cl_t) \right|^2}{\left| \bigcup_{j \in R_t(x)} ||\varphi_j|| \right| \times |Cl_t|}$$

and

$$score^-(Cl_t, x) = \frac{\left| \bigcup_{j \in R_{\neg t}(x)} (||\varphi_j|| \cap ||\psi_j||) \right|^2}{\left| \bigcup_{j \in R_{\neg t}(x)} ||\varphi_j|| \right| \times \left| \bigcup_{j \in R_{\neg t}(x)} ||\psi_j|| \right|}.$$

$score^+(Cl_t, x)$  and  $score^-(Cl_t, x)$  can be interpreted in terms of conditional probability as a product of confidence and coverage of the matching rules

$$\begin{aligned} score^+(Cl_t, x) &= \Pr(\{\varphi_j : j \in R_t(x)\} | Cl_t) \\ &\quad \times \Pr(Cl_t | \{\varphi_j : j \in R_t(x)\}), \\ score^-(Cl_t, x) &= \Pr(\{\varphi_j : j \in R_{\neg t}(x)\} | \neg Cl_t) \\ &\quad \times \Pr(\neg Cl_t | \{\varphi_j : j \in R_{\neg t}(x)\}). \end{aligned}$$

The recommendation of the univocal classification  $x \rightarrow Cl_t$  is such that

$$Cl_t = \arg \max_{t \in \{1, \dots, n\}} [score(Cl_t, x)].$$

Examples illustrating the application of DRSA to multi-criteria classification in a didactic way can be found in [22.12–14, 50].

## 22.4 The Dominance-based Rough Set Approach to Multi-Criteria Choice and Ranking

### 22.4.1 Differences with Respect to Multi-Criteria Classification

One of the very first extensions of DRSA concerned preference ordered data representing pairwise comparisons (i.e., binary relations) between objects on both, condition and decision attributes [22.7, 8, 25, 51]. Note that while classification is based on the absolute evaluation of objects, choice and ranking refer to pairwise comparisons of objects. In this case, the decision rules to be discovered from the data characterize a comprehensive binary relation on the set of objects. If this relation is a preference relation and if, among the condition attributes, there are some criteria which are semantically correlated with the comprehensive preference relation, then the data set (serving as the learning sample) can be considered as preference information provided by a DM in a multi-criteria choice or ranking problem. In consequence, the comprehensive preference relation characterized by the decision rules discovered from this data set can be considered as a *preference model* of the DM. It may be used to explain the decision policy of the DM and to recommend an optimal choice or preference ranking with respect to new objects.

Let us consider a finite set  $A$  of objects evaluated by a finite set  $C$  of criteria. The optimal choice (or the preference ranking) in set  $A$  is semantically correlated with the criteria from set  $C$ . The preference information concerning the multi-criteria choice or ranking problem is a data set in the form of a pairwise comparison table which includes pairs of some *reference objects* from a subset  $B \subseteq A \times A$ . This is described by preference relations on particular criteria and a comprehensive preference relation. One such example is a weak preference relation called the *outranking relation*. By using DRSA for the analysis of the pairwise

comparison table, we can obtain a rough approximation of the *outranking relation* by a dominance relation. The decision rules induced from the rough approximation are then applied to the complete set  $A$  of the objects associated with the choice or ranking. As a result, one obtains a four-valued outranking relation on this set. In order to obtain a recommendation, it is advisable to use an exploitation procedure based on the net flow score of the objects. We present this methodology in more detail below.

### 22.4.2 The Pairwise Comparison Table as Input Preference Information

Given a multi-criteria choice or ranking problem, a DM can express the preferences by pairwise comparisons of the reference objects. In the following,  $xSy$  denotes the presence, while  $xS^c y$  denotes the absence of the outranking relation for a pair of objects  $(x, y) \in A \times A$ . Relation  $xSy$  reads *object x is at least as good as object y*.

For each pair of reference objects  $(x, y) \in B \subseteq A \times A$ , the DM can select one of the three following possibilities:

1. Object  $x$  is as good as  $y$ , i.e.,  $xSy$ .
2. Object  $x$  is worse than  $y$ , i.e.,  $xS^c y$ .
3. The two objects are incomparable at the present stage.

A pairwise comparison table, denoted by  $S_{PCT}$ , is then created on the basis of this information. The first  $m$  columns correspond to the criteria from set  $C$ . The last, i.e., the  $(m+1)$ -th column, represents the comprehensive binary preference relation  $S$  or  $S^c$ . The rows correspond to the pairs from  $B$ . For each pair in  $S_{PCT}$ ,

a difference between criterion values is put in the corresponding column. If the DM judges that two objects are incomparable, then the corresponding pair does not appear in  $S_{PCT}$ .

We will define  $S_{PCT}$  more formally. For any criterion  $g_i \in C$ , let  $T_i$  be a finite set of binary relations defined on  $A$  on the basis of the evaluations of objects from  $A$  with respect to the considered criterion  $g_i$ , such that for every  $(x, y) \in A \times A$  exactly one binary relation  $t \in T_i$  is verified. More precisely, given the domain  $V_i$  of  $g_i \in C$ , if  $v'_i, v''_i \in V_i$  are the respective evaluations of  $x, y \in A$  by means of  $g_i$  and  $(x, y) \in t$ , with  $t \in T_i$ , then for each  $w, z \in A$  having the same evaluations  $v'_i, v''_i$  by means of  $g_i$ ,  $(w, z) \in t$ . Furthermore, let  $T_d$  be a set of binary relations defined on set  $A$  (comprehensive pairwise comparisons) such that at most one binary relation  $t \in T_d$  is verified for every  $(x, y) \in A \times A$ .

The *pairwise comparison table* is defined as the data table  $S_{PCT} = \langle B, C \cup \{d\}, T_G \cup T_d, f \rangle$ , where  $B \subseteq A \times A$  is a non-empty set of exemplary pairwise comparisons of reference objects,  $T_G = \bigcup_{g_i \in G} T_i$ ,  $d$  is a decision corresponding to the comprehensive pairwise comparison (comprehensive preference relation), and  $f : B \times (C \cup \{d\}) \rightarrow T_G \cup T_d$  is a total function such that  $f[(x, y), q] \in T_i$  for every  $(x, y) \in A \times A$  and for each  $g_i \in C$ , and  $f[(x, y), q] \in T_d$  for every  $(x, y) \in B$ . It follows that for any pair of reference objects  $(x, y) \in B$  there is verified one and only one binary relation  $t \in T_d$ . Thus,  $T_d$  induces a partition of  $B$ . In fact, the data table  $S_{PCT}$  can be seen as a decision table, since the set  $C$  of considered criteria and the decision  $d$  are distinguished.

We consider a pairwise comparison table where the set  $T_d$  is composed of two binary relations defined on  $A$ :

- $x$  outranks  $y$  (denoted by  $xSy$  or  $(x, y) \in S$ ), where  $(x, y) \in B$ ,
- $x$  does not outrank  $y$  (denoted by  $xS^c y$  or  $(x, y) \in S^c$ ), where  $(x, y) \in B$ , and  $S \cup S^c = B$ .

Observe that the binary relation  $S$  is reflexive, but not necessarily transitive or complete.

### 22.4.3 Rough Approximation of Preference Relations

In the following, we will distinguish between two types of evaluation scales of criteria: *cardinal* and *ordinal*. Let  $C^N$  be the set of criteria expressing preferences on a cardinal scale, and let  $C^O$  be the set of criteria expressing preferences on an ordinal scale, such that  $C^N \cup C^O = C$  and  $C^N \cap C^O = \emptyset$ . Moreover, for each  $P \subseteq C$ , we denote by  $P^O$  the subset of  $P$  composed of

criteria expressing preferences on an ordinal scale, i. e.,  $P^O = P \cap C^O$ , and by  $P^N$  we denote the subset of  $P$  composed of criteria expressing preferences on a cardinal scale, i. e.,  $P^N = P \cap C^N$ . Of course, for each  $P \subseteq C$ , we have  $P = P^N \cup P^O$  and  $P^N \cap P^O = \emptyset$ .

The meaning of the two scales is such that in the case of the cardinal scale we can specify the intensity of the preference for a given difference of evaluations, while in the case of the ordinal scale, this is not possible and we can only establish an order of evaluations.

#### Multi-Graded Dominance

We assume that the pairwise comparisons of reference objects on cardinal criteria from set  $C^N$  can be represented in terms of *graded preference relations* (for example, *very weak preference*, *weak preference*, *strict preference*, *strong preference*, and *very strong preference*), denoted by  $xP_q^h y$ : for each  $q \in C^N$  and for every  $(x, y) \in A \times A$ ,  $T_i = \{P_q^h, h \in H_i\}$ , where  $H_i$  is a particular subset of the relative integers and:

- $xP_q^h y, h > 0$ , means that object  $x$  is preferred to object  $y$  by degree  $h$  with respect to criterion  $g_i$ .
- $xP_q^h y, h < 0$ , means that object  $x$  is not preferred to object  $y$  by degree  $h$  with respect to criterion  $g_i$ .
- $xP_q^0 y$  means that object  $x$  is similar (asymmetrically indifferent) to object  $y$  with respect to criterion  $g_i$ .

Within the preference context, the similarity relation  $P_i^0$ , even if not symmetric, resembles the indifference relation. Thus, in this case, we call this similarity relation *asymmetric indifference*. Of course, for each  $g_i \in C$  and for every  $(x, y) \in A \times A$ ,

$$\begin{aligned} [xP_i^h y, h > 0] &\Rightarrow [yP_i^k x, k \leq 0], \\ [xP_i^h y, h < 0] &\Rightarrow [yP_i^k x, k \geq 0]. \end{aligned}$$

Let  $P = P^N$  and  $P^O = \emptyset$ . Given  $P \subseteq C$  ( $P \neq \emptyset$ ),  $(x, y), (w, z) \in A \times A$ , the pair of objects  $(x, y)$  is said to dominate  $(w, z)$  with respect to criteria from  $P$  (denoted by  $(x, y)D_P(w, z)$ ), if  $x$  is preferred to  $y$  at least as strongly as  $w$  is preferred to  $z$  with respect to each  $g_i \in P$ . More precisely, *at least as strongly as* means by *at least the same degree*, i. e.,  $h \geq k$ , where  $h, k \in H_i$ ,  $xP_i^h y$ , and  $wP_i^k z$ , for each  $g_i \in P$ .

Let  $D_{\{i\}}$  be the dominance relation confined to the single criterion  $g_i \in P$ . The binary relation  $D_{\{i\}}$  is reflexive  $((x, y)D_{\{i\}}(x, y)$  for every  $(x, y) \in A \times A$ ), transitive  $((x, y)D_{\{i\}}(w, z)$  and  $(w, z)D_{\{i\}}(u, v)$  imply  $(x, y)D_{\{i\}}(u, v)$  for every  $(x, y), (w, z), (u, v) \in A \times A$ ), and complete  $((x, y)D_{\{i\}}(w, z)$  and/or  $(w, z)D_{\{i\}}(x, y)$

for all  $(x, y), (w, z) \in A \times A$ . Therefore,  $D_{\{i\}}$  is a complete preorder on  $A \times A$ . Since the intersection of complete preorders is a partial preorder, and  $D_P = \bigcap_{g_i \in P} D_{\{i\}}$ ,  $P \subseteq C$ , the dominance relation  $D_P$  is a partial preorder on  $A \times A$ .

Let  $R \subseteq P \subseteq C$  and  $(x, y), (u, v) \in A \times A$ ; then the following implication holds

$$(x, y)D_P(u, v) \Rightarrow (x, y)D_R(u, v).$$

Given  $P \subseteq C$  and  $(x, y) \in A \times A$ , we define the following:

- A set of pairs of objects dominating  $(x, y)$ , called the *P-dominating set*, denoted by  $D_P^+(x, y)$  and defined as  $\{(w, z) \in A \times A : (w, z)D_P(x, y)\}$ .
- A set of pairs of objects dominated by  $(x, y)$ , called the *P-dominated set*, denoted by  $D_P^-(x, y)$  and defined as  $\{(w, z) \in A \times A : (x, y)D_P(w, z)\}$ .

The *P*-dominating sets and the *P*-dominated sets defined on  $B$  for all pairs of reference objects from  $B$  are *granules of knowledge* that can be used to express *P*-lower and *P*-upper approximations of the comprehensive outranking relations  $S$  and  $S^c$ , respectively,

$$\underline{P}(S) = \left\{ (x, y) \in B : D_P^+(x, y) \subseteq S \right\},$$

$$\overline{P}(S) = \bigcup_{(x, y) \in S} D_P^+(x, y).$$

$$\underline{P}(S^c) = \left\{ (x, y) \in B : D_P^-(x, y) \subseteq S^c \right\},$$

$$\overline{P}(S^c) = \bigcup_{(x, y) \in S^c} D_P^-(x, y).$$

It was proved in [22.7] that

$$\underline{P}(S) \subseteq S \subseteq \overline{P}(S), \quad \underline{P}(S^c) \subseteq S^c \subseteq \overline{P}(S^c).$$

Furthermore, the following complementarity properties hold

$$\underline{P}(S) = B - \overline{P}(S^c), \quad \overline{P}(S) = B - \underline{P}(S^c),$$

$$\underline{P}(S^c) = B - \overline{P}(S), \quad \overline{P}(S^c) = B - \underline{P}(S).$$

The *P*-boundaries (*P*-doubtful regions) of  $S$  and  $S^c$  are defined as

$$Bn_P(S) = \overline{P}(S) - \underline{P}(S),$$

$$Bn_P(S^c) = \overline{P}(S^c) - \underline{P}(S^c).$$

From the above it follows that  $Bn_P(S) = Bn_P(S^c)$ .

The concepts of the quality of approximation, reducts, and core can also be extended to the approximation of the outranking relation by the multi-graded dominance relations.

In particular, the coefficient

$$\gamma_P = \frac{|\underline{P}(S) \cup \overline{P}(S^c)|}{|B|}$$

defines the *quality of approximation of S and  $S^c$*  by  $P \subseteq C$ . It expresses the ratio of all pairs of reference objects  $(x, y) \in B$  correctly assigned to  $S$  and  $S^c$  by the set  $P$  of criteria to all the pairs of objects contained in  $B$ . Each minimal subset  $P \subseteq C$ , such that  $\gamma_P = \gamma_C$ , is called a *reduct* of  $C$  (denoted by  $RED_{SPCT}$ ). Note that  $SPCT$  can have more than one reduct. The intersection of all  $B$ -reducts is called the *core* (denoted by  $CORE_{SPCT}$ ).

It is also possible to use the variable consistency model on  $SPCT$  [22.52], if one is aware that some of the pairs in the positive or negative dominance sets belong to the opposite relation, while at least  $l * 100\%$  of pairs belong to the correct one. Then the definition of the lower approximations of  $S$  and  $S^c$  boils down to

$$\underline{P}(S) = \left\{ (x, y) \in B : \frac{|D_P^+(x, y) \cap S|}{|D_P^+(x, y)|} \geq l \right\},$$

$$\underline{P}(S^c) = \left\{ (x, y) \in B : \frac{|D_P^-(x, y) \cap S^c|}{|D_P^-(x, y)|} \geq l \right\}.$$

### Dominance Without Degrees of Preference

The degree of graded preference considered above is defined on a cardinal scale of the strength of preference. However, in many real world problems, the existence of such a quantitative scale is rather questionable. This is the case with ordinal scales of criteria. In this case, the dominance relation is defined directly on evaluations  $g_i(x)$  for all objects  $x \in A$ . Let us explain this latter case in more detail.

Let  $P = P^O$  and  $P^N = \emptyset$ , then, given  $(x, y), (w, z) \in A \times A$ , the pair  $(x, y)$  is said to dominate the pair  $(w, z)$  with respect to criteria from  $P$  (denoted by  $(x, y)D_P(w, z)$ ), if for each  $g_i \in P$ ,  $g_i(x) \geq g_i(w)$  and  $g_i(z) \geq g_i(y)$ .

Let  $D_{\{i\}}$  be the dominance relation confined to the single criterion  $g_i \in P^O$ . The binary relation  $D_{\{i\}}$  is reflexive, transitive, but non-complete (it is possible that *not*  $(x, y)D_{\{i\}}(w, z)$  and *not*  $(w, z)D_{\{i\}}(x, y)$  for some  $(x, y), (w, z) \in A \times A$ ). Therefore,  $D_{\{i\}}$  is a partial preorder. Since the intersection of partial preorders is also

a partial preorder and  $D_P = \bigcap_{g_i \in P} D_{\{i\}}$ ,  $P = P^O$ , the dominance relation  $D_P$  is a partial preorder.

If some criteria from  $P \subseteq C$  express preferences on a quantitative or a numerical non-quantitative scale and others on an ordinal scale, i.e., if  $P^N \neq \emptyset$  and  $P^O \neq \emptyset$ , then, given  $(x, y), (w, z) \in A \times A$ , the pair  $(x, y)$  is said to dominate the pair  $(w, z)$  with respect to criteria from  $P$ , if  $(x, y)$  dominates  $(w, z)$  with respect to both  $P^N$  and  $P^O$ . Since the dominance relation with respect to  $P^N$  is a partial preorder on  $A \times A$  (because it is a multi-graded dominance) and the dominance with respect to  $P^O$  is also a partial preorder on  $A \times A$  (as explained above), then the dominance  $D_P$ , being the intersection of these two dominance relations, is a partial preorder. In consequence, all the concepts introduced in the previous section can be restored using this specific definition of dominance.

#### 22.4.4 Induction of Decision Rules from Rough Approximations of Preference Relations

Using the rough approximations of preference relations  $S$  and  $S^c$  defined in Sect. 22.4.3, it is possible to induce a generalized description of the preference information contained in a given  $S_{PCT}$  in terms of suitable decision rules. The syntax of these rules involves the concept of *upward cumulated preferences* (denoted by  $P_i^{\geq h}$ ) and *downward cumulated preferences* (denoted by  $P_i^{\leq h}$ ), with the following interpretation:

- $xP_i^{\geq h}y$  means  
*x is preferred to y with respect to  $g_i$  by at least degree  $h$* ;
- $xP_i^{\leq h}y$  means  
*x is preferred to y with respect to  $g_i$  by at most degree  $h$* .

The exact definition of the cumulated preferences, for each  $(x, y) \in A \times A$ ,  $g_i \in C^N$ , and  $h \in H_i$ , can be represented as follows:

- $xP_i^{\geq h}y$  if  $xP_i^k y$ , where  $k \in H_i$  and  $k \geq h$ ;
- $xP_i^{\leq h}y$  if  $xP_i^k y$ , where  $k \in H_i$  and  $k \leq h$ .

Let also  $G_i = \{g_i(x), x \in A\}$ ,  $g_i \in C^O$ . The decision rules have then the following syntax:

1.  $D_{\geq}$ -decision rules:

If  $xP_{i1}^{\geq h(i1)}y$  and ...  $xP_{ie}^{\geq h(ie)}y$  and  $g_{ie+1}(x) \geq r_{ie+1}$  and  $g_{ie+1}(y) \leq s_{ie+1}$  and ...  $g_{ip}(x) \geq r_{ip}$  and  $g_{ip}(y) \leq s_{ip}$ , then  $xSy$ ,

where

$$P = \{g_{i1}, \dots, g_{ip}\} \subseteq C,$$

$$P^N = \{g_{i1}, \dots, g_{ie}\},$$

$$P^O = \{g_{ie+1}, \dots, g_{ip}\},$$

$$(h(i1), \dots, h(ie)) \in H_{i1} \times \dots \times H_{ie}$$

and

$$(r_{ie+1}, \dots, r_{ip}), (s_{ie+1}, \dots, s_{ip}) \in G_{ie+1} \times \dots \times G_{ip}.$$

These rules are supported by pairs of objects from the  $P$ -lower approximation of  $S$  only.

2.  $D_{\leq}$ -decision rules:

If  $xP_{i1}^{\leq h(i1)}y$  and ...  $xP_{ie}^{\leq h(ie)}y$  and  $g_{ie+1}(x) \leq r_{ie+1}$  and  $g_{ie+1}(y) \geq s_{ie+1}$  and ...  $g_{ip}(x) \leq r_{ip}$  and  $g_{ip}(y) \geq s_{ip}$ , then  $xS^c y$ ,

where

$$P = \{g_{i1}, \dots, g_{ip}\} \subseteq C,$$

$$P^N = \{g_{i1}, \dots, g_{ie}\},$$

$$P^O = \{g_{ie+1}, \dots, g_{ip}\},$$

$$(h(i1), \dots, h(ie)) \in H_{i1} \times \dots \times H_{ie}$$

and

$$(r_{ie+1}, \dots, r_{ip}), (s_{ie+1}, \dots, s_{ip}) \in G_{ie+1} \times \dots \times G_{ip}.$$

These rules are supported by pairs of objects from the  $P$ -lower approximation of  $S^c$  only.

3.  $D_{\geq \leq}$ -decision rules:

If  $xP_{i1}^{\geq h(i1)}y$  and ...  $xP_{ie}^{\geq h(ie)}y$  and  $xP_{ie+1}^{\leq h(ie+1)}y$  ...  $xP_{if}^{\leq h(if)}y$  and  $g_{if+1}(x) \geq r_{if+1}$  and  $g_{if+1}(y) \leq s_{if+1}$  and ...  $g_{ig}(x) \geq r_{ig}$  and  $g_{ig}(y) \leq s_{ig}$  and  $g_{ig+1}(x) \leq r_{ig+1}$  and  $g_{ig+1}(y) \geq s_{ig+1}$  and ...  $g_{ip}(x) \leq r_{ip}$  and  $g_{ip}(y) \geq s_{ip}$ , then  $xSy$  or  $xS^c y$ ,

where

$$O' = \{g_{i1}, \dots, g_{ie}\} \subseteq C,$$

$$O'' = \{g_{ie+1}, \dots, g_{if}\} \subseteq C,$$

$$P^N = O' \cup O'',$$

$O'$ , and  $O''$  are not necessarily disjoint,

$$P^O = \{g_{if+1}, \dots, g_{ip}\},$$

$$(h(i1), \dots, h(if)) \in H_{i1} \times \dots \times H_{if},$$

$$(r_{if+1}, \dots, r_{ip}), (s_{if+1}, \dots, s_{ip})$$

$$\in G_{if+1} \times \dots \times G_{ip}.$$

These rules are supported by pairs of objects from the  $P$ -boundary of  $S$  and  $S^c$  only.

### 22.4.5 Application of Decision Rules to Multi-Criteria Choice and Ranking

The decision rules induced from a given  $S_{PCT}$  describe the comprehensive preference relations  $S$  and  $S^c$  either exactly ( $D_{\geq}$ - and  $D_{\leq}$ -decision rules) or approximately ( $D_{\geq\leq}$ -decision rules). A set of these rules covering all pairs of  $S_{PCT}$  represents a preference model of the DM who gave the preference information in terms of pairwise comparison of reference objects. The application of these decision rules on a new subset  $M \subseteq A$  of objects induces a specific preference structure on  $M$ .

In fact, any pair of objects  $(u, v) \in M \times M$  can match the decision rules in one of four ways:

- At least one  $D_{\geq}$ -decision rule and neither  $D_{\leq}$  nor  $D_{\geq\leq}$ -decision rules.
- At least one  $D_{\leq}$ -decision rule and neither  $D_{\geq}$  nor  $D_{\geq\leq}$ -decision rules.
- At least one  $D_{\geq}$ -decision rule and at least one  $D_{\leq}$ -decision rule, or at least one  $D_{\geq\leq}$ -decision rule, or at least one  $D_{\geq\leq}$ -decision rule and at least one  $D_{\geq}$  and/or at least one  $D_{\leq}$ -decision rule.
- No decision rule.

These four ways correspond to the following four situations of outranking, respectively:

- $uSv$  and *not*  $uS^cv$ , i. e., *true* outranking (denoted by  $uS^T v$ ).
- $uS^cv$  and *not*  $uSv$ , i. e., *false* outranking (denoted by  $uS^F v$ ).
- $uSv$  and  $uS^cv$ , i. e., *contradictory* outranking (denoted by  $uS^K v$ ).
- *not*  $uSv$  and *not*  $uS^cv$ , i. e., *unknown* outranking (denoted by  $uS^U v$ ).

The above four situations, which together constitute the so-called *four-valued outranking* [22.53], have been introduced to underline the presence and absence of *positive* and *negative* reasons for the outranking. Moreover, they make it possible to distinguish contradictory situations from unknown ones.

A final *recommendation* (optimal choice or ranking) can be obtained upon suitable exploitation of this structure, i. e., of the presence and the absence of outranking  $S$  and  $S^c$  on  $M$ . A possible exploitation procedure consists of calculating a specific score, called the net flow score, for each object  $x \in M$

$$S_{nf}(x) = S^{++}(x) - S^{+-}(x) + S^{-+}(x) - S^-(x),$$

where

- $S^{++}(x) = |\{y \in M: \text{there is at least one decision rule which affirms } xSy\}|$ ;
- $S^{+-}(x) = |\{y \in M: \text{there is at least one decision rule which affirms } ySx\}|$ ;
- $S^{-+}(x) = |\{y \in M: \text{there is at least one decision rule which affirms } yS^cx\}|$ ;
- $S^-(x) = |\{y \in M: \text{there is at least one decision rule which affirms } xS^cy\}|$ .

The recommendation in ranking problems consists of the total preorder determined by  $S_{nf}(x)$  on  $M$ . In choice problems, it consists of the object(s)  $x^* \in M$  such that

$$S_{nf}(x^*) = \max_{x \in M} \{S_{nf}(x)\}.$$

The above procedure has been characterized with reference to a number of desirable properties in [22.53, 54]. A computer implementation of the whole approach, called jRank (ranking generator using DRSA) is publicly available [22.55].

Recently, Fortemps et al. [22.56] extended DRSA to multi-criteria choice and ranking on multi-graded preference relations, instead of uni-graded relations  $S$  and  $S^c$ .

It is also worth mentioning that there is a machine learning approach to multi-criteria choice and ranking using ensembles of decision rules. The approach presented by Dembczyński et al. [22.57] makes a bridge between stochastic methods of preference learning and DRSA for choice and ranking. Examples illustrating the application of DRSA to multi-criteria choice and ranking in a didactic way can be found in [22.12–14, 50, 54].

## 22.5 Important Extensions of DRSA

The existing literature describes many extensions of DRSA that make it a useful tool for other practical applications. These extensions are:

- DRSA to decision under risk and uncertainty [22.58];
- DRSA to decision under uncertainty and time preference [22.59];
- DRSA handling missing data [22.60, 61];
- DRSA for imprecise object evaluations and assignments [22.62];
- Dominance-based approach to induction of association rules [22.63];
- Fuzzy-rough hybridization of DRSA [22.8, 64–67];
- DRSA as a way of operator-free fuzzy-rough hybridization [22.28, 67, 68];
- DRSA to granular computing [22.36, 37];
- DRSA to case-based reasoning [22.69, 70];
- DRSA for hierarchical structure of evaluation criteria [22.71];
- DRSA to decision involving multiple decision makers [22.72, 73];
- DRSA to interactive multi-objective optimization [22.74];
- DRSA to interactive evolutionary multi-objective optimization under risk and uncertainty [22.75, 76].

It is worth stressing that dealing with ordinal data and monotonicity constraints also makes sense in general classification problems, where the notion of preference has no meaning. Even when the ordering seems irrelevant, the presence or the absence of a property have an ordinal interpretation. If two properties are related, one of the two: the presence or the absence of one property should make more (or less) probable the presence of the other property. A formal proof showing that the IRSA is a particular case of the DRSA was

given in [22.28]. With this in mind, DRSA can be seen as a general framework for analysis of classification data. Although it was designed for ordinal classification problems with monotonicity constraints, DRSA can be used to solve a general classification problem where no additional information about ordering is taken into account.

The idea behind this claim is the following [22.77]. We assume, without loss of generality, that the value sets of all regular attributes are number-coded. While this is natural for numerical attributes, categorical attributes must get numerical codes for categories. In this way, the value sets of all regular attributes become ordered (as all sets of numbers are ordered). Now, to analyze a non-ordinal classification problem using DRSA, we transform the decision table such that each regular attribute is cloned (doubled). It is assumed that the value set of each original attribute is ordered with respect to increasing preference (gain-type criterion), and the value set of its clone is ordered with respect to decreasing preference (cost-type criterion). Using DRSA, for each  $t \in \{1, \dots, n\}$ , we approximate two sets of objects from the decision table: class  $C_t$  and its complement  $\neg C_t$ . Obviously, we can calculate dominance-based rough approximations of the two sets. Moreover, they can serve to induce *if ..., then ...* decision rules recommending assignment to class  $C_t$  or to its complement  $\neg C_t$ . In this way, we reformulated the original non-ordinal classification problem to an ordinal classification problem with monotonicity constraints. Due to cloning of attributes with opposite preference orders, we can have rules that cover a subspace in the condition space, which is bounded from the top and from the bottom – this leads (without discretization) to more synthetic rules than those resulting from the IRSA.

## 22.6 DRSA to Operational Research Problems

DRSA is also a useful instrument in the toolbox of operational research (OR). DRSA has been adapted to solve the following OR problems:

- Interactive multi-objective optimization [22.74] applied to OR problems, such as portfolio management, project scheduling, and production planning.

- Interactive evolutionary multi-objective optimization under risk and uncertainty [22.75, 76].
- Decision under uncertainty and time preference [22.59], which is useful for dealing with many OR problems where uncertainty of outcomes and their distribution over time play a fundamental role, such as portfolio selection [22.78], scheduling with

- time-resource interactions, and inventory management.
- Global investment risk analysis on partially missing data [22.79].

- Explanation of recommendations following from robust ordinal regression applied to multi-criteria ranking problems in terms of rules [22.80].

## 22.7 Concluding Remarks on DRSA Applied to Multi-Criteria Decision Problems

Let us point out the main features of the methodology described:

- The input data set describing a given decision situation is the preference information elicited by the DM in terms of exemplary decisions (class assignments or pairwise comparisons of some objects).
- The rough set analysis of preference information using DRSA supplies some useful elements of knowledge about the decision situation. These are: the relevance of particular criteria, information about their interaction, minimal subsets of criteria (reducts) conveying important knowledge contained in the exemplary decisions and the set of the non-reducible criteria (core).
- The methodology presented is based on elementary concepts and mathematical tools (sets and set operations, binary relations), without recourse to any complex algebraic or analytical structures; the main idea is very natural and the key concept of dominance is rational and objective.
- DRSA structures the input data prior to induction of decision rules. The structuring takes into account inconsistencies of the preference information with respect to the dominance principle. Due to the structuring the induced decision rules are certain or possible, depending whether they are induced from lower or upper approximations (of unions of classes or preference relations), respectively.
- The preference model induced from the rough approximations defined on the preference information is expressed in the natural and comprehensible lan-

guage of *if ... , then ...* decision rules, fulfilling the postulate of transparency and interpretability of preference models in decision aiding; each decision rule can be clearly identified with those parts of the preference information (decision examples) which support the rule; the rules inform the DM about the relationships between conditions and decisions; in this way, the rules permit traceability of the decision aiding process and give understandable justifications for the decision to be made, so that the resulting preference model constituted for the DM is a *glass box* rather than a *black box*. Finally, the decision rule preference model is more general than all existing models of conjoint measurement due to its capacity of handling inconsistent preferences [22.9–11, 81].

- Apart from their clear meaning, the decision rules are characterized by some interestingness measures, among which Bayesian confirmation measures appear to be the most appropriate, as shown in the studies [22.43, 44].
- The decision rules do not convert ordinal information into numeric information but keep the ordinal character of input data due to the syntax proposed.
- Heterogeneous information (qualitative and quantitative, ordered and non-ordered) and scales of preference (ordinal, cardinal) can be processed within DRSA, while classical methods consider only quantitative ordered evaluations (with rare exceptions).
- No prior discretization of the quantitative domains of criteria is necessary.

# 23. Rule Induction from Rough Approximations

**Jerzy W. Grzymala-Busse**

Rule induction is an important technique in data mining or machine learning. Knowledge is frequently expressed by rules in many areas of artificial intelligence (AI), including rule-based expert systems. In this chapter we discuss only *supervised learning* in which all cases of the input data set are pre-classified by an expert.

## 23.1 Complete and Consistent Data

Our basic assumption is that the data sets are presented as decision tables. An example of a decision table is presented in Table 23.1. Rows of the decision table represent *cases* and columns represent *variables*. The set of all cases is denoted by  $U$ . In Table 23.1,  $U = \{1, 2, 3, 4, 5, 6, 7, 8\}$ . Some variables are called *attributes* while one selected variable is called a *decision* and is denoted by  $d$ . The set of all attributes will be denoted by  $A$ . In Table 23.1,  $A = \{\text{Wind}, \text{Humidity}, \text{Temperature}\}$  and  $d = \text{Trip}$ . For an attribute  $a$  and case  $x$ ,  $a(x)$  denotes the value of the attribute  $a$  for case  $x$ . For example,  $\text{Wind}(1) = \text{low}$ .

Let  $B$  be a subset of the set  $A$  of all attributes. Complete data sets are characterized by the indiscernibility relation  $\text{IND}(B)$  [23.1, 2] defined as follows: for any  $x, y \in U$ ,

$$(x, y) \in \text{IND}(B) \text{ if and only if } a(x) = a(y) \text{ for any } a \in B. \quad (23.1)$$

Obviously,  $\text{IND}(B)$  is an equivalence relation. The equivalence class of  $\text{IND}(B)$  containing  $x \in U$  will be denoted by  $[x]_B$  and called a *B-elementary set*. A-elementary sets will be called *elementary*. Any union

of  $B$ -elementary sets will be called a *B-definable set*. By analogy, the  $A$ -definable set will be called definable. The elementary sets of the partition  $\{d\}^*$  are called *concepts*. In Table 23.1, the concepts are  $\{1, 2, 3\}$ ,  $\{4, 5\}$ , and  $\{6, 7, 8\}$ . The set of all equivalence classes  $[x]_B$ , where  $x \in U$ , is a partition on  $U$  denoted by  $B^*$ . For Table 23.1,  $A^* = \{\{1\}, \{2\}, \{3\}, \{4\}, \{5\}, \{6\}, \{7\}, \{8\}\}$ . All members of  $A^*$  are elementary sets.

We will quote some definitions from [23.3]. A rule  $r$  is an expression of the following form

$$(a_1, v_1) \& (a_2, v_2) \& \dots \& (a_k, v_k) \rightarrow (d, w), \quad (23.2)$$

**Table 23.1** A complete and consistent decision table

Case	Attributes	Wind	Humidity	Temperature	Decision
					Trip
1	low	low	medium	medium	yes
2	low	low	low	low	yes
3	low	medium	medium	medium	yes
4	low	medium	high	high	maybe
5	medium	low	medium	medium	maybe
6	medium	high	low	low	no
7	high	high	high	high	no
8	medium	high	high	high	no

where  $a_1, a_2, \dots, a_k$  are distinct attributes,  $d$  is a decision,  $v_1, v_2, \dots, v_k$  are respective attribute values, and  $w$  is a decision value.

A case  $x$  is *covered* by a rule  $r$  if and only if any attribute–value pair of  $r$  is satisfied by the corresponding value of  $x$ . For example, case 1 from Table 23.1 is covered by the following rule  $r$ :

$$(Wind, low) \& (Humidity, low) \rightarrow (Trip, yes).$$

The concept  $C$  defined by rule  $r$  is *indicated* by  $r$ . The above rule  $r$  indicates concept  $\{1, 2, 3\}$ .

A rule  $r$  is *consistent* with the data set if and only if for any case  $x$  covered by  $r$ ,  $x$  is a member of the concept indicated by  $r$ . The above rule is consistent with the data set represented by Table 23.1. A rule set  $R$  is consistent with the data set if and only if for any  $r \in R$ ,  $r$  is consistent with the data set. The rule set containing the above rule is consistent with the data set represented by Table 23.1.

We say that a concept  $C$  is *completely covered* by a rule set  $R$  if and only if for every case  $x$  from  $C$  there exists a rule  $r$  from  $R$  such that  $r$  covers  $x$ . For example, the single rule

$$(Wind, low) \rightarrow (Trip, yes)$$

completely covers the concept  $\{1, 2, 3\}$ . On the other hand, this rule is not consistent with the data set represented by Table 23.1. A rule set  $R$  is *complete* for a data set if and only if every concept from the data set is completely covered by  $R$ .

In this chapter we will discuss how to induce rule sets that are complete and consistent with the data set.

### 23.1.1 Global Coverings

The simplest approach to rule induction is based on finding the smallest subset  $B$  of the set  $A$  of all attributes that is sufficient to be used in a rule set. Such reducing of the attribute set is one of the main and frequently used techniques in rough set theory [23.1, 2, 4]. This approach is also called a *feature selection*. In Table 23.1 the attribute *Humidity* is redundant (irrelevant). The remaining two attributes (*Wind* and *Temperature*) distinguish all eight cases. Let us make it more precise using the fundamental definitions of rough set theory [23.1, 2, 4].

For a decision  $d$  we say that  $\{d\}$  depends on  $B$  if and only if  $B^* \leq \{d\}^*$ , i.e., for any elementary set  $X$  in  $B$  there exists a concept  $C$  from  $\{d\}^*$  such that  $X \subseteq C$ .

note that for partitions  $\pi$  and  $\tau$  on  $U$ , if for any  $X \in \pi$  there exists  $Y \in \tau$  such that  $X \subseteq Y$ , then we say that  $\pi$  is smaller than or equal to  $\tau$  and denote it by  $\pi \leq \tau$ . A *global covering* (or *relative reduct*) of  $\{d\}$  is a subset  $B$  of  $A$  such that  $\{d\}$  depends on  $B$  and  $B$  is minimal in  $A$ . The algorithm to compute a single global covering is presented below.

---

#### Algorithm 23.1 Algorithm to compute a single global covering

```

1: (input: the set  $A$  of all attributes,
   partition  $\{d\}^*$  on  $U$ ;
   output: a single global covering  $R$ );
2: begin
3:   compute partition  $A^*$ ;
4:    $P := A$ ;
5:    $R := \emptyset$ ;
6:   if  $A^* \leq \{d\}^*$ 
7:     then
8:       begin
9:         for each attribute  $a$  in  $A$  do
10:           begin
11:              $Q := P - \{a\}$ ;
12:             compute partition  $Q^*$ ;
13:             if  $Q^* \leq \{d\}^*$ 
14:               then  $P := Q$ 
15:           end {for}
16:            $R := P$ 
17:       end {then}
18:     end {algorithm}.

```

---

Let us use this algorithm for Table 23.1. First,

$$\begin{aligned} A^* &= \{\{1\}, \{2\}, \{3\}, \{4\}, \{5\}, \{6\}, \{7\}, \{8\}\} \\ &\leq \{Trip\}^*. \end{aligned}$$

Initially,

$$\begin{aligned} P &= A \text{ and } Q = P - Wind, \\ Q &= \{Humidity, Temperature\}, \end{aligned}$$

and then we compute  $Q^*$ , where

$$Q^* = \{\{1, 5\}, \{2\}, \{3\}, \{4\}, \{6\}, \{7, 8\}\}.$$

We find that  $Q^* \not\leq \{Trip\}^*$ . Thus,  $P = A$ . Next, we try to delete *Humidity* from  $P$ . We obtain  $Q = \{Wind, Temperature\}$  and then we compute  $Q^*$ , where  $Q^* = \{\{1, 3\}, \{2\}, \{4\}, \{5\}, \{6\}, \{7\}, \{8\}\}$ . This time  $Q^* \leq \{Trip\}^*$ , so  $P = \{Wind, Temperature\}$ .

We still need to check  $Q = P - \{\text{Temperature}\}$ ,  $Q = \{\text{Wind}\}$  and  $Q^* = \{\{1, 2, 3, 4\}, \{5, 6, 8\}, \{7\}\}$ , and  $Q^* \not\leq \{\text{Trip}\}^*$ . Thus  $R = \{\text{Wind}, \text{Temperature}\}$  is a global covering.

For a given global covering rules are induced by examining cases of the data set. Initially, such a rule contains all attributes from the global covering with the corresponding attribute values, then a *dropping conditions* technique is used; we try to drop one condition (attribute–value pair) at a time, starting from the leftmost condition, checking whether the rule is still consistent with the data set, then we try to drop the next condition, and so on. For example,

$$(\text{Wind, low}) \& (\text{Temperature, medium}) \rightarrow (\text{Trip, yes})$$

is our first candidate for a rule. If we are going to drop the first condition, the above rule will be reduced to

$$(\text{Temperature, medium}) \rightarrow (\text{Trip, yes}).$$

However, this rule covers the case 5, so it is not consistent with the data set represented by Table 23.1. By dropping the second condition from the initial rule we obtain

$$(\text{Wind, low}) \rightarrow (\text{Trip, yes}),$$

but this rule is not consistent with the data represented by Table 23.1 either, since it covers case 4, so we conclude that the initial rule is the simplest possible. This rule covers two cases: 1 and 3.

It is not difficult to check that the rule

$$(\text{Wind, low}) \& (\text{Temperature, low}) \rightarrow (\text{Trip, yes})$$

is as simple as possible and that it covers only case 2. Thus, the above two rules consistently and completely cover the concept  $\{1, 2, 3\}$ .

The above algorithm is implemented as LEM1 (Learning from Examples Module, version 1). It is a component of the data mining system LERS (Learning from Examples Using Rough Sets). A similar system was described in [23.5].

### 23.1.2 Local Coverings

The LEM1 algorithm is based on calculus on partitions on the entire universe  $U$ . Another approach to rule induction, based on attribute–value pairs, is presented in

the LEM2 algorithm (Learning from Examples Module, version 2), another component of LERS. We will quote a few definitions from [23.6, 7].

For an attribute–value pair  $(a, v) = t$ , a *block* of  $t$ , denoted by  $[t]$ , is a set of all cases from  $U$  such that for attribute  $a$  have value  $v$ , i. e.,

$$[(a, v)] = \{x \mid a(x) = v\}. \quad (23.3)$$

Let  $T$  be a set of attribute–value pairs. The block of  $T$ , denoted by  $[T]$ , is the following set

$$\bigcap_{t \in T} [t]. \quad (23.4)$$

Let  $B$  be a subset of  $U$ . Set  $B$  depends on a set  $T$  of attribute–value pairs  $t = (a, v)$  if and only if  $[T]$  is nonempty and

$$[T] \subseteq B. \quad (23.5)$$

Set  $T$  is a *minimal complex* of  $B$  if and only if  $B$  depends on  $T$  and no proper subset  $T'$  of  $T$  exists such that  $B$  depends on  $T'$ . Let  $\mathcal{T}$  be a nonempty collection of nonempty sets of attribute–value pairs. Then  $\mathcal{T}$  is a *local covering* of  $B$  if and only if the following conditions are satisfied:

1. each member  $T$  of  $\mathcal{T}$  is a minimal complex of  $B$ ,
2.  $\bigcup_{t \in T} [t] = B$ , and  $\mathcal{T}$  is minimal, i. e.,  $\mathcal{T}$  has the smallest possible number of members.

An algorithm for finding a single local covering, called LEM2, is presented below. For a set  $X$ ,  $|X|$  denotes the cardinality of  $X$ .

#### Algorithm 23.2 LEM2

- 1: **(input:** a set  $B$ ,  
    **output:** a single local covering  $\mathcal{T}$  of set  $B$ );
- 2: **begin**
- 3:    $G := B$ ;
- 4:    $\mathcal{T} := \emptyset$ ;
- 5:   **while**  $G \neq \emptyset$
- 6:     **begin**
- 7:        $T := \emptyset$ ;
- 8:        $T(G) := \{t \mid [t] \cap G \neq \emptyset\}$ ;
- 9:       **while**  $T = \emptyset$  **or**  $[T] \not\subseteq B$
- 10:          **begin**
- 11:           select a pair  $t \in T(G)$ ,
- 12:           such that  $|[t] \cap G|$  is  
         maximum; if a tie

```

14:    occurs, select a pair
15:     $t \in T(G)$  with the
16:    smallest cardinality of  $[t]$ ;
17:    if another tie occurs,
18:    select first pair;
19:     $T := T \cup \{t\}$  ;
20:     $G := [t] \cap G$  ;
21:     $T(G) := \{t|[t] \cap G \neq \emptyset\}$ ;
22:     $T(G) := T(G) - T$  ;
23:    end {while}
24:    for each  $t \in T$  do
25:      if  $[T - \{t\}] \subseteq B$ 
26:        then  $T := T - \{t\}$ ;
27:       $\mathcal{T} := \mathcal{T} \cup \{T\}$ ;
28:       $G := B - \cup_{T \in \mathcal{T}} [T]$ ;
29:    end {while};
30:    for each  $T \in \mathcal{T}$  do
31:      if  $\bigcup_{S \in \mathcal{T} - \{T\}} [S] = B$ 
32:        then  $\mathcal{T} := \mathcal{T} - \{T\}$ ;
33:    end {procedure}.

```

We will trace the LEM2 algorithm applied to the following input set  $\{1, 2, 3\} = [(Trip, yes)]$ . The tracing of LEM2 is presented in the Tables 23.2 and 23.3. The corresponding comments are:

- The set  $G = \{1, 2, 3\}$ . The best attribute-value pair  $t$ , with the largest cardinality of the intersection of  $[t]$  and  $G$  (presented in the third column of Table 23.2) is  $(Wind, low)$ . The corresponding entry in the third column of Table 23.2 is bulleted. However,  $[(Wind, low)] = \{1, 2, 3, 4\} \not\subseteq \{1, 2, 3\} = B$ , hence we need to look for the next  $t$ .
- The set  $G$  is the same,  $G = \{1, 2, 3\}$ . There are four attribute-value pairs with  $|[t] \cap G| = 2$ . Two of them have the same cardinality as  $[t]$ , so we

**Table 23.2** Computing a local covering for the concept  $[(Trip, yes)]$ , part I

$(a, v) = t$	$[(a, v)]$	$\{1, 2, 3\}$	$\{1, 2, 3\}$
$(Wind, low)$	$\{1, 2, 3, 4\}$	$\{1, 2, 3\} \bullet$	$\{1, 3\}$
$(Wind, medium)$	$\{5, 6, 8\}$	—	—
$(Wind, high)$	$\{7\}$	—	—
$(Humidity, low)$	$\{1, 2, 5\}$	$\{1, 2\}$	$\{1, 2\} \bullet$
$(Humidity, medium)$	$\{3, 4\}$	$\{3\}$	$\{3\}$
$(Humidity, high)$	$\{6, 7, 8\}$	—	—
$(Temperature, low)$	$\{2, 6\}$	$\{2\}$	$\{1, 3\}$
$(Temperature, medium)$	$\{1, 3, 5\}$	$\{1, 3\}$	$\{1, 3\}$
$(Temperature, high)$	$\{4, 7, 8\}$	—	—
Comments		1	2

select the first (top) pair,  $(Humidity, low)$ . This time  $\{1, 2, 3, 4\} \cap \{1, 2, 5\} = \{1, 2\} \subseteq \{1, 2, 3\}$ , so  $\{(Wind, low), (Humidity, low)\}$  is the first element  $T$  of  $\mathcal{T}$ .

- The new set  $G = B - [T] = \{1, 2, 3\} - \{1, 2\} = \{3\}$ . The pair  $[(Humidity, medium)]$  has the smallest cardinality of  $[t]$ , so it is the best choice. However,  $[(Humidity, medium)] = \{3, 4\} \not\subseteq \{1, 2, 3\}$ , hence we need to look for the next  $t$ .
- The pair  $[(Temperature, medium)]$  is the best choice, and  $\{3, 4\} \cap \{1, 3, 5\} = \{3\} \subseteq \{1, 2, 3\}$ , so  $\{(Humidity, medium), (Temperature, medium)\}$  is the second element  $T$  of  $\mathcal{T}$ .

Thus,

$$\mathcal{T} = \{\{(Wind, low), (Humidity, low)\}, \\ \{(Humidity, medium), (Temperature, medium)\}\}.$$

Therefore, the LEM2 algorithm induces the following rule set

$$(Wind, low) \& (Humidity, low) \\ \rightarrow (Trip, yes) \\ (Humidity, medium) \& (Temperature, medium) \\ \rightarrow (Trip, yes).$$

Rules induced from local coverings differ from rules induced from global coverings. In many cases the former are simpler than the latter. For example, for Table 23.1 and the concept  $[(Trip, no)]$ , the LEM2 algorithm would induce just one rule that covers all three cases

$$(Humidity, high) \rightarrow (Trip, no).$$

**Table 23.3** Computing a local covering for the concept  $[(Trip, yes)]$ , part II

$(a, v) = t$	$[(a, v)]$	$\{3\}$	$\{3\}$
$(Wind, low)$	$\{1, 2, 3, 4\}$	$\{3\}$	$\{3\}$
$(Wind, medium)$	$\{5, 6, 8\}$	—	—
$(Wind, high)$	$\{7\}$	—	—
$(Humidity, low)$	$\{1, 2, 5\}$	—	—
$(Humidity, medium)$	$\{3, 4\}$	$\{3\} \bullet$	—
$(Humidity, high)$	$\{6, 7, 8\}$	—	—
$(Temperature, low)$	$\{2, 6\}$	—	—
$(Temperature, medium)$	$\{1, 3, 5\}$	$\{3\}$	$\{3\} \bullet$
$(Temperature, high)$	$\{4, 7, 8\}$	—	—
Comments		3	4

On the other hand, the attribute *Humidity* is not included in the global covering. The rules induced from the global covering are

$$\begin{aligned} (\text{Temperature}, \text{high}) &\rightarrow (\text{Trip}, \text{no}). \\ (\text{Wind}, \text{medium}) \& \ (\text{Temperature}, \text{low}) \\ &\rightarrow (\text{Trip}, \text{no}). \end{aligned}$$

### 23.1.3 Classification

Rule sets, induced from data sets, are used most frequently to classify new, unseen cases. A *classification system* has two inputs: a rule set and a data set containing new cases and it classifies every case as being a member of some concept. A classification system used in **LERS** is a modification of the well-known bucket brigade algorithm [23.7–9].

The decision of to which concept a case belongs is made on the basis of three factors: *strength*, *specificity*, and *support*. These factors are defined as follows: *strength* is the total number of cases correctly classified by the rule during training. *Specificity* is the total number of attribute–value pairs on the left-hand side of the rule. The matching rules with a larger number of attribute–value pairs are considered more specific. The third factor, *support*, is defined as the sum of products of strength and specificity for all matching rules indicating the same concept. The concept  $C$  for which the support, i. e., the following expression

$$\sum_{\substack{\text{matching rules } r \text{ describing } C}} \text{Strength}(r) * \text{Specificity}(r) \quad (23.6)$$

is the largest is the winner, and the case is classified as being a member of  $C$ .

In the classification system of **LERS**, if complete matching is impossible, all partially matching rules are identified. These are rules with at least one attribute–value pair matching the corresponding attribute–value pair of a case. For any partially matching rule  $r$ , the additional factor, called *Matching\_factor* ( $r$ ), is computed. *Matching\_factor* ( $r$ ) is defined as the ratio of the number of matched attribute–value pairs of  $r$  with a case to the total number of attribute–value pairs of  $r$ . In partial matching, the concept  $C$  for which the following expression

$$\sum_{\substack{\text{partially matching} \\ \text{rules } r \text{ describing } C}} \frac{\text{Matching\_factor}(r) * \text{Strength}(r) * \text{Specificity}(r)}{} \quad (23.7)$$

is the largest is the winner and the case is classified as being a member of  $C$ .

Since the classification system is a part of the **LERS** data mining system, rules induced by any component of **LERS**, such as **LEM1** or **LEM2**, are presented in the **LERS** format, in which every rule is associated with three numbers: the total number of attribute–value pairs on the left-hand side of the rule (i. e., specificity), the total number of cases correctly classified by the rule during training (i. e., strength), and the total number of training cases matching the left-hand side of the rule, i. e., the rule domain size.

## 23.2 Inconsistent Data

Frequently data sets contain conflicting cases, i. e., cases with the same attribute values but from different concepts. An example of such a data set is presented in Table 23.4. Cases 4 and 5 have the same values for all three attributes, yet their decision values are different (they belong to different concepts). Similarly, cases 7 and 8 also conflict. Rough set theory handles inconsistent data by introducing lower and upper approximations for every concept [23.1, 2].

There exists a very simple test for consistency:  $A^* \leq \{d\}^*$ . If this condition is false, the corresponding data set is not consistent. For Table 23.4,  $A^* = \{\{1\}, \{2\}, \{3\}, \{4, 5\}, \{6, 7, 8\}, \{9\}, \{10\}\}$ , and  $\{d\}^* = \{\{1, 2, 3, 4\}, \{5, 6, 7\}, \{8, 9, 10\}\}$ , so  $A^* \not\leq \{d\}^*$ .

Let  $B$  be a subset of the set  $A$  of all attributes. For inconsistent data sets, in general, a concept  $X$  is not a definable set. However, set  $X$  may be approximated by two  $B$ -definable sets; the first one is called a  *$B$ -lower approximation* of  $X$ , denoted by  $\underline{B}X$  and defined as follows

$$\{x \in U | [x]_B \subseteq X\}. \quad (23.8)$$

The second set is called a  *$B$ -upper approximation* of  $X$ , denoted by  $\overline{B}X$  and defined as follows

$$\{x \in U | [x]_B \cap X \neq \emptyset\}. \quad (23.9)$$

In (23.8) and (23.9) lower and upper approximations are constructed from singletons  $x$ ; we say that we

are using the so-called *first method*. The  $B$ -lower approximation of  $X$  is the largest  $B$ -definable set contained in  $X$ . The  $B$ -upper approximation of  $X$  is the smallest  $B$ -definable set containing  $X$ .

As was observed in [23.2], for complete decision tables we may use a *second method* to define the  $B$ -lower approximation of  $X$ , by the following formula

$$\cup\{[x]_B \mid x \in U, [x]_B \subseteq X\}, \quad (23.10)$$

while the  $B$ -upper approximation of  $x$  may be defined, using the second method, by

$$\cup\{[x]_B \mid x \in U, [x]_B \cap X \neq \emptyset\}. \quad (23.11)$$

Obviously, both (23.8) and (23.10) define the same set. Similarly, (23.9) and (23.11) also define the same set. For Table 23.4,

$$\underline{A}\{1, 2, 3, 4\} = \{1, 2, 3\}$$

and

$$\bar{A}\{1, 2, 3, 4\} = \{1, 2, 3, 4, 5\}.$$

It is well known that for any  $B \subseteq A$  and  $X \subseteq U$ ,

$$\underline{B}X \subseteq X \subseteq \bar{B}X, \quad (23.12)$$

hence any case  $x$  from  $\underline{B}X$  is *certainly* a member of  $X$ , while any member  $x$  of  $\bar{B}X$  is *possibly* a member of  $X$ . This observation is used in the LERS data mining system. If an input data set is inconsistent, LERS computes lower and upper approximations for any concept and then induces *certain* rules from the lower approximation and *possible* rules from the upper approximation. For example, if we want to induce certain and possible

**Table 23.4** An inconsistent decision table

Case	Attributes			Decision Trip
Case	Wind	Humidity	Temperature	Decision Trip
1	low	low	medium	yes
2	low	low	low	yes
3	low	medium	medium	yes
4	low	medium	high	yes
5	low	medium	high	maybe
6	medium	low	medium	maybe
7	medium	low	medium	maybe
8	medium	low	medium	no
9	high	high	high	no
10	medium	high	high	no

rule sets for the concept  $[(Trip, yes)]$  from Table 23.4, we need to consider the following two data sets, presented in Tables 23.5 and 23.6.

Table 23.5 was obtained from Table 23.4 by assigning the value *yes* of the decision *Trip* to all cases from the lower approximation of  $[(Trip, yes)]$  and by replacing all remaining values of *Trip* by a special value, say *SPECIAL*. Similarly, Table 23.6 was obtained from Table 23.4 by assigning the value *yes* of the decision *Trip* to all cases from the upper approximation of  $[(Trip, yes)]$  and by replacing all remaining values of *Trip* by the value *SPECIAL*. Obviously, both tables 23.5 and 23.6 are consistent. Therefore, we may use the LEM1 or LEM2 algorithms to induce rules from Tables 23.5 and 23.6. The rule set induced by the LEM2 algorithm from Table 23.5 is:

- 2, 2, 2

$$(Wind, low) \& (Humidity, low) \rightarrow (Trip, yes),$$

**Table 23.5** A new data set for inducing certain rules for the concept  $[(Trip, yes)]$

Case	Attributes			Decision Trip
Case	Wind	Humidity	Temperature	Decision Trip
1	low	low	medium	yes
2	low	low	low	yes
3	low	medium	medium	yes
4	low	medium	high	SPECIAL
5	low	medium	high	SPECIAL
6	medium	low	medium	SPECIAL
7	medium	low	medium	SPECIAL
8	medium	low	medium	SPECIAL
9	high	high	high	SPECIAL
10	medium	high	high	SPECIAL

**Table 23.6** A new data set for inducing possible rules for the concept  $[(Trip, yes)]$

Case	Attributes			Decision Trip
Case	Wind	Humidity	Temperature	Decision Trip
1	low	low	medium	yes
2	low	low	low	yes
3	low	medium	medium	yes
4	low	medium	high	yes
5	low	medium	high	yes
6	medium	low	medium	SPECIAL
7	medium	low	medium	SPECIAL
8	medium	low	medium	SPECIAL
9	high	high	high	SPECIAL
10	medium	high	high	SPECIAL

- 2, 1, 1  
 $(\text{Humidity}, \text{medium}) \& (\text{Temperature}, \text{medium}) \rightarrow (\text{Trip}, \text{yes}) ,$
- 1, 4, 4  
 $(\text{Temperature}, \text{high}) \rightarrow (\text{Trip}, \text{SPECIAL}) ,$
- 1, 4, 4  
 $(\text{Wind}, \text{medium}) \rightarrow (\text{Trip}, \text{SPECIAL}) ,$

where all rules are presented in the **LERS** format, see Sect. 23.1.3.

Obviously, only rules with  $(\text{Trip}, \text{yes})$  on the right-hand side are informative; the remaining rules, with  $(\text{Trip}, \text{SPECIAL})$  on the right-hand side should be ignored. These two rules are *certain*. The only informative rule induced by the **LEM2** algorithm from Table 23.6 is:

- 1, 4, 5  
 $(\text{Wind}, \text{low}) \rightarrow (\text{Trip}, \text{yes}) .$

This rule is *possible*.

## 23.3 Decision Table with Numerical Attributes

An example of a data set with numerical attributes is presented in Table 23.7.

In rule induction from numerical data a preliminary step called *discretization* [23.10–12] is usually conducted. During discretization a domain of the numerical attribute is divided into intervals defined by cut-points (left and right delimiters of intervals). Such an interval, delimited by two cut-points,  $c$  and  $d$ , will be denoted by  $c \dots d$ . In this chapter we will discuss how to do both processes concurrently: rule induction and discretization. First we need to check whether our data set is consistent. Note that numerical data are, in general, consistent, but inconsistent numerical data are possible. For inconsistent numerical data we need to compute lower and upper approximations and the induce certain and possible rule sets. In the data set from Table 23.7,  $A^* = \{\{1\}, \{2\}, \{3\}, \{4\}, \{5\}, \{6\}, \{7\}, \{8\}\}$ ,  $\{d\}^* = \{\{1, 2, 3\}, \{4, 5\}, \{6, 7, 8\}\}$ , so  $A^* \leq \{d\}^*$ , and the data set is consistent.

A modified **LEM2** algorithm for rule induction, called **MLEM2** [23.13], does not need any preliminary discretization of numerical attributes. The domain of

**Table 23.7** A data set with numerical attributes

Case	Attributes	Wind	Humidity	Temperature	Decision
					Trip
1	4	low	medium	medium	yes
2	8	low	low	high	yes
3	4	medium	medium	medium	yes
4	8	medium	high	high	maybe
5	12	low	medium	medium	maybe
6	16	high	low	high	no
7	30	high	high	high	no
8	12	high	high	high	no

any numerical attribute is sorted first. Then potential cut-points are selected as averages of any two consecutive values of the sorted list. For each cut-point  $c$  the **MLEM2** algorithm creates two blocks, the first block contains all cases for which values of the numerical attribute are smaller than  $c$ , the second block contains the remaining cases (with values of the numerical attribute larger than  $c$ ). Once all such blocks have been computed, rule induction in **MLEM2** is conducted the same way as in **LEM2**. We will illustrate rule induction

**Table 23.8** Computing a local covering for the concept  $[(\text{Trip}, \text{yes})]$ , part I

$(a, v) = t$	$I(a, v)$	$\{1, 2, 3\}$	$\{1, 2, 3\}$

Comments		3	4

from Table 23.7 using the MLEM2 rule induction algorithm. The MLEM2 algorithm is shown in Tables 23.8 and 23.9. The corresponding comments are

1. The set  $G = \{1, 2, 3\}$ . The best attribute–value pair  $t$ , with the largest cardinality of the intersection of  $[t]$  and  $G$  (presented in the third column of Table 23.8) is  $(Wind, 4..10)$ . The corresponding entry in the third column of Table 23.8 is bulleted. However,

$$[(Wind, 4..10)] = \{1, 2, 3, 4\} \not\subseteq \{1, 2, 3\} = B,$$

hence we need to look for the next  $t$ .

2. Set  $G$  is the same,  $G = \{1, 2, 3\}$ . There are dashes for rows  $(Wind, 4..14)$  and  $(Wind, 4..23)$  since the corresponding intervals contain 4..10. There are four attribute–value pairs with  $|[t \cap G]| = 2$ . The best attribute–value pair, with the smallest cardinality of  $[t]$ , is  $(Wind, 4..6)$ . This time

$$\{1, 2, 3, 4\} \cap \{1, 3\} = \{1, 3\} \subseteq \{1, 2, 3\}.$$

Obviously, the common part of both intervals is 4..6, so  $\{(Wind, 4..6)\}$  is the first element  $T$  of  $\mathcal{T}$ .

3. The new set  $G = B - [T] = \{1, 2, 3\} - \{1, 3\} = \{2\}$ . The pair  $[(Temperature, low)]$  has the smallest cardinality of  $[t]$ , so it is the best choice. However,  $[(Temperature, low)] = \{2, 6\} \not\subseteq \{1, 2, 3\}$ , hence we need to look for the next  $t$ .

4. The pair  $[(Humidity, low)]$  is the best choice, and

$$\{3, 4\} \cap \{1, 3, 5\} = \{3\} \subseteq \{1, 2, 3\},$$

so  $\{[(Temperature, low)], (Humidity, low)\}$  is the second element  $T$  of  $\mathcal{T}$ .

As a result,

$$\mathcal{T} = \{\{(Wind, 4..6)\}, \{(Temperature, low), (Humidity, low)\}\}.$$

In other words, the MLEM2 algorithm induces the following rule set for Table 23.7:

- 1, 2, 2  
 $(Wind, 4..6) \rightarrow (Trip, yes),$
- 2, 1, 1  
 $(Temperature, low) \& (Humidity, low)$   
 $\rightarrow (Trip, yes).$

## 23.4 Incomplete Data

Real-life data are frequently incomplete. In this section we will consider incompleteness in the form of missing attribute values. We will distinguish three types of missing attribute values:

- *Lost values*, denoted by ?, where the original values existed, but are currently unavailable, since these values have been, for example, erased or the operator forgot to input them. In rule induction we

will induce rules from existing, specified attribute values.

- *Do not care conditions*, denoted by \*, where the original values are mysterious. For example, data were collected in a form of the interview, some questions were considered to be irrelevant or were embarrassing. Let us say that in an interview associated with the diagnosis of a disease, there is a question about eye color. For some people such

a question is irrelevant. In rule induction we are assuming that the attribute value is any value from the attribute domain.

- *Attribute-concept value*, denoted by  $-$ . This interpretation is a special case of the *do not care* condition: it is restricted to attribute values typical for the concept to which the case belongs. For example, typical values of temperature for patients sick with flu are: high and very-high, for a patient the temperature value is missing, but we know that this patient is sick with flu, if using the attribute-concept interpretation, we will assume that possible temperature values are: high and very-high.

We will assume that for any case at least one attribute value is specified (i.e., is not missing) and that all decision values are specified. An example of a decision table with missing attribute values is presented in Table 23.10.

The definition of consistent data from Sect. 23.2 cannot be applied to data with missing attribute values, since for such data the standard definition of the indiscernibility relation must be extended. Moreover, it is well known that the standard definitions of lower and upper approximations are not applicable to data with missing attribute values. In Sect. 23.4.1 we will discuss three generalizations of the standard approximations: singleton, subset, and concept.

### 23.4.1 Singleton, Subset, and Concept Approximations

For incomplete data the definition of a block of an attribute-value pair is modified [23.14]:

- If for an attribute  $a$  there exists a case  $x$  such that  $a(x) = ?$ , i.e., the corresponding value is lost, then

**Table 23.10** An incomplete decision table

Case	Attributes			Decision Trip
	Wind	Humidity	Temperature	
1	low	low	medium	yes
2	?	low	*	yes
3	*	medium	medium	yes
4	low	?	high	maybe
5	medium	—	medium	maybe
6	*	high	low	no
7	—	high	*	no
8	medium	high	high	no

the case  $x$  should not be included in any blocks  $[(a, v)]$  for all values  $v$  of attribute  $a$ .

- If for an attribute  $a$  there exists a case  $x$  such that the corresponding value is a *do not care* condition, i.e.,  $a(x) = *$ , then the case  $x$  should be included in blocks  $[(a, v)]$  for all specified values  $v$  of attribute  $a$ .
- If for an attribute  $a$  there exists a case  $x$  such that the corresponding value is an attribute-concept value, i.e.,  $a(x) = -$ , then the corresponding case  $x$  should be included in blocks  $[(a, v)]$  for all specified values  $v \in V(x, a)$  of attribute  $a$ , where

$$V(x, a) = \{a(y) \mid a(y) \text{ is specified}, \\ y \in U, d(y) = d(x)\}. \quad (23.13)$$

For Table 23.10,

$$V(5, \text{Humidity}) = \emptyset \text{ and} \\ V(7, \text{Wind}) = \{\text{medium}\},$$

so the blocks of attribute-value pairs are

$$[(\text{Wind}, \text{low})] = \{1, 3, 4, 6\}, \\ [(Wind, medium)] = \{3, 5, 6, 7, 8\}, \\ [(\text{Humidity}, \text{low})] = \{1, 2\}, \\ [(\text{Humidity}, \text{medium})] = \{3\}, \\ [(\text{Humidity}, \text{high})] = \{6, 7, 8\}, \\ [(\text{Temperature}, \text{low})] = \{2, 6, 7\}, \\ [(\text{Temperature}, \text{medium})] = \{1, 2, 3, 5, 7\}, \\ [(\text{Temperature}, \text{high})] = \{2, 4, 7, 8\}.$$

For a case  $x \in U$ , the *characteristic set*  $K_B(x)$  is defined as the intersection of the sets  $K(x, a)$ , for all  $a \in B$ , where the set  $K(x, a)$  is defined in the following way:

- If  $a(x)$  is specified, then  $K(x, a)$  is the block  $[(a, a(x))]$  of attribute  $a$  and its value  $a(x)$ .
- If  $a(x) = ?$  or  $a(x) = *$  then the set  $K(x, a) = U$ .
- If  $a(x) = -$ , then the corresponding set  $K(x, a)$  is equal to the union of all blocks of attribute-value pairs  $(a, v)$ , where  $v \in V(x, a)$  if  $V(x, a)$  is nonempty. If  $V(x, a)$  is empty,  $K(x, a) = U$ .

For Table 23.10 and  $B = A$ ,

$$\begin{aligned} K_A(1) &= \{1, 3, 4, 6, 7\} \cap \{1, 2\} \cap \{1, 2, 3, 5, 7\} \\ &= \{1\}, \\ K_A(2) &= U \cap \{1, 2\} \cap U = \{1, 2\}, \\ K_A(3) &= U \cap \{3\} \cap \{1, 2, 3, 5, 7\} = \{3\}, \\ K_A(4) &= \{1, 3, 4, 6\} \cap U \cap \{1, 2, 3, 5, 7\} = \{4\}, \\ K_A(5) &= \{3, 5, 6, 7, 8\} \cap U \cap (\{1, 2, 3, 5, 7\} \\ &\quad = \{3, 5, 7\}), \\ K_A(6) &= U \cap \{6, 7, 8\} \cap \{2, 6, 7\} = \{6, 7\}, \\ K_A(7) &= \{3, 5, 6, 7, 8\} \cap \{6, 7, 8\} \cap U = \{6, 7, 8\}, \\ K_A(8) &= \{3, 5, 6, 7, 8\} \cap \{6, 7, 8\} \cap \{2, 4, 7, 8\} \\ &= \{7, 8\}. \end{aligned}$$

The characteristic set  $K_B(x)$  may be interpreted as the set of cases that are indistinguishable from  $x$  using all attributes from  $B$  and using a given interpretation of missing attribute values. For completely specified data sets (i.e., data sets with no missing attribute values), characteristic sets are reduced to elementary sets. The *characteristic relation*  $R(B)$  is a relation on  $U$  defined for  $x, y \in U$  as follows

$$(x, y) \in R(B) \text{ if and only if } y \in K_B(x). \quad (23.14)$$

The characteristic relation  $R(B)$  is reflexive but – in general – does not need to be symmetric or transitive. Obviously, the characteristic relation  $R(B)$  is known if we know characteristic sets  $K_B(x)$  for all  $x \in U$  and vice versa. In our example,  $R(A) = \{(1, 1), (2, 1), (2, 2), (3, 3), (4, 4), (5, 3), (5, 5), (6, 6), (6, 7), (7, 6), (7, 7), (7, 8), (8, 7), (8, 8)\}$ . For a complete decision table, the characteristic relation  $R(B)$  is reduced to the indiscernibility relation [23.2].

Definability for completely specified decision tables should be modified to fit into incomplete decision tables. For incomplete decision tables, a union of some intersections of attribute–value pair blocks, where such attributes are members of  $B$  and are distinct, will be called *B-locally definable* sets. A union of characteristic sets  $K_B(x)$ , where  $x \in X \subseteq U$  will be called a *B-globally definable* set. Any set  $X$  that is *B-globally definable* is *B-locally definable*; the converse is not true.

For example, the set  $\{2\}$  is *A-locally definable* since  $\{2\} = [(Humidity, low)] \cap [(Temperature, high)]$ . However, the set  $\{2\}$  is not *A-globally definable*. On the other hand, the set  $\{5\}$  is not even locally definable since all blocks of attribute–value pairs containing case 5 contain

also the case 7 as well. Obviously, if a set is not *B-locally definable* then it cannot be expressed by rule sets using attributes from  $B$ . Thus we should induce rules from sets that are at least *A-locally definable*.

For incomplete decision tables lower and upper approximations may be defined in a few different ways. We suggest three different definitions of lower and upper approximations for incomplete decision tables, following [23.14–16]. Let  $X$  be a concept, a subset of  $U$ , let  $B$  be a subset of the set  $A$  of all attributes, and let  $R(B)$  be the characteristic relation of the incomplete decision. Our first definition uses an idea similar to the first method in Sect. 23.2, and is based on constructing both approximations from single elements of the set  $U$ . We will call these approximations *singleton*. A singleton *B-lower approximation* of  $X$  is defined as follows

$$\underline{BX} = \{x \in U \mid K_B(x) \subseteq X\}. \quad (23.15)$$

A singleton *B-upper approximation* of  $X$  is

$$\overline{BX} = \{x \in U \mid K_B(x) \cap X \neq \emptyset\}. \quad (23.16)$$

In our example of the decision table presented in Table 23.10, the singleton *A-lower* and *A-upper* approximations of the concept: {1, 2, 3} are:

$$\underline{A}\{1, 2, 3\} = \{1, 2, 3\}, \quad (23.17)$$

$$\overline{A}\{1, 2, 3\} = \{1, 2, 3, 5\}. \quad (23.18)$$

We may easily observe that the set  $\{1, 2, 3, 5\} = \overline{A}\{1, 2, 3\}$  is not *A-locally definable* since in all blocks of attribute–value pairs cases 5 and 7 are inseparable. Thus, as it was observed in, e.g., [23.14–16], singleton approximations should not be used, theoretically, for rule induction.

The second method of defining lower and upper approximations for complete decision tables uses another idea: lower and upper approximations are unions of elementary sets, subsets of  $U$ . Therefore, we may define lower and upper approximations for incomplete decision tables by analogy with the second method in Sect. 23.2, using characteristic sets instead of elementary sets. There are two ways to do this. Using the first way, a *subset B-lower approximation* of  $X$  is defined as follows

$$\underline{BX} = \cup\{K_B(x) \mid x \in U, K_B(x) \subseteq X\}. \quad (23.19)$$

A *subset B-upper approximation* of  $X$  is

$$\overline{BX} = \cup\{K_B(x) \mid x \in U, K_B(x) \cap X \neq \emptyset\}. \quad (23.20)$$

For any concept  $X$ , singleton  $B$ -lower and  $B$ -upper approximations of  $X$  are subsets of the subset  $B$ -lower and  $B$ -upper approximations of  $X$ , respectively [23.16], because the characteristic relation  $R(B)$  is reflexive. For the decision table presented in Table 23.10, the subset  $A$ -lower and  $A$ -upper approximations are

$$\underline{A}\{1, 2, 3\} = \{1, 2, 3\}, \\ \overline{A}\{1, 2, 3\} = \{1, 2, 3, 5, 7\}.$$

The second possibility is to modify the subset definition of lower and upper approximation by replacing the universe  $U$  from the subset definition by a concept  $X$ . A *concept*  $B$ -lower approximation of the concept  $X$  is defined as follows

$$\underline{BX} = \cup\{K_B(x) \mid x \in X, K_B(x) \subseteq X\}. \quad (23.21)$$

Obviously, the subset  $B$ -lower approximation of  $X$  is the same set as the concept  $B$ -lower approximation of  $X$ . A *concept*  $B$ -upper approximation of the concept  $X$  is defined as follows

$$\overline{BX} = \cup\{K_B(x) \mid x \in X, K_B(x) \cap X \neq \emptyset\} \\ = \cup\{K_B(x) \mid x \in X\}. \quad (23.22)$$

The concept upper approximations were defined in [23.17] and [23.18] as well. The concept  $B$ -upper approximation of  $X$  is a subset of the subset  $B$ -upper approximation of  $X$  [23.16]. For the decision table presented in Table 23.10, the concept  $A$ -upper approximations is

$$\overline{A}\{1, 2, 3\} = \{1, 2, 3\}.$$

Note that for complete decision tables, all three definitions of lower and upper approximations, singleton, subset, and concept, are reduced to the same standard definition of lower and upper approximations, respectively.

### 23.4.2 Modified LEM2 Algorithm

The same MLEM2 rule induction from Sect. 23.3 may be used for rule induction from incomplete data; the only difference is a different definition of blocks of attribute–value pairs. Let us apply the MLEM2 algorithm to the data set from Table 23.10. First, we need to make a decision as to what kind of approximations we are going to use: singleton, subset, or concept. In our example, we use concept approximation. For Table 23.10,

$$\underline{A}\{1, 2, 3\} = \overline{A}\{1, 2, 3\} = \{1, 2, 3\},$$

we will trace the MLEM2 algorithm applied to the set  $\{1, 2, 3\}$ ; this way our certain rule set, for the concept  $[(Trip, yes)]$ , is at the same time certain and possible. The tracing of LEM2 is presented in the Tables 23.11.

The corresponding comments are:

1. The set  $G = \{1, 2, 3\}$ . The best attribute–value pair  $t$ , with the largest cardinality of the intersection of  $[t]$  and  $G$  (presented in the third column of Table 23.11) is  $(Temperature, medium)$ . The corresponding entry in the third column of Table 23.11 is bulleted. However,

$$[(Temperature, medium)] \\ = \{1, 2, 3, 5, 7\} \not\subseteq \{1, 2, 3\} = B,$$

hence we need to look for the next  $t$ .

2. Set  $G$  is the same,  $G = \{1, 2, 3\}$ . There are two attribute–value pairs with  $|[t \cap G]| = 2$ . One of them,  $(Humidity, low)$  has the smallest cardinality of  $[t]$ , so we select it. This time

$$\{1, 2, 3, 5, 7\} \cap \{1, 2\} = \{1, 2\} \subseteq \{1, 2, 3\}.$$

However,  $(Temperature, medium)$  is redundant, since  $[(Humidity, low)] \subseteq \{1, 2, 3\}$ , hence  $\{(Humidity, low)\}$  is the first element  $T$  of  $\mathcal{T}$ .

3. The new set  $G = B - [T] = \{1, 2, 3\} - \{1, 2\} = \{3\}$ . The pair  $(Humidity, medium)$  has the smallest cardinality of  $[t]$ , so it is the best choice. Additionally,  $[(Humidity, medium)] = \{3\} \subseteq \{1, 2, 3\}$ , hence we are done, the set  $T = \{(Humidity, medium)\}$ .

**Table 23.11** Computing a rule set for the concept  $[(Trip, yes)]$ , Table 23.10

$(a, v) = t$	$[(a, v)]$	$\{1, 2, 3\}$	$\{1, 2, 3\}$	$\{3\}$
$(Wind, low)$	$\{1, 3, 4, 6\}$	$\{1, 3\}$	$\{1, 3\}$	$\{3\}$
$(Wind, medium)$	$\{3, 5, 6, 7, 8\}$	$\{3\}$	$\{3\}$	$\{3\}$
$(Humidity, low)$	$\{1, 2\}$	$\{1, 2\}$	$\{1, 2\} \bullet$	$-$
$(Humidity, medium)$	$\{3\}$	$\{3\}$	$\{3\}$	$\{3\} \bullet$
$(Humidity, high)$	$\{6, 7, 8\}$	$-$	$-$	$-$
$(Temperature, low)$	$\{2, 6, 7\}$	$\{2\}$	$-$	$-$
$(Temperature, medium)$	$\{1, 2, 3, 5, 7\}$	$\{1, 2, 3\} \bullet$	$-$	$\{3\}$
$(Temperature, high)$	$\{2, 4, 7, 8\}$	$\{2\}$	$-$	$-$
Comments		1	2	3

Therefore,  $\mathcal{T} = \{\{(Humidity, low)\}, \{(Humidity, medium)\}\}$ . The MLEM2 algorithm induces the following rule set for Table 23.10:

- 1, 2, 2

$$(Humidity, low) \rightarrow (Trip, yes),$$

- 1, 1, 1

$$(Humidity, medium) \rightarrow (Trip, yes).$$

### 23.4.3 Probabilistic Approximations

In this section we are going to generalize singleton, subset, and concept approximations from Sect. 23.4.1 to corresponding approximations that are defined using an additional parameter (or threshold), denoted by  $\alpha$ , and interpreted as a probability. A generalization of standard approximations, called *probabilistic approximations*, has been studied in many papers [23.19–26].

Let  $B$  be a subset of the attribute set  $A$  and  $X$  be a subset of  $U$ .

A  $B$ -singleton probabilistic approximation of  $X$  with the threshold  $\alpha$ ,  $0 < \alpha \leq 1$ , denoted by  $\text{appr}_{\alpha, B}^{\text{singleton}}(X)$ , is defined as follows

$$\{x \mid x \in U, \Pr(X \mid K_B(x)) \geq \alpha\},$$

where

$$\Pr(X \mid K_B(x)) = \frac{|X \cap K_B(x)|}{|K_B(x)|}$$

is the conditional probability of  $X$  given  $K_B(x)$  and  $|Y|$  denotes the cardinality of set  $Y$ .

A  $B$ -subset probabilistic approximation of the set  $X$  with the threshold  $\alpha$ ,  $0 < \alpha \leq 1$ , denoted by  $\text{appr}_{\alpha, B}^{\text{subset}}(X)$ , is defined as follows

$$\cup\{K_B(x) \mid x \in U, \Pr(X \mid K_B(x)) \geq \alpha\}.$$

A  $B$ -concept probabilistic approximation of the set  $X$  with the threshold  $\alpha$ ,  $0 < \alpha \leq 1$ , denoted by  $\text{appr}_{\alpha, B}^{\text{concept}}(X)$ , is defined as follows

$$\cup\{K_B(x) \mid x \in X, \Pr(X \mid K_B(x)) \geq \alpha\}.$$

For simplicity, if  $B = A$ , an  $A$ -singleton,  $B$ -subset, and  $B$ -concept probabilistic approximations will be called singleton, subset, and concept prob-

abilistic approximations, and will be denoted by  $\text{appr}_{\alpha}^{\text{singleton}}(X)$ ,  $\text{appr}_{\alpha}^{\text{subset}}(X)$ , and  $\text{appr}_{\alpha}^{\text{concept}}(X)$ , respectively.

Obviously, for the concept  $X$ , the probabilistic approximation of a given type (singleton, subset, or concept) of  $X$  computed for the threshold equal to the smallest positive conditional probability  $\Pr(X \mid [x])$  is equal to the standard upper approximation of  $X$  of the same type. Additionally, the probabilistic approximation of a given type of  $X$  computed for the threshold equal to 1 is equal to the standard lower approximation of  $X$  of the same type.

For the data set from Table 23.12, the set of blocks of attribute–value pairs is

$$\begin{aligned} [(Wind, \text{low})] &= \{1, 3, 5\}, \\ [(Wind, \text{high})] &= \{4, 6, 7, 8\}, \\ [(Humidity, \text{low})] &= \{1, 2, 3, 5\}, \\ [(Humidity, \text{high})] &= \{1, 4, 6, 7, 8\}, \\ [(\text{Temperature}, \text{low})] &= \{1, 2, 5, 6\}, \\ [(\text{Temperature}, \text{high})] &= \{1, 4, 6, 7, 8\}. \end{aligned}$$

The corresponding characteristic sets are

$$\begin{aligned} K_A(1) &= K_A(3) = \{1, 3, 5\}, \\ K_A(2) &= \{1, 2, 5\}, \\ K_A(4) &= \{4, 6, 8\}, \\ K_A(5) &= \{1, 5\}, \\ K_A(6) &= K_A(8) = \{4, 6, 8\}, \\ K_A(7) &= \{4, 6, 7, 8\}. \end{aligned}$$

Conditional probabilities of the concept  $\{1, 2, 3, 4\}$  given a characteristic set  $K_A(x)$  are presented in Table 23.13.

**Table 23.12** An incomplete decision table

Case	Attributes			Decision Trip
	Wind	Humidity	Temperature	
1	low	low	*	yes
2	?	low	low	yes
3	low	low	?	yes
4	high	high	high	yes
5	low	*	low	no
6	high	high	*	no
7	high	?	high	no
8	high	high	high	no

**Table 23.13** Conditional probabilities

$K_A(x)$	{1, 2, 5}	{1, 3, 5}	{1, 5}	{4, 6, 8}	{4, 6, 7, 8}
$Pr\{\{1, 2, 4, 6\} \mid K_A(x)\}$	0.667	0.667	0.5	0.333	0.25

For Table 23.13, all probabilistic approximations (singleton, subset, and concept) are

$$\begin{aligned} \text{appr}_{0.25}^{\text{singleton}}(\{1, 2, 3, 4\}) &= U, \\ \text{appr}_{0.333}^{\text{singleton}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 4, 5, 6, 8\}, \\ \text{appr}_{0.5}^{\text{singleton}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 5\}, \\ \text{appr}_{0.667}^{\text{singleton}}(\{1, 2, 3, 4\}) &= \{1, 2, 3\}, \\ \text{appr}_1^{\text{singleton}}(\{1, 2, 3, 4\}) &= \emptyset, \\ \text{appr}_{0.25}^{\text{subset}}(\{1, 2, 3, 4\}) &= U, \\ \text{appr}_{0.333}^{\text{subset}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 4, 5, 6, 8\}, \\ \text{appr}_{0.5}^{\text{subset}}(\{1, 2, 3, 3\}) &= \{1, 2, 3, 5\}, \\ \text{appr}_{0.667}^{\text{subset}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 5\}, \\ \text{appr}_1^{\text{subset}}(\{1, 2, 3, 4\}) &= \emptyset, \\ \text{appr}_{0.25}^{\text{concept}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 4, 5, 6, 8\}, \\ \text{appr}_{0.333}^{\text{concept}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 4, 5, 6, 8\}, \\ \text{appr}_{0.5}^{\text{concept}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 5\}, \\ \text{appr}_{0.667}^{\text{concept}}(\{1, 2, 3, 4\}) &= \{1, 2, 3, 5\}, \\ \text{appr}_1^{\text{concept}}(\{1, 2, 3, 4\}) &= \emptyset. \end{aligned}$$

For rule induction from probabilistic approximations of the given concept a technique similar to the

**Table 23.14** A modified decision table

Case	Attributes			Decision
	Wind	Humidity	Temperature	Trip
1	low	low	*	yes
2	?	low	low	yes
3	low	low	?	yes
4	high	high	high	SPECIAL
5	low	*	low	no
6	high	high	*	SPECIAL
7	high	?	high	SPECIAL
8	high	high	high	SPECIAL

one in Sect. 23.2 may be used. For any concept and the probabilistic approximation of the concept we will create a new decision table. Let us illustrate this idea with inducing a rule set for the concept  $[(Trip, yes)]$  from Table 23.12 using concept probabilistic approximation with  $\alpha = 0.5$ . The corresponding modified decision table is presented in Table 23.14.

In the data set presented in Table 23.14, all values of  $Trip$  are copied from Table 23.12 for all cases from

$$\text{appr}_{0.5}^{\text{concept}}(\{1, 2, 3, 4\}) = \{1, 2, 3, 5\},$$

while for all remaining cases values of  $Trip$  are replaced by the SPECIAL value. The MLEM2 rule induction algorithm, using concept upper approximation should be used with the corresponding type of upper approximation (singleton, subset, and concept). In our example, the MLEM2 rule induction algorithm, using concept upper approximation, induces the following rule set from Table 23.14:

- 1, 3, 4  
 $(\text{Humidity, low}) \rightarrow (\text{Trip, yes}),$
  - 1, 4, 4  
 $(\text{Wind, high}) \rightarrow (\text{Trip, SPECIAL}),$
  - 2, 1, 2  
 $(\text{Wind, low}) \& (\text{Temperature, low}) \rightarrow (\text{Trip, no}).$
- The only rules that are useful should have  $(Trip, yes)$  on the right-hand side. Thus, the only rule that survives is:
- 1, 3, 4  
 $(\text{Humidity, low}) \rightarrow (\text{Trip, yes}).$

## 23.5 Conclusions

Investigation of rule induction methods is subject to intensive research activity. New versions of rule induction algorithms based on probabilistic approximations have been explored [23.27, 28]. Novel rule induction algorithms in which computation of proba-

bilistic approximations is done in parallel with rule induction were recently developed and experimentally tested [23.29]. The LEM2 algorithm was implemented in a bagged version [23.30], using ideas of ensemble learning.

# Probabilistic

## 24. Probabilistic Rough Sets

Yiyu Yao, Salvatore Greco, Roman Słowiński

As quantitative generalizations of Pawlak rough sets, probabilistic rough sets consider degrees of overlap between equivalence classes and the set. An equivalence class is put into the lower approximation if the conditional probability of the set, given the equivalence class, is equal to or above one threshold; an equivalence class is put into the upper approximation if the conditional probability is above another threshold hold. We review a basic model of probabilistic rough sets (i.e., decision-theoretic rough set model) and variations. We present the main results of probabilistic rough sets by focusing on three issues: (a) interpretation and calculation of the required thresholds, (b) estimation of the required conditional probabilities, and (c) interpretation and applications of probabilistic rough set approximations.

## 24.1 Motivation for Studying Probabilistic Rough Sets

Rough set theory [24.1, 2] provides a simple and elegant method for analyzing data represented in a tabular form called an information table. The rows of the table represent a finite set of objects, the columns represent a finite set of attributes, and each cell represents the value of an object on the corresponding attribute. With a limited number of attributes, we may only be able to describe some subsets of objects precisely [24.3, 4]. Those subsets that can be precisely described are called definable sets, and all other subsets are called undefinable sets. A fundamental notion of rough set theory is the approximation of a subset of objects by a pair of definable sets from below and above, or equivalently, by three pairwise disjoint positive, negative, and boundary regions [24.4].

Pawlak rough set approximations are characterized by a zero tolerance of errors. That is, an object in the lower approximation certainly belongs to set and an object in the complement of the upper approximation certainly does not belong to the set. This has motivated the introduction of many different generalizations of rough sets. By introducing certain levels of errors, probabilistic rough sets [24.5, 6] are quantitative generalizations of the qualitative Pawlak rough sets. Although several specific models of probabilistic rough sets had been considered by some authors [24.7–10], a more general model, called decision-theoretic rough set (DTRS)

model, was first proposed by Yao et al. [24.11, 12] based on the well-established Bayesian decision theory. Other probabilistic models include variable precision rough sets [24.13, 14], Bayesian rough sets [24.15–18], parameterized rough sets [24.19, 20], game-theoretic rough sets [24.21, 22], variable-consistency-indiscernibility-based and dominance-based rough sets [24.23, 24], stochastic dominance-based rough sets [24.25], naive Bayesian rough sets [24.26], information-theoretic rough sets [24.27], confirmation-theoretic rough sets [24.28], and many different types of probabilistic rough set approximations [24.29, 30].

In this chapter, we present a basic model of probabilistic rough sets and a brief review of other probabilistic rough set models. We examine in particular three fundamental issues, namely, the interpretation and computation of the pair of thresholds, the estimation of probability, and an application of three regions. We also show how a probabilistic approach can be applied when information related to some order representing the extent to which some property related to considered attributes has to be taken into account. This situation is handled by the well-known rough set extension called dominance-based rough set approach [24.31–34]. A full understanding of these issues will greatly increase the chance of success when applying probabilistic rough sets in real-world applications.

## 24.2 Pawlak Rough Sets

We present a semantically meaningful definition of rough set approximations and a simple method for constructing rough set approximations.

### 24.2.1 Rough Set Approximations

In rough set theory, a finite set of objects is described by using a finite set of attributes in a tabular form, called an information table [24.2]. Formally, an information table can be expressed as

$$S = (U, AT, \{V_a \mid a \in AT\}, \{I_a \mid a \in AT\}) ,$$

where

$U$  is a finite nonempty set of objects called universe ,  
 $AT$  is a finite nonempty set of attributes ,

$V_a$  is a nonempty set of values for  $a \in AT$  ,

$I_a : U \rightarrow V_a$  is an information function .

The information table provides all available information about the set of objects, based on which we can perform tasks of analysis and inference.

In an information table, one can introduce a description language, as suggested by Marek and Pawlak [24.3], to formally describe objects. We consider a language  $DL$  that is recursively defined as follows

- (1)  $(a = v) \in DL$ , where  $a \in AT, v \in V_a$  ,
- (2) if  $p, q \in DL$ , then  $\neg p, p \wedge q, p \vee q \in DL$  .

Formulas defined by (1) are called atomic formulas. The satisfiability of formula  $p$  by an object  $x$ , written

$x \models p$ , is defined as follows

- (i)  $x \models (a = v)$ , iff  $I_a(x) = v$ ,
- (ii)  $x \models \neg p$ , iff  $\neg(x \models p)$ ,
- (iii)  $x \models p \wedge q$ , iff  $x \models p$  and  $x \models q$ ,
- (iv)  $x \models p \vee q$ , iff  $x \models p$  or  $x \models q$ .

If  $p$  is a formula, the set  $m(p) \subseteq U$  defined by

$$m(p) = \{x \in U \mid x \models p\} \quad (24.1)$$

is called the meaning set of  $p$ . That is, the meaning set  $m(p)$  consists of all those objects that satisfy the formula  $p$ .

With the introduction of a description language, we can formally describe an important characteristics of an information table, namely, some subsets of objects are definable or describable while others are not. A subset of objects  $X \subseteq U$  is called a definable set [24.3, 4] if there exists a formula  $p$  such that

$$X = m(p), \quad (24.2)$$

otherwise,  $X$  is called an undefinable set. The formula  $p$  is called a description of  $X$ . Let  $\text{DEF}(U) \subseteq 2^U$  denote the family of all definable sets, where  $2^U$  is the power set of  $U$ . By definition,  $\text{DEF}(U)$  contains the empty set  $\emptyset$ , the entire universe  $U$  and is closed under set complement, intersection, and union. In other words,  $\text{DEF}(U)$  is a sub-Boolean algebra of the power set  $2^U$ .

For any subset of objects  $X \subseteq U$ , may be either definable or undefinable, we define the following pair of lower and upper approximations

$$\begin{aligned} \underline{\text{apr}}(X) &= \text{the largest definable set contained by } X \\ &= \bigcup\{G \in \text{DEF}(U) \mid G \subseteq X\}, \\ \overline{\text{apr}}(X) &= \text{the smallest definable set containing } X \\ &= \bigcap\{G \in \text{DEF}(U) \mid X \subseteq G\}. \end{aligned} \quad (24.3)$$

By definition, it follows that  $\underline{\text{apr}}(X) \subseteq X \subseteq \overline{\text{apr}}(X)$  for any  $X \subseteq U$ , and  $\underline{\text{apr}}(X) = X = \overline{\text{apr}}(X)$  if and only if  $X \in \text{DEF}(U)$ . The definition is semantically meaningful in the sense that it clearly explains the motivation for introducing rough set approximations and provides an interpretation of the approximations. However, one cannot use this definition to construct rough set approximations easily.

## 24.2.2 Construction of Rough Set Approximations

A simple method for constructing rough set approximations is through an equivalence relation. For an attribute  $a \in AT$ , the information function  $I_a$  maps an object in  $U$  to a value of  $V_a$ , that is,  $I_a(x) \in V_a$ . For an attribute  $a \in AT$ , we can define an equivalence relation  $E_a$  as follows: for  $x, y \in U$

$$xE_a y \iff I_a(x) = I_a(y). \quad (24.4)$$

The equivalence class containing  $x$  is denoted by  $[x]_a$ . Similarly, for a subset of attributes  $A \subseteq AT$ , we define an equivalence relation  $E_A$

$$xE_A y \iff \forall a \in A(I_a(x) = I_a(y)). \quad (24.5)$$

The equivalence class containing  $x$  is denoted by  $[x]_A$ . By definition, it follows that, for  $a \in AT$  and  $A \subseteq AT$ ,

$$\begin{aligned} E_{\{a\}} &= E_a, \quad [x]_{\{a\}} = [x]_a, \\ E_A &= \bigcap_{a \in A} E_a, \quad [x]_A = \bigcap_{a \in A} [x]_a. \end{aligned} \quad (24.6)$$

That is, we can construct the equivalence relation induced by a subset of attributes  $A$  by using equivalence relations induced by individual attributes in  $A$ .

Consider the equivalence relation  $E_A \subseteq U \times U$  induced by a subset of attributes  $A \subseteq AT$ . The equivalence relation  $E_A$  induces a partition  $U/E_A$  of  $U$ , i.e., a family of nonempty and pairwise disjoint subsets whose union is the universe. For an object  $x \in U$ , its equivalence class is given by

$$[x]_A = \{y \in U \mid xE_A y\}. \quad (24.7)$$

By taking the union of a family of equivalence classes, one can construct an atomic sub-Boolean  $B(U/E_A)$  of  $2^U$  with  $U/E_A$  as the set of atoms

$$B(U/E_A) = \{\bigcup F \mid F \subseteq U/E_A\}. \quad (24.8)$$

That is,  $B(U/E_A)$  contains the empty set  $\emptyset$ , the whole set  $U$ , and is closed with respect to set complement, intersection, and union. The three notions of equivalence relation  $E$ , the partition  $U/E_A$ , and atomic Boolean algebra  $B(U/E_A)$  uniquely determine each other. We can therefore use  $E_A$ ,  $U/E_A$ , and  $B(U/E_A)$  interchangeably.

The pair  $\underline{\text{apr}} = (U, E_A)$ , equivalently, the pair  $\overline{\text{apr}} = (U, U/E_A)$  or the pair  $\text{apr} = (U, B(U/E_A))$ , is called an

approximation space. Although three different representations are equivalent, each of them provides a different hint when we generalize rough sets. The pair  $\text{apr} = (U, E_A)$  is useful for generalizing rough sets using a nonequivalence relation [24.35]. The partition  $U/E_A$  may be viewed as a granulation of the universe  $U$  and the pair  $\text{apr} = (U, U/E_A)$  relates rough sets and granular computing [24.36]. The pair  $\text{apr} = (U, B(U/E_A))$  leads to a subsystem-based formulation and generalizations [24.37].

For a subset of attributes  $A \subseteq AT$ , if we restrict the formulas of  $DL$  by using only attributes in  $A$ , we obtain a sublanguage  $DL(A) \subseteq DL$ . It can be proved that the family of all definable sets  $\text{DEF}_A(U)$  defined by  $DL(A)$  is exactly the sub-Boolean algebra  $B(U/E_A)$ . With respect to a subset of attributes  $A \subseteq AT$ , each object  $x$  is described by a logic formula

$$\bigwedge_{a \in A} a = I_a(x), \quad (24.9)$$

where  $I_a(x) \in V_a$  and the atomic formula  $a = I_a(x)$  indicate that the value of an object on attribute  $a$  is  $I_a(x)$ . The equivalence class containing  $x$ , namely,  $[x]_{E_A}$ , is the set of those objects that satisfy the formula  $\wedge_{a \in A} a = I_a(x)$ . The formula can be viewed as a description of objects that are equivalent to  $x$  with respect to  $A$ , including  $x$  itself.

Based on the equivalence of  $\text{DEF}_A(U)$  and  $B(U/E_A)$ , we can equivalently define rough set approximations by using the equivalence classes  $[x]_A$ . For simplicity, we also simply write  $[x]$  when no confusion arises.

### 24.3 A Basic Model of Probabilistic Rough Sets

Decision-theoretic rough set (DTRS) model proposed by Yao et al. [24.11, 12] gives rises to a general form of probabilistic rough set approximations by using a pair of thresholds on conditional probabilities. The results enable us to formulate a basic model of probabilistic rough sets. However, we introduce the model in a way that is different from DTRS. We first interpret Pawlak rough sets in terms of probability and the two extreme value of probability (i.e., 1 and 0) and then generalize 1 and 0 into a pair of thresholds  $(\alpha, \beta)$  with  $0 \leq \beta < \alpha \leq 1$ .

The Pawlak rough sets consider only qualitative relationship between an equivalence class and a set, namely, an equivalence is a subset of the set or has

For a subset of objects  $X \subseteq U$ , the pair of lower and upper approximations can be equivalently defined by

$$\begin{aligned} \underline{\text{apr}}(X) &= \{x \in U \mid [x] \subseteq X\}, \\ \overline{\text{apr}}(X) &= \{x \in U \mid [x] \cap X \neq \emptyset\}. \end{aligned} \quad (24.10)$$

Construction of rough set approximation by this definition is much easier. Alternatively, one can also define three pairwise disjoint positive, negative, and boundary regions [24.38]

$$\begin{aligned} \text{POS}(X) &= \{x \in U \mid [x] \subseteq X\}, \\ \text{NEG}(X) &= \{x \in U \mid [x] \cap X = \emptyset\}, \\ \text{BND}(X) &= \{x \in U \mid [x] \not\subseteq X \wedge [x] \cap X \neq \emptyset\}. \end{aligned} \quad (24.11)$$

The pair of approximations and three regions determines each other as follows

$$\begin{aligned} \text{POS}(X) &= \underline{\text{apr}}(X), \\ \text{NEG}(X) &= (\overline{\text{apr}}(X))^c, \\ \text{BND}(X) &= \overline{\text{apr}}(X) - \underline{\text{apr}}(X), \end{aligned} \quad (24.12)$$

and

$$\begin{aligned} \underline{\text{apr}}(X) &= \text{POS}(X), \\ \overline{\text{apr}}(X) &= \text{POS}(X) \cup \text{BND}(X), \end{aligned} \quad (24.13)$$

where  $(\cdot)^c$  denotes the complement of a set. Each representation provides a distinctive interpretation of rough set approximations. We will use the three-region approximation in the rest of this chapter, due to its close connections to three-way decisions.

a nonempty intersection with the set. This qualitative nature becomes clearer with a probabilistic interpretation [24.6]. Suppose  $Pr(X|[x])$  denotes the conditional probability that an object is in  $X$  given that the object is in  $[x]$ . The conditions for defining rough set three regions can be equivalently expressed as

$$\begin{aligned} [x] \subseteq X &\iff Pr(X|[x]) \geq 1; \\ [x] \cap X = \emptyset &\iff Pr(X|[x]) \leq 0; \\ [x] \not\subseteq X \wedge [x] \cap X \neq \emptyset &\iff 0 < Pr(X|[x]) < 1. \end{aligned} \quad (24.14)$$

Although a probability can never be greater than 1 or less than 0, we purposely use the conditions  $\geq 1$  and

$\leq 0$  whose intended meaning will become clearer later. By those conditions, Pawlak three regions can be equivalently expressed as

$$\begin{aligned}\text{POS}(X) &= \{x \in U \mid \Pr(X|[x]) \geq 1\}, \\ \text{NEG}(X) &= \{x \in U \mid \Pr(X|[x]) \leq 0\}, \\ \text{BND}(X) &= \{x \in U \mid 0 < \Pr(X|[x]) < 1\}.\end{aligned}\quad (24.15)$$

They show that Pawlak rough sets only use the two extreme values, i.e., 1 and 0, of probability.

It is natural to generalize Pawlak rough sets by replacing 1 and 0 with some other values in the unit interval  $[0, 1]$ . Given a pair of thresholds  $\alpha, \beta$  with  $0 \leq \beta < \alpha \leq 1$ , the main results of probabilistic rough sets are the  $(\alpha, \beta)$ -probabilistic regions defined by

$$\begin{aligned}\text{POS}_{(\alpha,\beta)}(X) &= \{x \in U \mid \Pr(X|[x]) \geq \alpha\}, \\ \text{NEG}_{(\alpha,\beta)}(X) &= \{x \in U \mid \Pr(X|[x]) \leq \beta\}, \\ \text{BND}_{(\alpha,\beta)}(X) &= \{x \in U \mid \beta < \Pr(X|[x]) < \alpha\}.\end{aligned}\quad (24.16)$$

The Pawlak rough set model is a special case in which  $\alpha = 1$  and  $\beta = 0$ . In the case when  $0 < \beta = \alpha < 1$ , the three regions are given by

$$\begin{aligned}\text{POS}_{(\alpha,\alpha)}(X) &= \{x \in U \mid \Pr(X|[x]) > \alpha\}, \\ \text{NEG}_{(\alpha,\alpha)}(X) &= \{x \in U \mid \Pr(X|[x]) < \alpha\}, \\ \text{BND}_{(\alpha,\alpha)}(X) &= \{x \in U \mid \Pr(X|[x]) = \alpha\}.\end{aligned}\quad (24.17)$$

It may be commented that this special case is perhaps more of mathematical interest, rather than practical applications. We use this particular definition in order to establish connection to existing studies. As will be shown in subsequent discussions, when  $\Pr(X|[x]) = \alpha = \beta$ , the costs of assigning objects in  $[x]$  to the positive, boundary, and negative regions, respectively, are the same. In fact, one may simply define two regions by assigning objects in the boundary region into either the positive or boundary region.

The main results of the basic model of probabilistic rough sets were first proposed by Yao et al. [24.11, 12] in a **DTRS** model, based on Bayesian decision theory. The **DTRS** model covers all specific models introduced before it. The interpretation of Pawlak rough sets in terms of conditional probability, i.e., the model characterized by  $\alpha = 1$  and  $\beta = 0$ , was first given by Wong and Ziarko [24.10]. A 0.5-model, characterized by  $\alpha = \beta = 0.5$ , was introduced by Wong and Ziarko [24.8] and Pawlak et al. [24.7], in which the positive region is defined by probability greater than 0.5, the negative by probability less than 0.5, and the boundary by probability equal to 0.5. A model characterized by  $\alpha > 0.5$  and  $\beta = 0.5$  was suggested by Wong and Ziarko [24.9]. Most recent developments on decision-theoretic rough sets can be found in a book edited by Li et al. [24.39] and papers [24.21, 40–50] in a journal special issue edited by Yao et al. [24.51].

## 24.4 Variants of Probabilistic Rough Sets

Since the introduction of decision-theoretic rough set model, several new models have been proposed and investigated. They offer related but different directions in generalizing Pawlak rough sets by incorporating probabilistic information.

### 24.4.1 Variable Precision Rough Sets

The first version of variable precision rough sets was introduced by Ziarko [24.14], in which the standard set inclusion  $[x] \subseteq X$  is generalized into a graded set inclusion  $s([x], X)$  called a measure of the relative degree of misclassification of  $[x]$  with respect to  $X$ . A particular measure suggested by Ziarko is given by

$$s([x], X) = 1 - \frac{|[x] \cap X|}{|[x]|}, \quad (24.18)$$

where  $|\cdot|$  denotes the cardinality of a set. By introducing a threshold  $0 \leq z < 0.5$ , one can define three regions as follows

$$\begin{aligned}\text{VPOS}_z(X) &= \{x \in U \mid s([x], X) \leq z\}, \\ \text{VNEG}_z(X) &= \{x \in U \mid s([x], X) \geq 1 - z\}, \\ \text{VBND}_z(X) &= \{x \in U \mid z < s([x], X) < 1 - z\}.\end{aligned}\quad (24.19)$$

A more generalized version using a pair of thresholds was late introduced by Katzberg and Ziarko [24.13] as follows: for  $0 \leq l < u \leq 1$ ,

$$\begin{aligned}\text{VPOS}_{(l,u)}(X) &= \{x \in U \mid s([x], X) \leq l\}, \\ \text{VNEG}_{(l,u)}(X) &= \{x \in U \mid s([x], X) \geq u\}, \\ \text{VBND}_{(l,u)}(X) &= \{x \in U \mid l < s([x], X) < u\}.\end{aligned}\quad (24.20)$$

The one-threshold model may be considered as a special case of the two-threshold model with  $l = z$  and  $u = 1 - z$ .

One may interpret the ratio in (24.18) as an estimation of the conditional probability  $Pr(X|[x])$ , namely

$$s([x], X) = 1 - \frac{|[x] \cap X|}{|[x]|} = 1 - Pr(X|[x]). \quad (24.21)$$

By setting  $\alpha = 1 - l$  and  $\beta = 1 - u$ , we immediately have

$$\begin{aligned} \text{POS}_{(1-l, 1-u)}(X) &= \{x \in U \mid Pr(X|[x]) \geq 1 - l\} \\ &= \{x \in U \mid s([x], X) \leq l\} \\ &= \text{VPOS}_{(l,u)}(X), \\ \text{NEG}_{(1-l, 1-u)}(X) &= \{x \in U \mid Pr(X|[x]) \geq 1 - u\} \\ &= \{x \in U \mid s([x], X) \geq u\} \\ &= \text{VNNEG}_{(l,u)}(X), \\ \text{BND}_{(1-l, 1-u)}(X) &= \{x \in U \mid 1 - l < Pr(X|[x]) < 1 - u\} \\ &= \{x \in U \mid l < s([x], X) < u\} \\ &= \text{VBND}_{(l,u)}(X). \end{aligned} \quad (24.22)$$

It follows that, when the particular set-inclusion measure defined by (24.18) is used, the variable precision rough sets are coincident with the decision-theoretic rough sets.

Variable precision rough sets provide an alternative direction in generalizing Pawlak rough sets by considering a graded set-inclusion relation, which is not necessarily restricted to a probabilistic interpretation. If we use other set-inclusion measures, we will obtain other types of quantitative rough sets [24.38, 52]. Unfortunately, subsequent developments lose this crucial feature in an attempt to unify variable precision rough sets into probabilistic rough sets [24.53].

#### 24.4.2 Parameterized Rough Sets

Parameterized rough sets, proposed by Greco et al. [24.19, 20], generalize probabilistic rough sets by introducing a Bayesian confirmation measure and a pair of thresholds on the confirmation measure, in addition to a pair of thresholds on conditional probability. According to Fitelson [24.54], *measures of confirmation* quantify the degree to which a piece of evidence  $E$  provides *evidence for or against or support for or against* a hypothesis  $H$ .

A measure of confirmation of a piece of evidence  $E$  with respect to a hypothesis  $H$  is denoted by  $c(E, H)$ . A confirmation measure  $c(E, H)$  is required to satisfy the following minimal property:

$$c(E, H) = \begin{cases} > 0 & \text{if } Pr(H|E) > Pr(H) \\ = 0 & \text{if } Pr(H|E) = Pr(H) \\ < 0 & \text{if } Pr(H|E) < Pr(H). \end{cases} \quad (i)$$

Two well-known Bayesian confirmation measures are [24.55]

$$\begin{aligned} c_d([x], X) &= Pr(X|[x]) - Pr(X), \\ c_r([x], X) &= \frac{Pr(X|[x])}{Pr(X)}. \end{aligned} \quad (24.23)$$

These measures have a probabilistic interpretation. The parameterized rough sets can be therefore viewed as a different formulation of probabilistic rough sets.

A first discussion about relationships between confirmation measures and rough sets were proposed by Greco et al. [24.56]. Other contributions related to the properties of confirmation measures with special attention to application to rough sets are given in [24.57].

Given a pair of thresholds  $(s, t)$  with  $t < s$ , three  $(\alpha, \beta, s, t)$ -parameterized regions are defined in [24.19, 20]

$$\begin{aligned} \text{PPOS}_{(\alpha, \beta, s, t)}(X) &= \{x \in U \mid Pr(X|[x]) \geq \alpha \\ &\quad \wedge c([x], X) \geq s\}, \\ \text{PNEG}_{(\alpha, \beta, s, t)}(X) &= \{x \in U \mid Pr(X|[x]) \leq \beta \\ &\quad \wedge c([x], X) \leq t\}, \\ \text{PBND}_{(\alpha, \beta, s, t)}(X) &= \{x \in U \mid (Pr(X|[x]) > \beta \\ &\quad \vee c([x], X) > t) \\ &\quad \wedge (Pr(X|[x]) < \alpha \\ &\quad \vee c([x], X) < s)\}. \end{aligned} \quad (24.24)$$

There exist many Bayesian confirmation measures, which makes the model of parameterized rough sets more flexible. On the other hand, due to lack of a general agreement on a Bayesian confirmation measure, choosing an appropriate confirmation measure for a particular application may not be an easy task.

#### 24.4.3 Confirmation-Theoretic Rough Sets

Although many Bayesian confirmation measures are related to the conditional probability  $Pr(X|[x])$ , Zhou

and Yao [24.26] argued that the conditional probability  $Pr(X|[x])$  and a Bayesian confirmation measure have very different semantics and should be used for different purposes. For example, the conditional probability  $Pr(X|[x])$  gives us an absolute degree of confidence in classifying objects from  $[x]$  as belonging to  $X$ . On the other hand, a Bayesian measure, for example,  $c_d$  or  $c_r$ , normally reflects a change of confidence in  $X$  before and after knowing  $[x]$ . Thus, a Bayesian confirmation measures is useful to weigh the strength of evidence  $[x]$  with respect to the hypothesis  $X$ . A mixture of conditional probability and confirmation measure in the parameterized rough sets may cause a semantic difficulty in interpreting the three regions.

To resolve this difficulty, Zhou and Yao [24.28] suggested a separation of the parameterized model into two models. One is the conventional probabilistic model and the other is a confirmation-theoretic model. For a Bayesian confirmation measure  $c([x], X)$  and a pair of thresholds  $(s, t)$  with  $t < s$ , three confirmation regions are defined by

$$\begin{aligned} \text{CPOS}_{(s,t)}(X) &= \{[x] \in U/R \mid c([x], X) \geq s\}, \\ \text{CNEG}_{(s,t)}(X) &= \{[x] \in U/R \mid c([x], X) \leq t\}, \\ \text{CBND}_{(s,t)}(X) &= \{[x] \in U/R \mid t < c([x], X) < s\}. \end{aligned} \quad (24.25)$$

For the case with  $s = t$ , we define

$$\begin{aligned} \text{CPOS}_{(s,s)}(X) &= \{[x] \in U/R \mid c([x], X) > s\}, \\ \text{CNEG}_{(s,s)}(X) &= \{[x] \in U/R \mid c([x], X) < s\}, \\ \text{CBND}_{(s,s)}(X) &= \{[x] \in U/R \mid c([x], X) = s\}. \end{aligned} \quad (24.26)$$

In the definition, each equivalence class may be viewed as a piece of evidence. Thus, the partition  $U/E$ , instead of the universe, is divided into three regions. An equivalence class in the positive region supports  $X$  to a degree at least  $s$ , an equivalence class in the negative region supports  $X$  to a degree at most  $t$  and may be viewed as against  $X$ , and an equivalence class in the boundary region is interpreted as neutral toward  $X$ .

#### 24.4.4 Bayesian Rough Sets

Bayesian rough sets were proposed by Ślezak and Ziarko [24.15, 16] as a probabilistic model in which the required pair of thresholds is interpreted using the a priori probability  $Pr(X)$ . They introduced Bayesian rough sets and variable precision Bayesian rough sets.

For the Bayesian rough sets, the three regions are defined by

$$\begin{aligned} \text{BPOS}(X) &= \{x \in U \mid Pr(X|[x]) > Pr(X)\}, \\ \text{BNEG}(X) &= \{x \in U \mid Pr(X|[x]) < Pr(X)\}, \\ \text{BBND}(X) &= \{x \in U \mid Pr(X|[x]) = Pr(X)\}. \end{aligned} \quad (24.27)$$

Bayesian rough sets can be viewed as a special case of the decision-theoretic rough sets when  $\alpha = \beta = Pr(X)$ . Semantically, they are very different, however. In contrast to decision-theoretic rough sets, for a set with a higher a priori probability  $Pr(X)$ , many equivalence classes may not be put into the positive region in the Bayesian rough set model, as the condition  $Pr(X|[x]) > Pr(X)$  may not hold. For example, the positive region of the entire universe is always empty, namely,  $\text{BPOS}(U) = \emptyset$ . This leads to a difficulty in interpreting the positive region as a lower approximation of a set.

The difficulty with Bayesian rough sets stems from the fact that they are in fact a special model of confirmation-theoretic rough sets, which is suitable for classifying pieces of evidence (i.e., equivalence classes), but is inappropriate for approximating a set. Recall that one Bayesian confirmation measure is given by  $c_d([x], X) = Pr(X|[x]) - Pr(X)$ . Therefore, Bayesian rough sets can be expressed as confirmation-theoretic rough sets as follows,

$$\begin{aligned} \text{BPOS}(X) &= \{x \in U \mid Pr(X|[x]) > Pr(X)\}, \\ &= \{x \in U \mid c_d([x], X) > 0\}, \\ &= \bigcup \text{CPOS}_{(0,0)}(X), \\ \text{BNEG}(X) &= \{x \in U \mid Pr(X|[x]) < Pr(X)\}, \\ &= \{x \in U \mid c_d([x], X) < 0\}, \\ &= \bigcup \text{CNEG}_{(0,0)}(X), \\ \text{BBND}(X) &= \{x \in U \mid Pr(X|[x]) = Pr(X)\}, \\ &= \{x \in U \mid c_d([x], X) = 0\}, \\ &= \bigcup \text{CBND}_{(0,0)}(X). \end{aligned} \quad (24.28)$$

That is, the Bayesian rough sets are a model of confirmation-theoretic rough sets characterized by the Bayesian confirmation measure  $c_d$  with a pair of thresholds  $s = t = 0$ . Ślezak and Ziarko [24.17] showed that

Bayesian rough sets can also be interpreted by using other Bayesian confirmation measures.

The three regions of the variable precision Bayesian rough sets are defined as follows [24.16]: for  $\epsilon \in [0, 1)$

$$\begin{aligned} \text{VBPOS}_\epsilon(X) &= \{x \in U \mid Pr(X|[x]) \\ &\geq 1 - \epsilon(1 - Pr(X))\}, \\ \text{VBNeg}_\epsilon(X) &= \{x \in U \mid Pr(X|[x]) \leq \epsilon Pr(X)\}, \\ \text{VBBND}_\epsilon(X) &= \{x \in U \mid \epsilon Pr(X) < Pr(X|[x]) \\ &< 1 - \epsilon(1 - Pr(X))\}. \end{aligned} \quad (24.29)$$

Consider the Bayesian confirmation measure

$$c_r([x], X) = Pr(X|[x])/Pr(X).$$

For the condition of the positive region, when  $Pr(X^c) \neq 0$  we have

$$Pr(X|[x]) \geq 1 - \epsilon(1 - Pr(X)) \iff c_r([x], X^c) \leq \epsilon. \quad (24.30)$$

Similarly, for the condition defining the negative region, when  $Pr(X) \neq 0$  we have

$$Pr(X|[x]) \leq \epsilon Pr(X) \iff c_r([x], X) \leq \epsilon. \quad (24.31)$$

That is,  $[x]$  is put into the positive region if it confirms  $X^c$  to a degree less than or equal to  $\epsilon$  and is put into the negative region if it confirms  $X$  to a degree less than or equal to  $\epsilon$ . In this way, we get a confirmation-theoretic interpretation of variable precision Bayesian rough sets.

Unlike the confirmation-theoretic model defined by (24.25), the positive region of variable precision Bayesian rough sets is defined based on the confirmation of the complement of  $X$  and negative region is defined based on the confirmation of  $X$ . This definition is a bit awkward to interpret. Generally speaking, it may be more natural to define the positive region by those equivalence classes that confirm  $X$  to at least a certain degree. This suggests that one can redefine variable precision Bayesian rough sets by using the framework of confirmation-theoretic rough sets. Moreover, one can use a pair of thresholds instead of one threshold.

## 24.5 Three Fundamental Issues of Probabilistic Rough Sets

For practical applications of probabilistic rough sets, one must consider at least the following three fundamental issues [24.58, 59]:

- Interpretation and determination of the required pair of thresholds,
- Estimation of the required conditional probabilities, and
- Interpretation and applications of three probabilistic regions.

For each of the three issues, this section reviews one example of the possible methods.

### 24.5.1 Decision-Theoretic Rough Set Model: Determining the Thresholds

A decision-theoretic model formulates the construction of rough set approximations as a Bayesian decision problem with a set of two states and a set of three actions [24.11, 12]. The set of states is given by  $\Omega = \{X, X^c\}$  indicating that an element is in  $X$  and not in  $X$ , respectively. For simplicity, we use the same symbol to denote both a subset  $X$  and the corresponding state. Corresponding to the three regions, the set of actions

is given by  $\mathcal{A} = \{a_P, a_B, a_N\}$ , denoting the actions in classifying an object  $x$ , namely, deciding  $x \in \text{POS}(X)$ , deciding  $x \in \text{BND}(X)$ , and deciding  $x \in \text{NEG}(X)$ , respectively. The losses regarding the actions for different states are given by the  $3 \times 2$  matrix

	$X (P)$	$X^c (N)$
$a_P$	$\lambda_{PP}$	$\lambda_{PN}$
$a_B$	$\lambda_{BP}$	$\lambda_{BN}$
$a_N$	$\lambda_{NP}$	$\lambda_{NN}$

In the matrix,  $\lambda_{PP}$ ,  $\lambda_{BP}$ , and  $\lambda_{NP}$  denote the losses incurred for taking actions  $a_P$ ,  $a_B$ , and  $a_N$ , respectively, when an object belongs to  $X$ , and  $\lambda_{PN}$ ,  $\lambda_{BN}$  and  $\lambda_{NN}$  denote the losses incurred for taking the same actions when the object does not belong to  $X$ .

The expected losses associated with taking different actions for objects in  $[x]$  can be expressed as

$$\begin{aligned} R(a_P|[x]) &= \lambda_{PP}Pr(X|[x]) + \lambda_{PN}Pr(X^c|[x]), \\ R(a_B|[x]) &= \lambda_{BP}Pr(X|[x]) + \lambda_{BN}Pr(X^c|[x]), \\ R(a_N|[x]) &= \lambda_{NP}Pr(X|[x]) + \lambda_{NN}Pr(X^c|[x]). \end{aligned} \quad (24.32)$$

The Bayesian decision procedure suggests the following minimum-risk decision rules

- (P) If  $R(a_P|[x]) \leq R(a_B|[x])$   
and  $R(a_P|[x]) \leq R(a_N|[x])$ , decide  $x \in \text{POS}(X)$ ;
- (B) If  $R(a_B|[x]) \leq R(a_P|[x])$   
and  $R(a_B|[x]) \leq R(a_N|[x])$ , decide  $x \in \text{BND}(X)$ ;
- (N) If  $R(a_N|[x]) \leq R(a_P|[x])$   
and  $R(a_N|[x]) \leq R(a_B|[x])$ , decide  $x \in \text{NEG}(X)$ .

In order to make sure that the three regions are mutually disjoint, tie-breaking criteria should be added when two or three actions have the same risk. We use the following ordering for breaking a tie:  $a_P, a_N, a_B$ .

Consider a special class of loss functions with

$$(c0) \quad \lambda_{PP} \leq \lambda_{BP} < \lambda_{NP}, \quad \lambda_{NN} \leq \lambda_{BV} < \lambda_{PN}. \quad (24.33)$$

That is, the loss of classifying an object  $x$  belonging to  $X$  into the positive region  $\text{POS}(X)$  is less than or equal to the loss of classifying  $x$  into the boundary region  $\text{BND}(X)$ , and both of these losses are strictly less than the loss of classifying  $x$  into the negative region  $\text{NEG}(X)$ . The reverse order of losses is used for classifying an object not in  $X$ . With the condition (c0) and the equation  $Pr(X|[x]) + Pr(X^c|[x]) = 1$ , we can express the decision rules (P)–(N) in the following simplified form (for a detailed derivation, see references [24.58])

- (P) If  $Pr(X|[x]) \geq \alpha$   
and  $Pr(X|[x]) \geq \gamma$ , decide  $x \in \text{POS}(X)$ ;
- (B) If  $Pr(X|[x]) \leq \alpha$   
and  $Pr(X|[x]) \geq \beta$ , decide  $x \in \text{BND}(X)$ ;
- (N) If  $Pr(X|[x]) \leq \beta$   
and  $Pr(X|[x]) \leq \gamma$ , decide  $x \in \text{NEG}(X)$ ,

where

$$\begin{aligned} \alpha &= \frac{(\lambda_{PN} - \lambda_{BV})}{(\lambda_{PN} - \lambda_{BV}) + (\lambda_{BP} - \lambda_{PP})}, \\ \beta &= \frac{(\lambda_{BV} - \lambda_{NN})}{(\lambda_{BV} - \lambda_{NN}) + (\lambda_{NP} - \lambda_{BP})}, \\ \gamma &= \frac{(\lambda_{PN} - \lambda_{NN})}{(\lambda_{PN} - \lambda_{NN}) + (\lambda_{NP} - \lambda_{PP})}. \end{aligned} \quad (24.34)$$

Each rule is defined by two out of the three parameters. By setting  $\alpha > \beta$ , namely

$$\begin{aligned} &\frac{(\lambda_{PN} - \lambda_{BV})}{(\lambda_{PN} - \lambda_{BV}) + (\lambda_{BP} - \lambda_{PP})} \\ &> \frac{(\lambda_{BV} - \lambda_{NN})}{(\lambda_{BV} - \lambda_{NN}) + (\lambda_{NP} - \lambda_{BP})}, \end{aligned} \quad (24.35)$$

we obtain the following condition on the loss function [24.58]

$$(c1) \quad \frac{\lambda_{NP} - \lambda_{BP}}{\lambda_{BV} - \lambda_{NN}} > \frac{\lambda_{BP} - \lambda_{PP}}{\lambda_{PN} - \lambda_{BV}}. \quad (24.36)$$

The condition (c1) implies that  $1 \geq \alpha > \gamma > \beta \geq 0$ . In this case, after tie-breaking, we have the simplified rules [24.58]

- (P) If  $Pr(X|[x]) \geq \alpha$ , decide  $x \in \text{POS}(X)$ ;
- (B) If  $\beta < Pr(X|[x]) < \alpha$ , decide  $x \in \text{BND}(X)$ ;
- (N) If  $Pr(X|[x]) \leq \beta$ , decide  $x \in \text{NEG}(X)$ .

The parameter  $\gamma$  is no longer needed. Each object can be put into one and only one region by using rules (P), (B), and (N). The  $(\alpha, \beta)$ -probabilistic positive, negative and boundary regions are given, respectively, by

$$\begin{aligned} \text{POS}_{(\alpha, \beta)}(X) &= \{x \in U \mid Pr(X|[x]) \geq \alpha\}, \\ \text{BND}_{(\alpha, \beta)}(X) &= \{x \in U \mid \beta < Pr(X|[x]) < \alpha\}, \\ \text{NEG}_{(\alpha, \beta)}(X) &= \{x \in U \mid Pr(X|[x]) \leq \beta\}. \end{aligned} \quad (24.37)$$

The formulation provides a solid theoretical basis and a practical interpretation of the probabilistic rough sets. The threshold parameters are systematically calculated from a loss function.

In the development of decision-theoretic rough sets, we assume that a loss function is given by experts in a particular application. There are studies on other types of loss functions and their acquisition [24.60]. Several other proposals have also been made regarding the interpretation and computation of the thresholds, including game-theoretic rough sets [24.21, 22], information-theoretic rough sets [24.27], and an optimization-based framework [24.43, 61, 62].

### 24.5.2 Naive Bayesian Rough Set Model: Estimating the Conditional Probability

Naive Bayesian rough set model was proposed by Yao and Zhou [24.59] as a practical method for estimating

the conditional probability. First, we perform the logit transformation of the conditional probability

$$\begin{aligned}\text{logit}(\Pr(X|[x])) &= \log \frac{\Pr(X|[x])}{1 - \Pr(X|[x])} \\ &= \log \frac{\Pr(X|[x])}{\Pr(X^c|[x])},\end{aligned}\quad (24.38)$$

which is a monotonically increasing transformation of  $\Pr(X|[x])$ . Then, we apply the Bayes' theorem

$$\Pr(X|[x]) = \frac{\Pr([x]|X)\Pr(X)}{\Pr([x])},\quad (24.39)$$

to infer the a posteriori probability  $\Pr(X|[x])$  from the likelihood  $\Pr([x]|X)$  of  $[x]$  with respect to  $X$  and the a priori probability  $\Pr(X)$ . Similarly, for  $X^c$  we also have

$$\Pr(X^c|[x]) = \frac{\Pr([x]|X^c)\Pr(X^c)}{\Pr([x])}.\quad (24.40)$$

By substituting results of (24.39) and (24.40) into (24.38), we immediately have

$$\begin{aligned}\text{logit}(\Pr(X|[x])) &= \log O(X|[x]) \\ &= \log \frac{\Pr(X|[x])}{\Pr(X^c|[x])} \\ &= \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} \cdot \frac{\Pr(X)}{\Pr(X^c)} \\ &= \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} + \log O(X),\end{aligned}\quad (24.41)$$

where  $O(X|[x])$  and  $O(X)$  are the a posterior and the a prior odds, respectively, and  $\Pr([x]|X)/\Pr([x]|X^c)$  is the likelihood ratio.

A threshold value on the probability can be expressed as another threshold value on logarithm of the likelihood ratio. For the positive region, we have

$$\begin{aligned}\Pr(X|[x]) &\geq \alpha \\ \iff \log \frac{\Pr(X|[x])}{\Pr(X^c|[x])} &\geq \log \frac{\alpha}{1-\alpha} \\ \iff \log \left( \frac{\Pr([x]|X)}{\Pr([x]|X^c)} \cdot \frac{\Pr(X)}{\Pr(X^c)} \right) &\geq \log \frac{\alpha}{1-\alpha} \\ \iff \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} &\geq \log \frac{\Pr(X^c)}{\Pr(X)} + \log \frac{\alpha}{1-\alpha} \\ &= \alpha'.\end{aligned}\quad (24.42)$$

Similar expressions can be obtained for the negative and boundary regions. The three regions can now be written as

$$\begin{aligned}\text{POS}_{(\alpha,\beta)}(X) &= \left\{ x \in U \mid \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} \geq \alpha' \right\}, \\ \text{BND}_{(\alpha,\beta)}(X) &= \left\{ x \in U \mid \beta' < \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} < \alpha' \right\}, \\ \text{NEG}_{(\alpha,\beta)}(X) &= \left\{ x \in U \mid \log \frac{\Pr([x]|X)}{\Pr([x]|X^c)} \leq \beta' \right\},\end{aligned}\quad (24.43)$$

where

$$\begin{aligned}\alpha' &= \log \frac{\Pr(X^c)}{\Pr(X)} + \log \frac{\alpha}{1-\alpha}, \\ \beta' &= \log \frac{\Pr(X^c)}{\Pr(X)} + \log \frac{\beta}{1-\beta}.\end{aligned}\quad (24.44)$$

With the transformation, we need to estimate the likelihoods that are relatively easier to obtain.

Suppose that an equivalence relation  $E_A$  is defined by using a subset of attributes  $A \subseteq AT$ . In the naive Bayesian rough set model, we estimate the likelihood ratio  $\Pr([x]_A|X)/\Pr([x]_A|X^c)$  through the likelihoods  $\Pr([x]_a|X)$  and  $\Pr([x]_a|X^c)$  defined by individual attributes, as the latter can be estimated more accurately. For this purpose, based on the results in (24.6), we make the following naive conditional independence assumptions

$$\begin{aligned}\Pr([x]_A|X) &= \Pr\left(\bigcap_{a \in A} [x]_a|X\right) = \prod_{a \in A} \Pr([x]_a|X), \\ \Pr([x]_A|X^c) &= \Pr\left(\bigcap_{a \in A} [x]_a|X^c\right) = \prod_{a \in A} \Pr([x]_a|X^c).\end{aligned}\quad (24.45)$$

By inserting them into (24.42) and assuming that  $[x]$  is defined by a subset of attributes  $A \subseteq AT$ , namely,  $[x] = [x]_A$ , we have

$$\begin{aligned}\log \frac{\Pr([x]_A|X)}{\Pr([x]_A|X^c)} &\geq \alpha' \\ \iff \log \frac{\prod_{a \in A} \Pr([x]_a|X)}{\prod_{a \in A} \Pr([x]_a|X^c)} &\geq \alpha' \\ \iff \sum_{a \in A} \log \frac{\Pr([x]_a|X)}{\Pr([x]_a|X^c)} &\geq \alpha'.\end{aligned}\quad (24.46)$$

Similar conditions can be derived for negative and boundary regions. Finally, the three regions can be defined as

$$\begin{aligned} \text{POS}_{(\alpha, \beta)}(X) &= \left\{ x \in U \mid \sum_{a \in A} \log \frac{\Pr([x]_a|X)}{\Pr([x]_a|X^c)} \geq \alpha' \right\}, \\ \text{BND}_{(\alpha, \beta)}(X) &= \left\{ x \in U \mid \beta' \right. \\ &\quad \left. < \sum_{a \in A} \log \frac{\Pr([x]_a|X)}{\Pr([x]_a|X^c)} < \alpha' \right\}, \\ \text{NEG}_{(\alpha, \beta)}(C) &= \left\{ x \in U \mid \sum_{a \in A} \log \frac{\Pr([x]_a|X)}{\Pr([x]_a|X^c)} \leq \beta' \right\}, \end{aligned} \quad (24.47)$$

where

$$\begin{aligned} \alpha' &= \log \frac{\Pr(X^c)}{\Pr(X)} + \log \frac{\alpha}{1-\alpha}, \\ \beta' &= \log \frac{\Pr(X^c)}{\Pr(X)} + \log \frac{\beta}{1-\beta}. \end{aligned} \quad (24.48)$$

We obtain a model in which we only need to estimate likelihoods of equivalence classes induced by individual attributes.

The likelihoods  $\Pr([x]_a|X)$  and  $\Pr([x]_a|X^c)$  may be simply estimated based on the following frequencies

$$\begin{aligned} \Pr([x]_a|X) &= \frac{|[x]_a \cap X|}{|X|}, \\ \Pr([x]_a|X^c) &= \frac{|[x]_a \cap X^c|}{|X^c|}, \end{aligned}$$

where  $[x]_a = \{y \in U \mid I_a(y) = I_a(x)\}$ . An equivalence class defined by a single attribute is usually large in comparison with an equivalence classes defined by a subset of attributes. Probability estimation based on the former may be more accurate than based on the latter.

Naive Bayesian rough sets provide only one of possible ways to estimate the conditional probability. Other estimation methods include logistic regress [24.46] and the maximum likelihood estimators [24.63].

### 24.5.3 Three-Way Decisions: Interpreting the Three Regions

A theory of three-way decisions [24.64] is motivated by the needs for interpreting the three regions [24.65–67]

and moves beyond rough sets. The main results of three-way decisions can be found in two recent books edited by Jia et al. [24.68] and Liu et al. [24.69], respectively. We present an interpretation of rough set three regions based on the framework of three-way decisions.

In an information table, with respect to a subset of attributes  $A \subseteq AT$ , an object  $x$  induces a logic formula

$$\bigwedge_{a \in A} a = I_a(x), \quad (24.49)$$

where  $I_a(x) \in V_a$  and the atomic formula  $a = I_a(x)$  indicates that the value of an object on attribute  $a$  is  $I_a(x)$ . An object  $y$  satisfies the formula if  $I_a(y) = I_a(x)$  for all  $a \in A$ , that is

$$\left( y \models \bigwedge_{a \in A} a = I_a(x) \right) \iff \forall a \in A \ (I_a(y) = I_a(x)). \quad (24.50)$$

With these notations, we are ready to interpret rough set in three regions.

From the three regions, we can construct three classes of rules for classifying an object, called the positive, negative, and boundary rules [24.58, 66, 67]. They are expressed in the following forms, for  $y \in U$ :

- Positive rule induced by an equivalence class  $[x] \subseteq \text{POS}_{(\alpha, \beta)}(X)$

$$\text{if } y \models \bigwedge_{a \in A} a = I_a(x), \text{ accept } y \in X$$

- Negative rule induced by an equivalence class  $[x] \subseteq \text{NEG}_{(\alpha, \beta)}(X)$

$$\text{if } y \models \bigwedge_{a \in A} a = I_a(x), \text{ reject } y \in X$$

- Boundary rule induced by an equivalence class  $[x] \subseteq \text{BND}_{(\alpha, \beta)}(X)$

$$\begin{aligned} \text{if } y \models \bigwedge_{a \in A} a = I_a(x), \text{ neither accept} \\ \text{nor reject } y \in X. \end{aligned}$$

The three types of rules have very different semantic interpretations as defined by their respective decisions. A positive rule allows us to *accept* an object  $y$  to be a member of  $X$ , because  $y$  has a higher probability of be-

ing in  $X$  due to the facts that  $y \in [x]_A$  and  $Pr(X|[x]_A) \geq \alpha$ . A negative rule enables us to *reject* an object  $y$  to be a member of  $X$ , because  $y$  has lower probability of being in  $X$  due to the facts that  $y \in [x]_A$  and  $Pr(X|[x]_A) \leq \beta$ . When the probability of  $y$  being in  $X$  is neither high nor low, a boundary rule makes a noncommitment decision. Although we explicitly give the class of boundary rules for convenience and completeness, we do not really need this class, once we have both classes of positive and negative rules. Whenever we can not accept nor reject an object to be a member of  $X$ , we choose a noncommitment decision.

Both actions of acceptance and rejection are associated with errors and costs. The error rate of a positive

rule is given by  $1 - Pr(X|[x])$ , which, by definition of the three regions, is at or below  $1 - \alpha$ . The error rate of negative rule is given by  $Pr(X|[x])$  and is at or below  $\beta$ . It becomes clear that the introduction of a noncommitment decision is to ensure both a low level of acceptance error and a low level of rejection error. According to the  $3 \times 2$  table in Sect. 24.5.1, the cost a positive rule is  $\lambda_{PP}Pr(X|[x]_A) + \lambda_{PN}(1 - Pr(X|[x]_A))$  and is bounded above by  $\alpha\lambda_{PP} + (1 - \alpha)\lambda_{PN}$ . The cost a negative rule is  $\lambda_{NP}Pr(X|[x]_A) + \lambda_{NN}(1 - Pr(X|[x]_A))$  and is bounded above by  $\beta\lambda_{NP} + (1 - \beta)\lambda_{NN}$ . From view of cost, a noncommitment decision is preferred if its cost is less than an action of acceptance or rejection.

## 24.6 Dominance-Based Rough Set Approaches

Very often value sets  $V_a$  of some attributes  $a \in AT$  are ordered in the sense that it is meaningful to consider a binary relation  $\gtrsim_a$  on  $V_a$  such that for  $x, y \in U$ ,  $I_a(x) \gtrsim_a I_a(y)$  means that  $x$  possesses some property related to attribute  $a$  at least as much as  $y$ . In this case, it is natural to consider  $\gtrsim_a$  as complete preorder on  $V_a$ , i.e., a transitive and strongly complete binary relation on  $V_a$  (let us remember that strong completeness means that for all  $v_a, u_a \in V_a$  we have  $v_a \gtrsim_a u_a$  or  $u_a \gtrsim_a v_a$  and that this implies the reflexivity of  $\gtrsim_a$ ). Observe that the binary relation  $\gtrsim_a^U$  on  $U$  defined as  $x \gtrsim_a^U y$  if  $I_a(x) \gtrsim_a I_a(y)$  for all  $x, y \in U$  is a complete preorder. The first type of properties considered in this perspective were preferences encountered in Multiple Criteria Decision Aiding (MCDA) (for a comprehensive collection of state of the art surveys see [24.70]), where for  $x, y \in U$ ,  $I_a(x) \gtrsim_a I_a(y)$  means  $x$  is at least as good as  $y$  with respect to attribute  $a$  that in this case is called *criterion*. If there are attributes  $a \in AT$  related to some complete preorder  $\gtrsim_a$ , then the indiscernibility relation is unable to produce granules in  $U$  taking into account the order generated by  $\gtrsim_a$ . To do so, the indiscernibility relation has to be substituted by a new binary relation on  $U$  that, using a term coming from MCDA, is called *dominance relation*. Suppose, for simplicity, all attributes  $a$  from  $AT$  are criteria related to corresponding complete preorders  $\gtrsim_a$ .

We say that  $x$  *dominates*  $y$  with respect to  $A \subseteq AT$  (shortly,  $x$  *A-dominates*  $y$ ) denoted by  $x \gtrsim_A^U y$ , if  $I_a(x) \gtrsim_a I_a(y)$  for all  $a \in A$ . Since  $\gtrsim_a^U$  is a complete preorder on  $U$  for each  $a \in AT$ ,  $\gtrsim_A$  is a partial preorder on  $U$ , i.e.  $\gtrsim_A$  is a reflexive and transitive binary relation on  $U$ .

For any  $x \in U$  and for each nonempty  $A \subseteq AT$ , we can define a positive and a negative cone of dominance, denoted by  $D_A^+(x)$  and  $D_A^-(x)$ , respectively,

$$\begin{aligned} D_A^+(x) &= \{y \in U \mid y \gtrsim_A^U x\}, \\ D_A^-(x) &= \{y \in U \mid x \gtrsim_A^U y\}. \end{aligned} \quad (24.51)$$

For simplicity, we also simply write  $D^+(x)$  and  $D^-(x)$  when no confusion arises.

Let us explain how the rough set concept has been generalized to the dominance-based rough set approach (DRSA) in order to enable granular computing with dominance cones (for more details, see Chap. 22, and [24.31–34, 71–74]).

For any  $X \subseteq U$  we define upward lower and upper approximations  $\underline{apr}^+(X)$  and  $\overline{apr}^+(X)$ , as well as downward lower and upper approximations  $\underline{apr}^-(X)$  and  $\overline{apr}^-(X)$ , as follows

$$\begin{aligned} \underline{apr}^+(X) &= \{x \in U \mid D^+(x) \subseteq X\}, \\ \overline{apr}^+(X) &= \{x \in U \mid D^-(x) \cap X \neq \emptyset\}, \\ \underline{apr}^-(X) &= \{x \in U \mid D^-(x) \subseteq X\}, \\ \overline{apr}^-(X) &= \{x \in U \mid D^+(x) \cap X \neq \emptyset\}. \end{aligned} \quad (24.52)$$

For any  $X \subseteq U$ , using cones of dominance  $D^+(x)$  and  $D^-(x)$ , we can define three upward pairwise disjoint positive, negative and boundary regions

$$\begin{aligned} \text{POS}^+(X) &= \{x \in U \mid D^+(x) \subseteq X\}, \\ \text{NEG}^+(X) &= \{x \in U \mid D^-(x) \cap X = \emptyset\}, \\ \text{BND}^+(X) &= \{x \in U \mid D^+(x) \not\subseteq X \\ &\quad \text{and } D^-(x) \cap X \neq \emptyset\}. \end{aligned} \quad (24.53)$$

Analogously, for any  $X \subseteq U$ , we can define three downward pairwise disjoint positive, negative, and boundary regions

$$\begin{aligned} \text{POS}^-(X) &= \{x \in U \mid D^-(x) \subseteq X\}, \\ \text{NEG}^-(X) &= \{x \in U \mid D^+(x) \cap X = \emptyset\}, \\ \text{BND}^-(X) &= \{x \in U \mid D^-(x) \not\subseteq X \\ &\quad \text{and } D^+(x) \cap X \neq \emptyset\}. \end{aligned} \quad (24.54)$$

Observe that the following complementarity properties hold: For all  $X \subseteq U$

$$\begin{aligned} \text{POS}^+(X) &= \text{NEG}^-(U-X), \\ \text{POS}^-(X) &= \text{NEG}^+(U-X), \\ \text{BND}^+(X) &= \text{BND}^-(U-X), \\ \text{BND}^-(X) &= \text{BND}^+(U-X). \end{aligned} \quad (24.55)$$

For all  $X \subseteq U$ , the pair of upward approximations and three upward regions determine each others as follows

$$\begin{aligned} \text{POS}^+(X) &= \underline{\text{apr}}^+(X), \\ \text{NEG}^+(X) &= (\overline{\text{apr}}^+(X))^c, \\ \text{BND}^+(X) &= \overline{\text{apr}}^+(X) - \underline{\text{apr}}^+(X), \end{aligned} \quad (24.56)$$

and

$$\begin{aligned} \underline{\text{apr}}^+(X) &= \text{POS}^+(X), \\ \overline{\text{apr}}^+(X) &= \text{POS}^+(X) \cup \text{BND}(X). \end{aligned} \quad (24.57)$$

Analogously, for all  $X \subseteq U$ , the pair of downward approximations and three downward regions determine each others as follows

$$\begin{aligned} \text{POS}^-(X) &= \underline{\text{apr}}^-(X), \\ \text{NEG}^-(X) &= (\overline{\text{apr}}^-(X))^c, \\ \text{BND}^-(X) &= \overline{\text{apr}}^-(X) - \underline{\text{apr}}^-(X), \end{aligned} \quad (24.58)$$

and

$$\begin{aligned} \underline{\text{apr}}^-(X) &= \text{POS}^-(X), \\ \overline{\text{apr}}^-(X) &= \text{POS}^-(X) \cup \text{BND}(X). \end{aligned} \quad (24.59)$$

## 24.7 A Basic Model of Dominance-Based Probabilistic Rough Sets

DRSA considers only qualitative relationship between positive and negative cones  $D^+(x)$  and  $D^-(x)$ , and a set  $X$ , namely, a positive or negative cone is a subset of the set or has a nonempty intersection with the set. This qualitative nature becomes clearer with a probabilistic interpretation. Suppose  $\Pr(X|D^+(x))$  denotes the conditional probability that an object is in  $X$ , given that the object is in  $D^+(x)$ , as well as  $\Pr(X|D^-(x))$  denotes the conditional probability that an object is in  $X$ , given that the object is in  $D^-(x)$ . The conditions for defining rough set three upward regions can be equivalently expressed as

$$\begin{aligned} D^+(x) \subseteq X &\iff \Pr(X|D^+(x)) \geq 1; \\ D^-(x) \cap X = \emptyset &\iff \Pr(X|D^-(x)) \leq 0; \\ D^+(x) \not\subseteq X \wedge D^-(x) \cap X \neq \emptyset &\iff \Pr(X|D^+(x)) < 1 \\ &\quad \wedge \Pr(X|D^-(x)) > 0. \end{aligned} \quad (24.60)$$

Analogously, the conditions for defining rough set three upward regions can be equivalently expressed

as

$$\begin{aligned} D^-(x) \subseteq X &\iff \Pr(X|D^-(x)) \geq 1; \\ D^+(x) \cap X = \emptyset &\iff \Pr(X|D^+(x)) \leq 0; \\ D^-(x) \not\subseteq X \wedge D^+(x) \cap X \neq \emptyset &\iff \Pr(X|D^-(x)) < 1 \wedge \Pr(X|D^+(x)) > 0. \end{aligned} \quad (24.61)$$

By those conditions, DRSA upward and downward three regions can be equivalently expressed as

$$\begin{aligned} \text{POS}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) \geq 1\}, \\ \text{NEG}^+(X) &= \{x \in U \mid \Pr(X|D^-(x)) \leq 0\}, \\ \text{BND}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) < 1 \\ &\quad \wedge \Pr(X|D^-(x)) > 0\}, \\ \text{POS}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) \geq 1\}, \\ \text{NEG}^-(X) &= \{x \in U \mid \Pr(X|D^+(x)) \leq 0\}, \\ \text{BND}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) < 1 \\ &\quad \wedge \Pr(X|D^+(x)) > 0\}. \end{aligned} \quad (24.62)$$

Observe that DRSA approximations use only the two extreme values, i.e., 1 and 0, of probability.

It is natural to generalize DRSA approximations by replacing 1 and 0 with some other values in the unit interval  $[0, 1]$ . Given a pair of thresholds  $\alpha, \beta$  with  $0 \leq \beta < \alpha \leq 1$ , the main results of probabilistic DRSA are the  $(\alpha, \beta)$ -probabilistic regions defined by

$$\begin{aligned} \text{POS}_{(\alpha, \beta)}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) \geq \alpha\}, \\ \text{NEG}_{(\alpha, \beta)}^+(X) &= \{x \in U \mid \Pr(X|D^-(x)) \leq \beta\}, \\ \text{BND}_{(\alpha, \beta)}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) < \alpha \\ &\quad \wedge \Pr(X|D^-(x)) > \beta\}, \\ \text{POS}_{(\alpha, \beta)}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) \geq \alpha\}, \\ \text{NEG}_{(\alpha, \beta)}^-(X) &= \{x \in U \mid \Pr(X|D^+(x)) \leq \beta\}, \\ \text{BND}_{(\alpha, \beta)}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) < \alpha \\ &\quad \wedge \Pr(X|D^+(x)) > \beta\}. \end{aligned} \quad (24.63)$$

The DRSA rough set model is a special case in which  $\alpha = 1$  and  $\beta = 0$ . In the case when  $0 < \beta = \alpha < 1$ , the three regions are given by

$$\begin{aligned} \text{POS}_{(\alpha, \alpha)}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) \geq \alpha\}, \\ \text{NEG}_{(\alpha, \alpha)}^+(X) &= \{x \in U \mid \Pr(X|D^-(x)) \leq \alpha\}, \\ \text{BND}_{(\alpha, \alpha)}^+(X) &= \{x \in U \mid \Pr(X|D^+(x)) < \alpha \\ &\quad \wedge \Pr(X|D^-(x)) > \alpha\}, \\ \text{POS}_{(\alpha, \alpha)}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) \geq \alpha\}, \\ \text{NEG}_{(\alpha, \alpha)}^-(X) &= \{x \in U \mid \Pr(X|D^+(x)) \leq \alpha\}, \\ \text{BND}_{(\alpha, \alpha)}^-(X) &= \{x \in U \mid \Pr(X|D^-(x)) < \alpha \\ &\quad \wedge \Pr(X|D^+(x)) > \alpha\}. \end{aligned} \quad (24.64)$$

## 24.8 Variants of Probabilistic Dominance-Based Rough Set Approach

Several models generalizing dominance-based rough sets by incorporating probabilistic information can be considered.

### 24.8.1 Variable Consistency Dominance-Based Rough Sets

In a first version of variable consistency dominance-based rough sets [24.23] (see also [24.24]) the standard set inclusions  $D^+(x) \subseteq X$  and  $D^-(x) \subseteq X$  can be generalized into graded set inclusion  $s^+(D^+(x), X)$  and  $s^-(D^-(x), X)$  called measure of the relative upward and downward degree of misclassification of  $D^+(x)$  and  $D^-(x)$  with respect to  $X$ , respectively. A particular upward and downward measure is given by

$$\begin{aligned} s^+(D^+(x), X) &= 1 - \frac{|D^+(x) \cap X|}{|D^+(x)|}, \\ s^-(D^-(x), X) &= 1 - \frac{|D^-(x) \cap X|}{|D^-(x)|}. \end{aligned} \quad (24.65)$$

By introducing a threshold  $0 \leq z < 0.5$ , one can define three upward and downward regions as follows

$$\begin{aligned} \text{VPOS}_z^+(X) &= \{x \in U \mid s^+(D^+(x), X) \leq z\}, \\ \text{VNEG}_z^+(X) &= \{x \in U \mid s^-(D^-(x), X) \geq 1-z\}, \\ \text{VBND}_z^+(X) &= \{x \in U \mid s^+(D^+(x), X) > z \\ &\quad \wedge s^-(D^-(x), X) < 1-z\}, \\ \text{VPOS}_z^-(X) &= \{x \in U \mid s^-(D^-(x), X) \leq z\}, \\ \text{VNEG}_z^-(X) &= \{x \in U \mid s^+(D^+(x), X) \geq 1-z\}, \\ \text{VBND}_z^-(X) &= \{x \in U \mid s^-(D^-(x), X) > z \\ &\quad \wedge s^+(D^+(x), X) < 1-z\}. \end{aligned} \quad (24.66)$$

A more generalized version using a pair of thresholds can be defined as follows: for  $0 \leq l < u \leq 1$ ,

$$\begin{aligned} \text{VPOS}_{(l,u)}^+(X) &= \{x \in U \mid s^+(D^+(x), X) \leq l\}, \\ \text{VNEG}_{(l,u)}^+(X) &= \{x \in U \mid s^-(D^-(x), X) \geq u\}, \\ \text{VBND}_{(l,u)}^+(X) &= \{x \in U \mid s^+(D^+(x), X) > l \\ &\quad \wedge s^-(D^-(x), X) < u\}, \\ \text{VPOS}_{(l,u)}^-(X) &= \{x \in U \mid s^-(D^-(x), X) \leq l\}, \\ \text{VNEG}_{(l,u)}^-(X) &= \{x \in U \mid s^+(D^+(x), X) \geq u\}, \\ \text{VBND}_{(l,u)}^-(X) &= \{x \in U \mid s^-(D^-(x), X) > l \\ &\quad \wedge s^+(D^+(x), X) < u\}. \end{aligned} \quad (24.67)$$

The one-threshold model may be considered as a special case of the two-threshold model with  $l = z$  and  $u = 1 - z$ .

One may interpret the ratio in (24.65) as an estimation of the conditional probability  $Pr(X|D^+(x))$  and  $Pr(X|D^-(x))$ , namely,

$$\begin{aligned}s^+(Pr(X|D^+(x)), X) &= 1 - \frac{|D^+(x) \cap X|}{|D^+(x)|} \\&= 1 - Pr(X|D^+(x)) , \\s^-(Pr(X|D^-(x)), X) &= 1 - \frac{|D^-(x) \cap X|}{|D^-(x)|} \\&= 1 - Pr(X|D^-(x)) .\end{aligned}\quad (24.68)$$

By setting  $\alpha = 1 - l$  and  $\beta = 1 - u$ , we immediately get

$$\begin{aligned}\text{POS}_{(1-l,1-u)}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) \geq 1 - l\} \\&= \{x \in U \mid s^+(D^+(x), X) \leq l\} \\&= \text{VPOS}_{(l,u)}^+(X) ,\end{aligned}$$

$$\begin{aligned}\text{NEG}_{(1-l,1-u)}^+(X) &= \{x \in U \mid Pr(X|D^-(x)) \leq 1 - u\} \\&= \{x \in U \mid s^-(D^-(x), X) \geq u\} \\&= \text{VNEG}_{(l,u)}^+(X) ,\end{aligned}$$

$$\begin{aligned}\text{BND}_{(1-l,1-u)}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) < 1 - l \\&\quad \wedge Pr(X|D^-(x)) > 1 - u\} \\&= \{x \in U \mid s^+(D^+(x), X) > l \\&\quad \wedge s^-(D^-(x), X) < u\} \\&= \text{VBND}_{(l,u)}^+(X) ,\end{aligned}$$

$$\begin{aligned}\text{POS}_{(1-l,1-u)}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) \geq 1 - l\} \\&= \{x \in U \mid s^-(D^-(x), X) \leq l\} \\&= \text{VPOS}_{(l,u)}^-(X) ,\end{aligned}$$

$$\begin{aligned}\text{NEG}_{(1-l,1-u)}^-(X) &= \{x \in U \mid Pr(X|D^+(x)) \leq 1 - u\} \\&= \{x \in U \mid s^+(D^+(x), X) \geq u\} \\&= \text{VNEG}_{(l,u)}^-(X) ,\end{aligned}$$

$$\begin{aligned}\text{BND}_{(1-l,1-u)}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) < 1 - l \\&\quad \wedge Pr(X|D^+(x)) > 1 - u\} \\&= \{x \in U \mid s^-(D^-(x), X) > l \\&\quad \wedge s^+(D^+(x), X) < u\} \\&= \text{VBND}_{(l,u)}^-(X) .\end{aligned}\quad (24.69)$$

## 24.8.2 Parameterized Dominance-Based Rough Sets

Parameterized rough sets based on dominance [24.24] generalize variable consistency DRSA by introducing a Bayesian confirmation measure and a pair of thresholds on the confirmation measure, in addition to a pair of thresholds on conditional probability. Let  $c^+(D^+(x), X)$  and  $c^-(D^-(x), X)$  denote a Bayesian upward and downward confirmation measure, respectively, that indicate the degree to which positive or negative cones  $D^+(x)$  and  $D^-(x)$  confirm the hypothesis  $X$ . The upward and downward Bayesian confirmation measures corresponding to those ones introduced in Sect. 24.4.3 are

$$\begin{aligned}c_d^+(D^+(x), X) &= Pr(X|D^+(x)) - Pr(X) , \\c_d^-(D^-(x), X) &= Pr(X|D^-(x)) - Pr(X) , \\c_r^+(D^+(x), X) &= \frac{Pr(X|D^+(x))}{Pr(X)} , \\c_r^-(D^-(x), X) &= \frac{Pr(X|D^-(x))}{Pr(X)} .\end{aligned}\quad (24.70)$$

Given a pair of thresholds  $(s, t)$  with  $t < s$ , three  $(\alpha, \beta, s, t)$ -parameterized regions can be defined as follows

$$\begin{aligned}\text{PPOS}_{(\alpha,\beta,s,t)}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) \geq \alpha \\&\quad \wedge c^+(D^+(x), X) \geq s\} ,\end{aligned}$$

$$\begin{aligned}\text{PNEG}_{(\alpha,\beta,s,t)}^+(X) &= \{x \in U \mid Pr(X|D^-(x)) \leq \beta \\&\quad \wedge c^-(D^-(x), X) \leq t\} ,\end{aligned}$$

$$\begin{aligned}\text{PBND}_{(\alpha,\beta,s,t)}^+(X) &= \{x \in U \mid (Pr(X|D^+(x)) < \alpha \\&\quad \vee c^+(D^+(x), X) < s) \\&\quad \wedge (Pr(X|D^-(x)) > \beta \\&\quad \vee c^-(D^-(x), X) > t)\} ,\end{aligned}$$

$$\begin{aligned}\text{PPOS}_{(\alpha,\beta,s,t)}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) \geq \alpha \\&\quad \wedge c^-(D^-(x), X) \geq s\} ,\end{aligned}$$

$$\begin{aligned}\text{PNEG}_{(\alpha,\beta,s,t)}^-(X) &= \{x \in U \mid Pr(X|D^+(x)) \leq \beta \\&\quad \wedge c^+(D^+(x), X) \leq t\} ,\end{aligned}$$

$$\begin{aligned}\text{PBND}_{(\alpha,\beta,s,t)}^-(X) &= \{x \in U \mid (Pr(X|D^-(x)) < \alpha \\&\quad \vee c^-(D^-(x), X) < s) \\&\quad \wedge (Pr(X|D^+(x)) > \beta \\&\quad \vee c^+(D^+(x), X) > t)\} .\end{aligned}\quad (24.71)$$

Let us remember that a family of consistency measures, called gain-type consistency measures, and

inconsistency measures, called cost-type consistency measures, larger than confirmation measures, and the related dominance-based rough sets have been considered in [24.24]. For any  $x \in U$  and  $X \subseteq U$ , for a consistency measure  $m_c(x, X)$ ,  $x$  can be assigned to the positive region of  $X$  if  $m_c(x, X) \geq \alpha$ , with  $\alpha$  being a proper threshold, while for an inconsistency measure  $m_{ic}(x, X)$ ,  $x$  can be assigned to the positive region of  $X$  if  $m_{ic}(x, X) \leq \alpha$ . A consistency measure  $m_c(x, X)$  or an inconsistency measure  $m_{ic}(x, X)$  are monotonic (Sect. 22.3.2 in Chap. 22) if they do not deteriorate when:

- (m1) The set of attributes is growing,
- (m2) The set of objects is growing,
- (m3)  $x$  improves its evaluation, so that it dominates more objects.

Among the considered consistency and inconsistency measures, one that can be considered very interesting because it enjoys all the considered monotony properties (m1)–(m3) while maintaining a reasonably easy formulation is the inconsistency measures  $\varepsilon'$  which is expressed as follows:

- In the case of dominance-based upward approximation

$$\varepsilon'^+(x, X) = \frac{|D^+(x) \cap (U - X)|}{|X|}$$

- In the case of dominance-based downward approximation

$$\varepsilon'^-(x, X) = \frac{|D^-(x) \cap (U - X)|}{|X|}.$$

Observe that as explained in [24.24], consistency and inconsistency measures can be properly reformulated in order to be used in indiscernibility-based rough sets. For example, inconsistency measure  $\varepsilon'$  in case of indiscernibility-based rough sets becomes

$$\varepsilon'^+(x, X) = \frac{|[x] \cap (U - X)|}{|X|}.$$

### 24.8.3 Confirmation-Theoretic Dominance-Based Rough Sets

A separation of the parameterized model into two models within DRSA can be constructed as follows. One is the conventional probabilistic model and the other is a confirmation-theoretic model. For an upward and a downward Bayesian confirmation measure ( $c^+(D^+(x), X)$  and  $c^-(D^-(x), X)$ ), and a pair of

thresholds  $(s, t)$  with  $t < s$ , three confirmation regions are defined by

$$\begin{aligned} \text{CPOS}_{(s,t)}^+(X) &= \{x \in U \mid c^+(D^+(x), X) \geq s\}, \\ \text{CNEG}_{(s,t)}^+(X) &= \{x \in U \mid c^-(D^-(x), X) \leq t\}, \\ \text{CBND}_{(s,t)}^+(X) &= \{x \in U \mid c^+(D^+(x), X) < s \\ &\quad \wedge c^-(D^-(x), X) > t\}, \\ \text{CPOS}_{(s,t)}^-(X) &= \{x \in U \mid c^+(D^-(x), X) \geq s\}, \\ \text{CNEG}_{(s,t)}^-(X) &= \{x \in U \mid c^-(D^+(x), X) \leq t\}, \\ \text{CBND}_{(s,t)}^-(X) &= \{x \in U \mid c^-(D^-(x), X) < s \\ &\quad \wedge c^+(D^+(x), X) > t\}. \end{aligned} \quad (24.72)$$

For the case with  $s = t$ , we define

$$\begin{aligned} \text{CPOS}_{(s,s)}^+(X) &= \{x \in U \mid c^+(D^+(x), X) \geq s\}, \\ \text{CNEG}_{(s,s)}^+(X) &= \{x \in U \mid c^-(D^-(x), X) \leq s\}, \\ \text{CBND}_{(s,s)}^+(X) &= \{x \in U \mid c^+(D^+(x), X) < s \\ &\quad \wedge c^-(D^-(x), X) > s\}, \\ \text{CPOS}_{(s,s)}^-(X) &= \{x \in U \mid c^+(D^-(x), X) \geq s\}, \\ \text{CNEG}_{(s,s)}^-(X) &= \{x \in U \mid c^-(D^+(x), X) \leq s\}, \\ \text{CBND}_{(s,s)}^-(X) &= \{x \in U \mid c^-(D^-(x), X) < s \\ &\quad \wedge c^+(D^+(x), X) > s\}. \end{aligned} \quad (24.73)$$

### 24.8.4 Bayesian Dominance-Based Rough Sets

Bayesian DRSA model in which the required pair of thresholds is interpreted using a priori probability  $Pr(X)$  can be defined as an extension of the Bayesian DRSA and variable consistency Bayesian DRSA, as explained below.

For the Bayesian DRSA, the three upward and downward regions are defined by

$$\begin{aligned} \text{BPOS}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) > Pr(X)\}, \\ \text{BNEG}^+(X) &= \{x \in U \mid Pr(X|D^-(x)) < Pr(X)\}, \\ \text{BBND}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) \leq Pr(X) \\ &\quad \wedge Pr(X|D^-(x)) \geq Pr(X)\}, \\ \text{BPOS}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) > Pr(X)\}, \\ \text{BNEG}^-(X) &= \{x \in U \mid Pr(X|D^+(x)) < Pr(X)\}, \\ \text{BBND}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) \leq Pr(X) \\ &\quad \wedge Pr(X|D^+(x)) \geq Pr(X)\}. \end{aligned} \quad (24.74)$$

Bayesian dominance-based rough sets can be viewed as a special case of the decision-theoretic DRSA when  $\alpha = \beta = Pr(X)$ .

Recalling the upward and downward DRSA, Bayesian confirmation measures

$$c_d^+(D^+(x), X) = Pr(X|D^+(x)) - Pr(X)$$

and

$$c_d^-(D^-(x), X) = Pr(X|D^-(x)) - Pr(X),$$

Bayesian dominance-based rough sets can be expressed as confirmation-theoretic dominance-based rough sets as follows

$$\begin{aligned} BPOS^+(X) &= \{x \in U \mid Pr(X|D^+(x)) > Pr(X)\}, \\ &= \{x \in U \mid c_d^+(D^+(x), X) > 0\}, \end{aligned}$$

$$\begin{aligned} BNNEG^+(X) &= \{x \in U \mid Pr(X|D^-(x)) < Pr(X)\}, \\ &= \{x \in U \mid c_d^-(D^-(x), X) < 0\}, \end{aligned}$$

$$\begin{aligned} BBND(X)^+ &= \{x \in U \mid Pr(X|D^+(x)) \leq Pr(X) \\ &\quad \wedge Pr(X|D^-(x)) \geq Pr(X)\} \\ &= \{x \in U \mid c_d^+(D^+(x), X) \leq 0 \\ &\quad \wedge c_d^-(D^-(x), X) \geq 0\}, \end{aligned}$$

$$\begin{aligned} BPOS^-(X) &= \{x \in U \mid Pr(X|D^-(x)) > Pr(X)\}, \\ &= \{x \in U \mid c_d^-(D^-(x), X) > 0\}, \\ BNNEG^-(X) &= \{x \in U \mid Pr(X|D^-(x)) < Pr(X)\}, \\ &= \{x \in U \mid c_d^+(D^+(x), X) < 0\}, \\ BBND(X)^- &= \{x \in U \mid Pr(X|D^-(x)) \leq Pr(X) \\ &\quad \wedge Pr(X|D^+(x)) \geq Pr(X)\} \\ &= \{x \in U \mid c_d^-(D^-(x), X) \leq 0 \\ &\quad \wedge c_d^+(D^+(x), X) \geq 0\}. \end{aligned} \quad (24.75)$$

That is, the Bayesian rough sets are models of confirmation-theoretic rough sets characterized by the upward and downward Bayesian confirmation measures  $c_d^+$  and  $c_d^-$  with a pair of thresholds  $s = t = 0$ .

The three upward and downward regions of the variable precision Bayesian rough sets are defined as follows: for  $\epsilon \in [0, 1)$ ,

$$\begin{aligned} VBPOS_\epsilon^+(X) &= \{x \in U \mid Pr(X|[x]) \\ &\geq 1 - \epsilon(1 - Pr(X))\}, \\ VBNNEG_\epsilon(X) &= \{x \in U \mid Pr(X|[x]) \leq \epsilon Pr(X)\}, \\ VBBND_\epsilon(X) &= \{x \in U \mid \epsilon Pr(X) < Pr(X|[x]) \\ &< 1 - \epsilon(1 - Pr(X))\}. \end{aligned} \quad (24.76)$$

## 24.9 Three Fundamental Issues of Probabilistic Dominance-Based Rough Sets

Also for probabilistic dominance-based rough sets, one must consider the three fundamental issues of interpretation and determination of the required pair of thresholds, estimation of the required conditional probabilities, and interpretation and applications of three probabilistic regions.

These three issues are considered in this section with respect to dominance-based rough sets.

### 24.9.1 Decision-Theoretic Dominance-Based Rough Set Model: Determining the Thresholds

Following [24.75], a decision-theoretic model formulates the construction of dominance-based rough set approximations as a Bayesian decision problem with a set of two states  $\Omega = \{X, X^c\}$ , indicating that an element is in  $X$  and not in  $X$ , respectively. In the case of up-

ward dominance-based rough sets, we consider a set of three actions  $\mathcal{A}^+ = \{a_p^+, a_B^+, a_N^+\}$ , with  $a_p^+$  deciding  $x \in POS^+(X)$ ,  $a_B^+$  deciding  $x \in BND^+(X)$ , and  $a_N^+$  deciding  $x \in NEG^+(X)$ , respectively. In case of downward dominance-based rough sets, we consider a set of three actions  $\mathcal{A}^- = \{a_p^-, a_B^-, a_N^-\}$ , with  $a_p^-$  deciding  $x \in POS^-(X)$ ,  $a_B^-$  deciding  $x \in BND^-(X)$ , and  $a_N^-$  deciding  $x \in NEG^-(X)$ , respectively. The losses regarding the actions for different states are given by the  $6 \times 2$  matrix

	$X(P)$	$X^c(N)$
$a_p^+$	$\lambda_{PP}^+$	$\lambda_{PN}^+$
$a_B^+$	$\lambda_{BP}^+$	$\lambda_{BN}^+$
$a_N^+$	$\lambda_{NP}^+$	$\lambda_{NN}^+$
$a_p^-$	$\lambda_{PP}^-$	$\lambda_{PN}^-$
$a_B^-$	$\lambda_{BP}^-$	$\lambda_{BN}^-$
$a_N^-$	$\lambda_{NP}^-$	$\lambda_{NN}^-$

In the matrix:

- In the case that upward dominance-based rough approximations are considered,  $\lambda_{PP}^+$ ,  $\lambda_{BP}^+$ , and  $\lambda_{NP}^+$  denote the losses incurred for taking actions  $a_P^+$ ,  $a_B^+$ , and  $a_N^+$ , respectively, when an object belongs to  $X$ , and  $\lambda_{PN}^+$ ,  $\lambda_{BV}^+$  and  $\lambda_{NN}^+$  denote the losses incurred for taking the same actions when the object does not belong to  $X$ ,
- In the case that downward dominance-based rough approximations are considered,  $\lambda_{PP}^-$ ,  $\lambda_{BP}^-$ , and  $\lambda_{NP}^-$  denote the losses incurred for taking actions  $a_P^-$ ,  $a_B^-$ , and  $a_N^-$ , respectively, when an object belongs to  $X$ , and  $\lambda_{PN}^-$ ,  $\lambda_{BV}^-$  and  $\lambda_{NN}^-$  denote the losses incurred for taking the same actions when the object does not belong to  $X$ .

In the case that upward dominance-based rough approximations are considered, the expected losses associated with taking different actions for objects in  $D^+(x)$  can be expressed as

$$\begin{aligned} R(a_P^+ | D^+(x)) &= \lambda_{PP}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{PN}^+ Pr(X^c|D^+(x)), \\ R(a_B^+ | D^+(x)) &= \lambda_{BP}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{BV}^+ Pr(X^c|D^+(x)), \\ R(a_N^+ | D^+(x)) &= \lambda_{NP}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{NN}^+ Pr(X^c|D^+(x)). \end{aligned} \quad (24.77)$$

In the case that downward dominance-based rough approximations are considered, the expected losses associated with taking different actions for objects in  $D^-(x)$  can be expressed as

$$\begin{aligned} R(a_P^- | D^-(x)) &= \lambda_{PP}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{PN}^- Pr(X^c|D^-(x)), \\ R(a_B^- | D^-(x)) &= \lambda_{BP}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{BV}^- Pr(X^c|D^-(x)), \\ R(a_N^- | D^-(x)) &= \lambda_{NP}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{NN}^- Pr(X^c|D^-(x)). \end{aligned} \quad (24.78)$$

In the case that upward dominance-based rough approximations are considered, the Bayesian decision procedure suggests the following minimum-risk deci-

sion rules

- (P<sup>+</sup>) If  $R(a_P^+ | D^+(x)) \leq R(a_B^+ | D^+(x))$   
and  $R(a_P^+ | [x]) \leq R(a_N^+ | D^+(x))$ ,  
decide  $x \in \text{POS}^+(X)$ ;
- (B<sup>+</sup>) If  $R(a_B^+ | D^+(x)) \leq R(a_P^+ | D^+(x))$   
and  $R(a_B^+ | [x]) \leq R(a_N^+ | D^+(x))$ ,  
decide  $x \in \text{BND}^+(X)$ ;
- (N<sup>+</sup>) If  $R(a_N^+ | D^+(x)) \leq R(a_P^+ | D^+(x))$   
and  $R(a_N^+ | [x]) \leq R(a_B^+ | D^+(x))$ ,  
decide  $x \in \text{NEG}^+(X)$ .

In the case that downward dominance-based rough approximations are considered, the Bayesian decision procedure suggests the following minimum-risk decision rules

- (P<sup>-</sup>) If  $R(a_P^- | D^-(x)) \leq R(a_B^- | D^-(x))$   
and  $R(a_P^- | [x]) \leq R(a_N^- | D^-(x))$ ,  
decide  $x \in \text{POS}^-(X)$ ;
- (B<sup>-</sup>) If  $R(a_B^- | D^-(x)) \leq R(a_P^- | D^-(x))$   
and  $R(a_B^- | [x]) \leq R(a_N^- | D^-(x))$ ,  
decide  $x \in \text{BND}^-(X)$ ;
- (N<sup>-</sup>) If  $R(a_N^- | D^-(x)) \leq R(a_P^- | D^-(x))$   
and  $R(a_N^- | [x]) \leq R(a_B^- | D^-(x))$ ,  
decide  $x \in \text{NEG}^-(X)$ .

Also in the case that dominance-based rough approximations are considered, when two or three actions have the same risk, one can use the same ordering for breaking a tie used in case indiscernibility-based rough approximations are used:  $a_P^+, a_N^+, a_B^+$  in case upward rough approximations are considered, and  $a_P^-, a_N^-, a_B^-$  in case downward rough approximations are considered.

Analogously to Sect. 24.5.1, let us consider the special class of loss functions with

$$\begin{aligned} (\text{c0}^+). \quad &\lambda_{PP}^+ \leq \lambda_{BP}^+ < \lambda_{NP}^+, \quad \lambda_{NN}^+ \leq \lambda_{BV}^+ < \lambda_{PN}^+, \\ (\text{c0}^-). \quad &\lambda_{PP}^- \leq \lambda_{BP}^- < \lambda_{NP}^-, \quad \lambda_{NN}^- \leq \lambda_{BV}^- < \lambda_{PN}^-. \end{aligned} \quad (24.79)$$

With the conditions (c0<sup>+</sup>) and (c0<sup>-</sup>), and the equations

$$Pr(X|D^+(x)) + Pr(X^c|D^+(x)) = 1$$

and

$$Pr(X|D^-(x)) + Pr(X^c|D^-(x)) = 1,$$

we can express the decision rules  $(P^+) \rightarrow (N^+)$  and  $(P^-) \rightarrow (N^-)$  in the following simplified form

- $(P^+)$  If  $Pr(X|D^+(x)) \geq \alpha^+$   
and  $Pr(X|D^+(x)) \geq \gamma^+$ ,  
decide  $x \in \text{POS}^+(X)$ ;
- $(B^+)$  If  $Pr(X|D^+(x)) \leq \alpha^+$   
and  $Pr(X|D^+(x)) \geq \beta^+$ ,  
decide  $x \in \text{BND}^+(X)$ ;
- $(N^+)$  If  $Pr(X|D^+(x)) \leq \beta^+$   
and  $Pr(X|D^+(x)) \leq \gamma^+$ ,  
decide  $x \in \text{NEG}^+(X)$ ;
- $(P^-)$  If  $Pr(X|D^-(x)) \geq \alpha^-$   
and  $Pr(X|D^-(x)) \geq \gamma^-$ ,  
decide  $x \in \text{POS}^-(X)$ ;
- $(B^-)$  If  $Pr(X|D^-(x)) \leq \alpha^-$   
and  $Pr(X|D^-(x)) \geq \beta^-$ ,  
decide  $x \in \text{BND}^-(X)$ ;
- $(N^-)$  If  $Pr(X|D^-(x)) \leq \beta^-$   
and  $Pr(X|D^-(x)) \leq \gamma^-$ ,  
decide  $x \in \text{NEG}^-(X)$ .

where

$$\begin{aligned}\alpha^+ &= \frac{(\lambda_{PN}^+ - \lambda_{BN}^+)}{(\lambda_{PN}^+ - \lambda_{BN}^+) + (\lambda_{BP}^+ - \lambda_{PP}^+)} , \\ \beta^+ &= \frac{(\lambda_{BN}^+ - \lambda_{NN}^+)}{(\lambda_{BN}^+ - \lambda_{NN}^+) + (\lambda_{NP}^+ - \lambda_{BP}^+)} , \\ \gamma^+ &= \frac{(\lambda_{PN}^+ - \lambda_{NN}^+)}{(\lambda_{PN}^+ - \lambda_{NN}^+) + (\lambda_{NP}^+ - \lambda_{PP}^+)} , \\ \alpha^- &= \frac{(\lambda_{PN}^- - \lambda_{BN}^-)}{(\lambda_{PN}^- - \lambda_{BN}^-) + (\lambda_{BP}^- - \lambda_{PP}^-)} , \\ \beta^- &= \frac{(\lambda_{BN}^- - \lambda_{NN}^-)}{(\lambda_{BN}^- - \lambda_{NN}^-) + (\lambda_{NP}^- - \lambda_{BP}^-)} , \\ \gamma^- &= \frac{(\lambda_{PN}^- - \lambda_{NN}^-)}{(\lambda_{PN}^- - \lambda_{NN}^-) + (\lambda_{NP}^- - \lambda_{PP}^-)} .\end{aligned}\quad (24.80)$$

By setting  $\alpha^+ > \beta^+$  and  $\alpha^- > \beta^-$ , we obtain that  $1 \geq \alpha^+ > \gamma^+ > \beta^+ \geq 0$  and  $1 \geq \alpha^- > \gamma^- > \beta^- \geq 0$ , that, after tie breaking, we give the following simplified rules

- $(P^+)$  If  $Pr(X|D^+(x)) \geq \alpha^+$ ,  
decide  $x \in \text{POS}^+(X)$ ;
- $(B^+)$  If  $\beta^+ < Pr(X|D^+(x)) < \alpha^+$ ,  
decide  $x \in \text{BND}^+(X)$ ;
- $(N^+)$  If  $Pr(X|D^+(x)) \leq \beta^+$ ,  
decide  $x \in \text{NEG}^+(X)$ ;
- $(P^-)$  If  $Pr(X|D^-(x)) \geq \alpha^-$ ,  
decide  $x \in \text{POS}^-(X)$ ;
- $(B^-)$  If  $\beta^- < Pr(X|D^-(x)) < \alpha^-$ ,  
decide  $x \in \text{BND}^-(X)$ ;
- $(N^-)$  If  $Pr(X|D^-(x)) \leq \beta^-$ ,  
decide  $x \in \text{NEG}^-(X)$ ,

so that the parameters  $\gamma^+$  and  $\gamma^-$  are no longer needed. Each object can be put into one and only one upward region, and one and only one downward region by using rules  $(P^+)$ ,  $(B^+)$  and  $(N^+)$ , and  $(P^-)$ ,  $(B^-)$  and  $(N^-)$ , respectively. The upward  $(\alpha^+, \beta^+)$ -probabilistic positive, negative, and boundary regions and downward  $(\alpha^-, \beta^-)$ -probabilistic positive, negative, and boundary regions are given, respectively, by

$$\begin{aligned}\text{POS}_{(\alpha^+, \beta^+)}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) \geq \alpha^+\} , \\ \text{BND}_{(\alpha^+, \beta^+)}^+(X) &= \{x \in U \mid \beta^+ < Pr(X|D^+(x)) \\ &\quad < \alpha^+\} , \\ \text{NEG}_{(\alpha^+, \beta^+)}^+(X) &= \{x \in U \mid Pr(X|D^+(x)) \leq \beta^+\} , \\ \text{POS}_{(\alpha^-, \beta^-)}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) \geq \alpha^-\} , \\ \text{BND}_{(\alpha^-, \beta^-)}^-(X) &= \{x \in U \mid \beta^- < Pr(X|D^-(x)) \\ &\quad < \alpha^-\} , \\ \text{NEG}_{(\alpha^-, \beta^-)}^-(X) &= \{x \in U \mid Pr(X|D^-(x)) \leq \beta^-\} .\end{aligned}\quad (24.81)$$

An alternative decision theoretic model for dominance-based rough sets taking into account in the cost function the conditional probabilities  $P(X|D^+(x))$  and  $P(X^c|D^-(x))$  for upward rough approximations, as well as the conditional probabilities  $P(X|D^-(x))$  and  $P(X^c|D^+(x))$  for downward rough approximations, can be defined as follows.

In the case that upward dominance-based rough approximations are considered, the expected losses associated with taking different actions for objects in

$D^+(x)$  can be expressed as

$$\begin{aligned} R(a_P^+|D^+(x), D^-(x)) &= \lambda_{pp}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{pn}^+ Pr(X^c|D^-(x)), \\ R(a_B^+|D^+(x), D^-(x)) &= \lambda_{bp}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{bv}^+ Pr(X^c|D^-(x)), \\ R(a_N^+|D^+(x), D^-(x)) &= \lambda_{np}^+ Pr(X|D^+(x)) \\ &\quad + \lambda_{nn}^+ Pr(X^c|D^-(x)). \end{aligned} \tag{24.82}$$

In the case that downward dominance-based rough approximations are considered, the expected losses associated with taking different actions for objects in  $D^-(x)$  can be expressed as

$$\begin{aligned} R(a_P^-|D^+(x), D^-(x)) &= \lambda_{pp}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{pn}^- Pr(X^c|D^+(x)), \\ R(a_B^-|D^+(x), D^-(x)) &= \lambda_{bp}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{bv}^- Pr(X^c|D^+(x)), \\ R(a_N^-|D^+(x), D^-(x)) &= \lambda_{np}^- Pr(X|D^-(x)) \\ &\quad + \lambda_{nn}^- Pr(X^c|D^+(x)). \end{aligned} \tag{24.83}$$

### 24.9.2 Stochastic Dominance-Based Rough Set Approach: Estimating the Conditional Probability

Naive Bayesian rough set model presented for rough sets based on indiscernibility in Sect. 24.5.2 can be extended quite straightforwardly to rough sets based on dominance. Thus, in this section, we present a different approach to estimate probabilities for rough approximations: stochastic rough set approach [24.25] (see also Sect. 22.3.3 in Chap. 22). It can be applied also to rough sets based on indiscernibility, but here we present this approach taking into consideration rough sets based on dominance. In the following, we shall consider upward dominance-based approximations of a given  $X \subseteq U$ . However, the same approach can be used for downward dominance-based approximations. From a probabilistic point of view, the assignment of object  $x$  to  $X \subseteq U$  can be made with probability  $Pr(X|D^+(x))$  and  $Pr(X|D^-(x))$ . This probability is supposed to satisfy the usual axioms of probability

$$Pr(U|D^+(x)) = 1,$$

$$Pr(U-X|D^+(x)) = 1 - Pr(X|D^+(x)),$$

$$Pr(U|D^-(x)) = 1,$$

$$Pr(U-X|D^-(x)) = 1 - Pr(X|D^-(x)).$$

Moreover, this probability has to satisfy an axiom related to the choice of the rough upward approximation, i.e., the positive monotonic relationships one expects between membership in  $X \subseteq U$  and possession of the properties related to attributes from  $AT$ , i.e., the dominance relation  $\gtrsim$ : for any  $x, y \in U$  such that  $x \gtrsim y$

- (i)  $Pr(X|D^+(x)) \geq Pr(X|D^+(y))$ ,
- (ii)  $Pr(U-X|D^-(x)) \leq Pr(U-X|D^-(y))$ .

Condition (i) says that if objects  $x$  possesses properties related to attributes from  $AT$  at least as object  $y$ , i.e.,  $x \gtrsim y$ , then the probability that  $x$  belongs to  $X$  has to be not smaller than the probability that  $y$  belongs to  $X$ . Analogously, Condition (ii) says that since  $x \gtrsim y$ , then the probability that  $x$  does not belong to  $X$  should not be greater than the probability that  $y$  does not belong to  $X$ . Observe that (ii) can be written also as

$$(ii) Pr(X|D^-(x)) \geq Pr(X|D^-(y)).$$

These probabilities are unknown but can be estimated from data. For each  $X \subseteq U$ , we have a binary problem of estimating the conditional probabilities  $Pr(X|D^+(x)) = 1 - Pr(U-X|D^+(x))$  and the conditional probabilities  $Pr(X|D^-(x)) = 1 - Pr(U-X|D^-(x))$ . It can be solved by *isotonic regression* [24.25]. For  $X \subseteq U$  and for any  $x \in U$ , let  $y(x, X) = 1$  if  $x \in X$ , otherwise  $y(x, X) = 0$ . Then one can choose estimates  $Pr^*(X|D^+(x))$  and  $Pr^*(X|D^-(x))$  with  $Pr^*(X|D^+(x))$  and  $Pr^*(X|D^-(x))$  which minimize the squared distance to the class assignment  $y(x, X)$ , subject to the monotonicity constraints related to the dominance relation  $\gtrsim$  on the attributes from  $AT$  (see also Sect. 22.3.3 in Chap. 22)

Minimize

$$\sum_{x \in U} (y(x, X) - Pr(X|D^+(x)))^2$$

$$+ (y(x, X) - Pr(X|D^-(x)))^2$$

subject to

$$Pr(X|D^+(x)) \geq Pr(X|D^+(z)) \text{ and}$$

$$Pr(X|D^-(x)) \geq Pr(X|D^-(z)) \text{ if } x \gtrsim z,$$

for all  $x, z \in U$ .

Then, stochastic  $\alpha$ -lower approximations of  $X \subseteq U$  can be defined as

$$\begin{aligned} P^\alpha(X) &= \{x \in U : Pr(X|D^+(x)) \geq \alpha\}, \\ P^\alpha(U-X) &= \{x \in U : Pr(U-X|D^-(x)) \geq \alpha\}. \end{aligned}$$

Replacing the unknown probabilities

$$Pr(X|D^+(x))$$

and

$$Pr(U-X|D^-(x))$$

by their estimates

$$Pr^*(X|D^+(x))$$

and

$$Pr^*(U-X|D^-(x))$$

obtained from isotonic regression, we get

$$\begin{aligned} P^\alpha(X) &= \left\{x \in U : Pr^*(X|D^+(x)) \geq \alpha\right\}, \\ P^\alpha(U-X) &= \left\{x \in U : Pr^*(U-X|D^-(x)) \geq \alpha\right\}, \end{aligned}$$

where parameter  $\alpha \in [0.5, 1]$  controls the allowed amount of inconsistency.

Solving isotonic regression requires  $O(|U|^4)$  time, but a good heuristic needs only  $O(|U|^2)$ .

In fact, as shown in [24.25] and recalled in Sect. 22.3.3 in Chap. 22, we do not really need to know the probability estimates to obtain stochastic lower approximations. We only need to know for which object  $x \in U$ ,  $Pr^*(X|D^+(x)) \geq \alpha$  and for which  $x \in U$ ,  $Pr^*(U-X|D^-(x)) \geq \alpha$  (i.e.,  $Pr^*(X|D^-(x)) \leq 1 - \alpha$ ). This can be found by solving a linear programming (reassignment) problem.

As before,  $y(x, X) = 1$  if  $x \in X$ , otherwise  $y(x, X) = 0$ . Let  $d(x, X)$  be the decision variable which determines a new class assignment for object  $x$ . Then, reassign objects to  $X$  if  $d^*(x, X) = 1$ , and to  $U-X$  if  $d^*(x, X) = 0$ , such that the new class assignments are consistent with the dominance principle, where  $d^*(x, X)$  results from solving the following linear programming problem

$$\text{Minimize } \sum_{x \in U} w_{y(x, X)} |y(x, X) - d(x, X)|$$

subject to  $d(x, X) \geq d(z, X)$  if  $x \succsim z$   
for all  $x, z \in U$

where  $w_1$  and  $w_0$  are arbitrary positive weights.

Due to unimodularity of the constraint matrix, the optimal solution of this linear programming problem is always integer, i.e.,  $d^*(x, X) \in \{0, 1\}$ . For all objects consistent with the dominance principle,  $d^*(x, X) = y(x, X)$ . If we set  $w_0 = \alpha$  and  $w_1 = \alpha - 1$ , then the optimal solution  $d^*(x, X)$  satisfies:  $d^*(x, X) = 1 \Leftrightarrow Pr^*(X|D^+(x)) \geq \alpha$ . If we set  $w_0 = 1 - \alpha$  and  $w_1 = \alpha$ , then the optimal solution  $d^*(x, X)$  satisfies:  $d^*(x, X) = 0 \Leftrightarrow Pr^*(X|D^-(x)) \leq 1 - \alpha$ .

Solving the reassignment problem twice, we can obtain the lower approximations  $P^\alpha(X)$ ,  $P^\alpha(U-X)$ , without knowing the probability estimates.

### 24.9.3 Three-Way Decisions: Interpreting the Three Regions in the Case of Dominance-Based Rough Sets

In this section, we present an interpretation of dominance-based rough set three regions taking into consideration the framework of three-way decisions.

In an information table, with respect to a subset of attributes  $A \subseteq AT$ , an object  $x$  induces logic formulae

$$\bigwedge_{a \in A} I_a(x) \succsim_a v_a, \quad (24.84)$$

$$\bigwedge_{a \in A} v_a \succsim_a I_a(x), \quad (24.85)$$

where  $I_a(x), v_a \in V_a$  and

- The atomic formula  $v_a \succsim_a I_a(x)$  indicates that object  $x$  taking value  $I_a(x)$  on attribute  $a$  possess a property related to  $a$  not more than any object  $y$  taking value  $I_a(y) = v_a$  on attribute  $a$ .
- The atomic formula  $I_a(x) \succsim_a v_a$  indicates that object  $x$  taking value  $I_a(x)$  on attribute  $a$  possess a property related to  $a$  not less than any object  $y$  taking value  $I_a(y) = v_a$  on attribute  $a$ .

Thus, an object  $y$  satisfies the formula

$$\bigwedge_{a \in A} I_a(x) \succsim_a v_a, \text{ if } I_a(y) \succsim v_a \text{ for all } a \in A,$$

that is,

$$\left( y \models \bigwedge_{a \in A} I_a(x) \succsim_a v_a \iff \forall a \in A, (I_a(y) \succsim_a v_a) \right). \quad (24.86)$$

Analogously, an object  $y$  satisfies the formula

$$\bigwedge_{a \in A} v_a \succsim_a I_a(x), \text{ if } v_a \succsim I_a(y) \text{ for all } a \in A,$$

that is,

$$\left( y \models \bigwedge_{a \in A} v_a \succsim_a I_a(x) \iff \forall a \in A, (v_a \succsim_a I_a(y)) \right). \quad (24.87)$$

With these notations, we are ready to interpret upward and downward dominance-based rough set three regions.

From the upward and downward three regions, we can construct three classes of rules for classifying an object, called the upward and downward positive, negative, and boundary rules.

They are expressed in the following forms: for  $y \in U$ ,

- Positive rule induced by an upward cone

$$D^+(x) \subseteq \text{POS}_{(\alpha, \beta)}^+(X) :$$

$$\text{if } y \models \bigwedge_{a \in A} I_a(x) \succsim_a v_a, \text{ accept } y \in X,$$

- Negative rule induced by the complement of an upward cone

$$U - D^+(x) \subseteq \text{NEG}_{(\alpha, \beta)}^+(X) :$$

$$\text{if } y \models \neg \bigwedge_{a \in A} I_a(x) \succsim_a v_a, \text{ reject } y \in X,$$

- Boundary rule induced by an upward cone  $D^+(x)$  and its complement  $U - D^+(x)$  such that

$$D^+(x) \not\subseteq \text{POS}_{(\alpha, \beta)}^+(X)$$

$$\text{and } (U - D^+(x)) \not\subseteq \text{NEG}_{(\alpha, \beta)}^+(X) :$$

$$\text{if } y \models \bigwedge_{a \in A} I_a(x) \succsim_a v_a \wedge \neg \bigwedge_{a \in A} I_a(x) \succsim_a u_a,$$

neither accept nor reject  $y \in X$ ,

- Positive rule induced by an downward cone

$$D^-(x) \subseteq \text{POS}_{(\alpha, \beta)}^-(X) :$$

$$\text{if } y \models \bigwedge_{a \in A} v_a \succsim_a I_a(x), \text{ accept } y \in X,$$

- Negative rule induced by the complement of a downward cone

$$U - D^-(x) \subseteq \text{NEG}_{(\alpha, \beta)}^-(X) :$$

$$\text{if } y \models \neg \bigwedge_{a \in A} v_a \succsim_a I_a(x), \text{ reject } y \in X,$$

- Boundary rule induced by a downward cone  $D^-(x)$  and its complement  $U - D^-(x)$  such that

$$D^-(x) \not\subseteq \text{POS}_{(\alpha, \beta)}^-(X)$$

$$\text{and } U - D^-(x) \not\subseteq \text{NEG}_{(\alpha, \beta)}^-(X) :$$

$$\text{if } y \models \bigwedge_{a \in A} v_a \succsim_a I_a(x) \wedge \neg \bigwedge_{a \in A} u_a \succsim_a I_a(x),$$

neither accept nor reject  $y \in X$ .

The three types of rules have a semantic interpretations analogous to those induced by probabilistic rough sets based on indiscernibility presented in Sect. 24.5.3. Let us consider the rules related to  $\text{POS}^+$  and  $\text{NEG}^+$ . A positive rule allows us to *accept* an object  $y$  to be a member of  $X$ , because  $y$  has a higher probability of being in  $X$  due to the facts that  $y \in D^+(x)$  and  $\Pr(X|D^+(x)) \geq \alpha^+$ . A negative rule enables us to *reject* an object  $y$  to be a member of  $X$ , because  $y$  has lower probability of being in  $X$  due to the facts that  $y \in D^+(x)$  and  $\Pr(X|D^+(x)) \leq \beta^+$ . When the probability of  $y$  being in  $X$  is neither high nor low, a boundary rule makes a noncommitment decision.

The error rate of a positive rule is given by  $1 - \Pr(X|D^+(x))$ , which, by definition of the three regions, is at or below  $1 - \alpha^+$ . The error rate of negative rule is given by  $\Pr(X|D^+(x))$  and is at or below  $\beta^+$ . The cost of a positive rule is  $\lambda_{pp}^+ \Pr(X|D^+(x)) + \lambda_{pn}^+ (1 - \Pr(X|D^+(x)))$  and is bounded above by  $\alpha^+ \lambda_{pp}^+ + (1 - \alpha^+) \lambda_{pn}^+$ . The cost of a negative rule is  $\lambda_{np}^+ \Pr(X|D^+(x)) + \lambda_{nn}^+ (1 - \Pr(X|D^+(x)))$  and is bounded above by  $\beta^+ \lambda_{np}^+ + (1 - \beta^+) \lambda_{nn}^+$ .

## 24.10 Conclusions

A basic probabilistic rough set model is formulated by using a pair of thresholds on conditional probabilities, which leads to flexibility and robustness when performing classification or decision-making tasks. Three theories are the supporting pillars of probabilistic rough sets. Bayesian decision theory enables us to determine and interpret the required thresholds by using more operable notions such as loss, cost, risk, etc. Bayesian inference ensures us to estimate the conditional probability accurately. A theory of three-way decisions allows us to make a wise decision in the presence of incomplete or insufficient information.

Other probabilistic rough set models have also been described. We have shown how a probabilistic approach can be applied when information related to some order. The order concerns degrees in which an object has some properties related to considered attributes. This kind of order can be handled by the well-known rough set extension called dominance-based rough set approach.

One may expect a continuous growth of interest in probabilistic approaches to rough sets. An important task is to examine fully, in the light of three fundamental issues concerning the basic model, the semantics of each model, in order to identify its limitations and appropriate areas of applications.

# Generalized

## 25. Generalized Rough Sets

JingTao Yao, Davide Ciucci, Yan Zhang

This chapter reviews three formulations of rough set theory, i. e., element-based definition, granule-based definition, and subsystem-based definition. These formulations are adopted to generalize rough sets from three directions. The first direction is to use an arbitrary binary relation to generalize the equivalence relation in the element-based definition. The second is to use a covering to generalize the partition in the granule-based definition, and the third to use a subsystem to generalize the Boolean algebra in the subsystem-based definition. In addition, we provide some insights into the theoretical aspects of these generalizations, mainly with respect to relations with non-classical logic and topology theory.

<b>References.....</b>	<b>423</b>

In the *Pawlak* rough set model, the relationships of objects are defined by equivalence relations [25.1, 2]. In addition, we may obtain two other equivalent structures: the partition, induced by the equivalence relations, and an atomic Boolean algebra, formed by the equivalence classes as its set of atoms [25.2, 3]. In other words, we have three equivalent formulations of rough sets, namely, the equivalence relation-based formulation, the partition-based formulation, and the Boolean algebra-based formulation [25.4]. The approximation operators  $\text{apr}$  and  $\overline{\text{apr}}$  are defined by an equivalence relation  $E$ , a partition  $U/E$ , and Boolean algebra  $B(U/E)$ , respectively [25.3, 5]. Although mathematically equivalent, these three formulations give different insights into the theory. More interestingly, when rough sets are generalized, the three formulations are no longer equivalent and thus

give new directions for the exploration of rough sets.

This chapter aims to explore these different generalizations. The discussion is organized in two parts. In the first part, we review and summarize relation-based, covering-based, and subsystem-based rough sets, based on several articles by Yao [25.4, 6, 7]. In the second part, we will give some insight into the theoretical aspects of these generalizations, mainly with respect to relations with nonclassical logic (modal and many-valued) and topology theory. It is to be noted that this second part partially overlaps with the first one, however, the scopes are different. Indeed, whereas the first part explains the models and their genesis, the second one is only devoted to some theoretical aspects. As such, the second part can be skipped by readers who are not so interested in fine details but may still have a clear view of the whole landscape of these kinds of generalized rough sets.

## 25.1 Definition and Approximations of the Models

In this section we discuss three equivalent formulations, namely, the equivalence relation-based formulation, the partition-based formulation, and the Boolean algebra-based formulation.

### 25.1.1 A Framework for Generalizing Rough Sets

For a systematic study on the generalization of Pawlak rough sets, Yao provided a framework to classifying commonly used definitions of rough set approximations into three types: the element-based definition, the granule-based definition, and the subsystem-based definition [25.5]. He argued that these types offer three directions for generalizing rough set models. We adapt this framework in the following discussion.

Suppose the universe  $U$  is a finite and nonempty set and let  $E \subseteq U \times U$  be an equivalence relation on  $U$ . The equivalence class containing  $x$  is denoted as

$$[x]_E = \{y | y \in U, xEy\}.$$

The family of all equivalence classes is known as a quotient set denoted by

$$U/E = \{[x]_E | x \in U\}.$$

$U/E$  defines a partition of  $U$ . A family of all definable sets form  $B(U/E)$ . A family of all definable sets can be obtained from  $U/E$  by adding the empty set  $\emptyset$  and making itself closed under set union. A family of all definable sets is a subsystem of  $2^U$ , that is,  $B(U/E) \subseteq 2^U$  [25.1]. The standard rough set theory deals with the approximation of any subset of  $U$  in terms of definable subsets in  $B(U/E)$ . From different representations of an equivalence relation, three definitions of Pawlak rough set approximations can be obtained as follows:

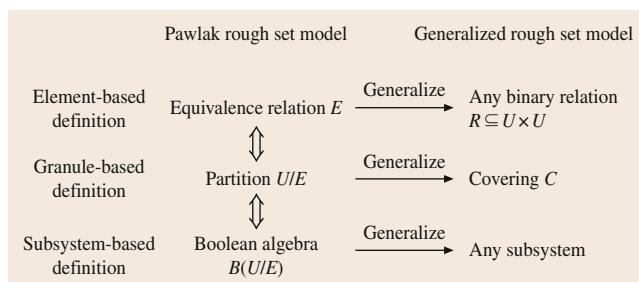

Fig. 25.1 Different formulations of approximation operators

- Element-based definitions [25.3, 5]

$$\begin{aligned}\underline{\text{apr}}(A) &= \{x | x \in U, [x]_E \subseteq A\} \\ &= \{x | x \in U, \forall y \in U [xEy \Rightarrow y \in A]\}, \\ \overline{\text{apr}}(A) &= \{x | x \in U, [x]_E \cap A \neq \emptyset\} \\ &= \{x | x \in U, \exists y \in U [xEy \wedge y \in A]\}. \quad (25.1)\end{aligned}$$

- Granule-based definitions [25.3, 5, 8]

$$\begin{aligned}\underline{\text{apr}}(A) &= \bigcup \{[x]_E | [x]_E \in U/E, [x]_E \subseteq A\} \\ &= \bigcup \{X | X \in U/E, X \subseteq A\}, \\ \overline{\text{apr}}(A) &= \bigcup \{[x]_E | [x]_E \in U/E, [x]_E \cap A \neq \emptyset\} \\ &= \bigcup \{X | X \in U/E, X \cap A \neq \emptyset\}. \quad (25.2)\end{aligned}$$

- Subsystem-based definition [25.3, 5, 8]

$$\begin{aligned}\underline{\text{apr}}(A) &= \bigcup \{X | X \in B(U/E), X \subseteq A\}, \\ \overline{\text{apr}}(A) &= \bigcap \{X | X \in B(U/E), A \subseteq X\}. \quad (25.3)\end{aligned}$$

The three equivalent definitions offer different interpretations of rough set approximations [25.5]. According to the element-based definition, an element  $x$  is in the lower approximation  $\underline{\text{apr}}(A)$  of a set  $A$  if all of its equivalent elements are in  $A$ ; the element is in the upper approximation  $\overline{\text{apr}}(A)$  if at least one of its equivalent elements is in  $A$  [25.5]. According to the granule-based definition,  $\underline{\text{apr}}(A)$  is the union of equivalence classes that are subsets of  $A$ ;  $\overline{\text{apr}}(A)$  is the union of equivalence classes that have a nonempty intersection with  $A$  [25.5]. According to the subsystem-based definition,  $\underline{\text{apr}}(A)$  is the largest definable set in the subsystem  $B(U/E)$  that is contained in  $A$ ;  $\overline{\text{apr}}(A)$  is the smallest definable set in the subsystem  $B(U/E)$  that contains  $A$  [25.5].

Figure 25.1, adapted from Yao and Yao [25.4], shows three directions in generalized rough set models. In the Pawlak model, the definitions of approximation operators based on the equivalence relation, partition and Boolean algebra  $B(U/E)$  are equivalent. The symbol  $\Updownarrow$  is used to show a one-to-one two-way construction process. However, the generalized definitions of approximation operators using arbitrary binary relations, coverings, and subsystems are not equivalent.

In other words, the corresponding subsystem or covering may not be found based on an arbitrary binary relation. With each formulation, various definitions of approximation operators can be examined. One may consider an arbitrary binary relation in generalizing the equivalence relation in the element-based definition, a covering in generalizing the partition in the granule-based definition, and other subsystems in generalizing the Boolean algebra in the subsystem-based definition [25.4, 5].

### 25.1.2 Binary Relation-Based Rough Sets

In the development of the theory of rough sets, approximation operators are typically defined by using equivalence relations which are reflexive, symmetric, and transitive [25.2]. The Pawlak rough set model can be extended by using any arbitrary binary relation to replace the equivalence relation. Wybraniec-Skardowska introduced different rough set models based on various types of binary relations [25.9]. Pawlak pointed out that any type of relations may be assumed on the universe for the development of a rough set theory [25.10]. Yao et al. extended conventional rough set models by considering various types of relations by drawing results from modal logics [25.11]. Similarly to defining different types of modal logic systems, different rough set models were defined by using classes of binary relations satisfying various sets of properties, formed by serial, reflective, symmetric, transitive, and Euclidean relations, and their combinations. Slowinski and Vanderpooten considered a special case in which a reflexive (not necessarily symmetric and transitive) similarity relation was used [25.12]. Greco et al. examined a fuzzy rough approximation based on fuzzy similarity relations [25.13]. Guan and Wang investigated the relationships among 12 different basic definitions of approximations and suggested the suitable generalized definitions of approximations for each class of generalized indiscernibility relations [25.14].

A binary relation  $R$  may be conveniently represented by a mapping  $n: U \rightarrow 2^U$ , i.e.,  $n$  is a neighborhood operator and  $n(x)$  consists of all  $R$ -related elements of  $x$ . In the element-based definition, the equivalence class  $[x]_E$  can be viewed as a neighborhood of  $x$  consisting of objects equivalent to  $x$ . In general, one may consider any type neighborhood of  $x$ , consisting of objects related to  $x$ , to form more general approximation operators. By extending (25.1), we can define lower and upper approximation operators as fol-

lows [25.15]

$$\begin{aligned}\underline{\text{apr}}_n(A) &= \{x|x \in U, n(x) \subseteq A\} \\ &= \{x|x \in U, \forall y \in U(y \in n(x) \Rightarrow y \in A)\}, \\ \overline{\text{apr}}_n(A) &= \{x|x \in U, n(x) \cap A \neq \emptyset\} \\ &= \{x|x \in U, \exists y(y \in n(x) \wedge y \in A)\}. \end{aligned}\quad (25.4)$$

The set  $\underline{\text{apr}}_n(A)$  consists of elements whose  $R$ -related elements are all in  $A$ , and  $\overline{\text{apr}}_n(A)$  consists of elements such that at least one of whose  $R$ -related elements is in  $A$ . The lower and upper approximation operators  $\underline{\text{apr}}_n$  and  $\overline{\text{apr}}_n$  pair are a generalized rough set of  $A$  induced by the binary relation  $R$ .

A neighborhood operator can be defined by using a binary relation [25.6, 12, 16]. Suppose  $R \subseteq U \times U$  is a binary relation on the universe  $U$ . A successor neighborhood operator  $R^\cdot : U \rightarrow 2^U$  can be defined as

$$xR^\cdot = \{y|y \in U, xRy\}.$$

Conversely, a binary relation can be constructed from its successor neighborhood as

$$xRy \Leftrightarrow y \in xR^\cdot.$$

Generalized approximations by a neighborhood operator can be equivalently formulated by using a binary relation [25.4]. This formulation connects generalized approximation operators with the necessity and possibility operators in modal logic [25.6]. There are many types of generalized approximation operators defined by neighborhood operators that are induced by a binary relation or a family of binary relations [25.3, 15–19].

For an arbitrary relation, generalized rough set operators do not necessarily satisfy all the properties in the Pawlak rough set model. Nevertheless, the following properties hold in rough set models induced by any binary relation [25.3, 6, 20]

- (L1)  $\underline{\text{apr}}(A) = (\overline{\text{apr}}(A^c))$ ,
- (L2)  $\underline{\text{apr}}(U) = U$ ,
- (L3)  $\underline{\text{apr}}(A \cap B) = \underline{\text{apr}}(A) \cap \underline{\text{apr}}(B)$ ,
- (L4)  $\underline{\text{apr}}(A \cup B) \supseteq \underline{\text{apr}}(A) \cup \underline{\text{apr}}(B)$ ,
- (L5)  $A \subseteq B \Rightarrow \underline{\text{apr}}(A) \subseteq \underline{\text{apr}}(B)$ ,
- (K)  $\underline{\text{apr}}(A^c \cup B) \subseteq (\underline{\text{apr}}(A))^c \cup \underline{\text{apr}}(B)$ ,
- (U1)  $\overline{\text{apr}}(A) = (\underline{\text{apr}}(A^c))$ ,

- (U2)  $\overline{\text{apr}}(\emptyset) = \emptyset$ ,  
(U3)  $\overline{\text{apr}}(A \cup B) = \overline{\text{apr}}(A) \cup \overline{\text{apr}}(B)$ ,  
(U4)  $\overline{\text{apr}}(A \cap B) \subseteq \overline{\text{apr}}(A) \cap \overline{\text{apr}}(B)$ ,  
(U5)  $A \subseteq B \Rightarrow \overline{\text{apr}}(A) \subseteq \overline{\text{apr}}(B)$ .

A relation  $R$  is a serial relation if for all  $x \in U$  there exists a  $y \in U$  such that  $xRy$ ; a relation is a reflexive relation if for all  $x \in U$  the relationship  $xRx$  holds; a relation is symmetric relation if for all  $x, y \in U$ ,  $xRy$  implies  $yRx$  holds; a relation is transitive relation if for three elements  $x, y, z \in U$ ,  $xRy$  and  $yRz$  imply  $xRz$ ; a relation is Euclidean when for all  $x, y, z \in U$ ,  $xRy$  and  $xRz$  imply  $yRz$  [25.6, 15]. By using mapping  $n$ , we can express equivalently the conditions on a binary relation as follows [25.6, 15, 21]:

Serial	$x \in U, n(x) \neq \emptyset$
Reflexive	$x \in U, x \in n(x)$
Symmetric	$x, y \in U, x \in n(y) \Rightarrow y \in n(x)$
Transitive	$x, y \in U, y \in n(x) \Rightarrow n(y) \subseteq n(x)$
Euclidean	$x, y \in U, y \in n(x) \Rightarrow n(x) \subseteq n(y)$ .

Different binary relations have different properties. The five properties of a binary relation, namely, the serial, reflexive, symmetric, transitive, and Euclidean properties, induce five properties for the approximation operators [25.6, 20, 21]. We use the same labeling system as in modal logic to label these properties [25.6]:

Serial	Property (D) $\text{apr}(A) \subseteq \overline{\text{apr}}(A)$ holds
Reflexive	Property (T) $\overline{\text{apr}}(A) \subseteq A$ holds
Symmetric	Property (B) $A \subseteq \overline{\text{apr}}(\overline{\text{apr}}(A))$ holds
Transitive	Property (4) $\overline{\text{apr}}(A) \subseteq \overline{\text{apr}}(\overline{\text{apr}}(A))$ holds
Euclidean:	Property (5) $\overline{\text{apr}}(A) \subseteq \overline{\text{apr}}(\overline{\text{apr}}(A))$ holds.

By combining these properties, one can construct more rough set models [25.6, 20]. Other than the above mentioned properties, (K) denotes the property that any binary relation holds, i.e., no special property is required. We use a series of property labels, i.e., (K), (D), (T), (B), (4), (5), to represent the rough set models built on relations with these properties. For example, the KTB rough set model is built on a compatibility relation R, i.e., with reflexive and symmetric properties. In such a model, properties (K), (D), (T) and (B) hold, however, properties (4) and (5) do not hold. Property (D) does not explicitly appear in this label because (D) can

be obtained from (T). If  $R$  is reflexive, symmetric, and transitive, i.e.,  $R$  is an equivalence relation, we obtain the Pawlak rough set model [25.6, 20]. The approximation operators satisfies all properties (D), (T), (B), (4), and (5).

Figure 25.2 summarizes the relationships between these models [25.6, 20, 21]. The label of the model indicates the characterization properties of that model. A line connecting two models indicates that the model on the upper level is also a model on the lower level. For example, a KT5 model is a KT4 model, as KT5 connects down to KT4. It should be noted that the lines that can be derived by transitivity are not explicitly shown. The model K may be considered as the basic model because it does not require any special property on the binary relation. All other models are built on top of the model K and it can be regarded as the weakest model. The model KT5, i.e., the Pawlak rough set model, is the strongest model.

With the element-based definition, we can obtain binary relation-based rough set models by generalizing the equivalence relation to binary relations. Different binary relations can induce different rough set models with different properties, as was discussed above. This generalization not only deepens our understanding of rough sets, but also enriches the rough set theory.

### 25.1.3 Covering-Based Rough Sets

A covering of a universe is a family of subsets of the universe such that their union is the universe. By allowing nonempty overlap of two subsets, a covering is a generalized mathematical structure of a partition [25.22]. These subsets in a covering or a partition can be considered as granules based on the concepts

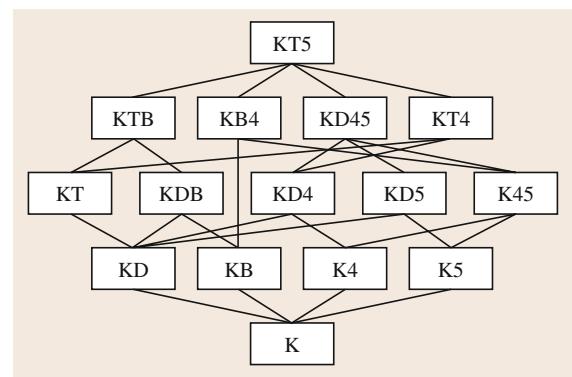

Fig. 25.2 Rough set models (after [25.6])

in granular computing [25.23]. By generalizing the partition to covering in granule-based approximation definitions, we form a more general definition and we call this approach a granule-based definition. In this section, we mainly investigate covering-based rough sets.

*Zakowski* proposed the notion of covering-based rough set approximations in 1983 [25.24]. Lower and upper approximation operators are defined by a straightforward generalization of the rough set definition proposed by Pawlak. However, the generalized approximation operators are not dual to each other with respect to set complements [25.15, 25]. *Pomykala* studied two pairs of dual approximation operators [25.25]. The lower approximation operator in one pair is the same as the *Zakowski* lower approximation operator, and the upper approximation operator in the other pair is same as the *Zakowski* upper approximation operator [25.25]. *Pomykala* also suggested and examined additional pairs of dual approximation operators that are induced by a covering. Furthermore, he considered coverings produced by tolerance relations in an incomplete information table [25.26].

Instead of using duality, *Wybraniec-Skardowska* studied pairs of approximation operators linked together by a different type of relations [25.9]. Given an upper approximation operator, the corresponding lower approximation operator is defined based on the upper approximations of singleton subsets. Several such pairs of approximation operators were studied based on a covering and a tolerance relation defined by a covering, including some of those used by *Zakowski* [25.24] and *Pomykala* [25.25]. *Yao* investigated dual approximation operators by using coverings induced by the predecessor and/or successor neighborhoods of serial or inverse serial binary relations. The two pairs of dual approximation operators introduced by *Pomykala* were examined and the conditions for their equivalence to those obtained from a binary relation were given [25.5, 15]. *Cousuo* and *Dubois* proposed a loose pair and a tight pair [25.27]. They presented an interesting investigation of the two pairs of approximation operators within the context of incomplete information. The two pairs of operators were shown to be related to the family of approximation operators produced by all partitions consistent with a covering induced by an ill-known attribute function in an incomplete information table. *Restrepo* et al. investigated different relationships between commonly used operators using concepts of duality and other properties [25.28]. They also showed that a pair of lower operators and an upper approxi-

mation operator can be dual and adjoint at the same time.

By using the minimum neighborhood of an object (i.e., the intersection of subsets in the minimal description of the object), *Wang* et al. introduced a pair of dual approximation operators [25.29]. The same pair of approximation operators was also used and examined by *Xu* and *Wang* [25.30] and *Xu* and *Zhang* [25.31]. *Zhu*'s team systematically studied five types of approximation operators [25.19, 32–36]. The lower approximation operator is the *Zakowski* lower approximation operator, and the upper approximation operators are different. They investigated properties of these operators and their relationships and provided set of axioms for characterizing these operators. *Liu* examined covering-based rough sets from constructive and axiomatic approaches [25.37]. The relationships among four types of covering-based rough sets and the topologies induced by different covering approximations were discussed. *Zhang* and *Luo* investigated relationships between relation-based rough sets and covering-based rough sets [25.38]. They also presented some sufficient and necessary conditions for different types of covering-based rough sets to be equal.

We will elaborate on how to obtain rough sets by generalizing a partition to a covering, as well as duality, loose pairs, and tight pairs of approximation operators. Let  $\mathbb{C}$  be a covering of the universe  $U$ . By replacing a partition  $U/E$  with a covering  $\mathbb{C}$  and equivalence classes with subsets in  $\mathbb{C}$  in the granule-based definition, a pair of approximation operators can be obtained [25.24]. However, they are not a pair of dual operators [25.25]. To overcome this problem, *Yao* suggested that one can generalize one of them and define the other by duality [25.7, 15]. The granule-based definition can be generalized in two ways, i.e., (1) the lower approximation operator is extended from partition to covering and the upper approximation operator is redefined by duality, (2) the upper approximation operator is extended from partition to covering and the lower approximation operator is redefined by duality [25.4, 7]. The results are two pairs of dual approximation operators [25.4]

$$\begin{aligned}\underline{\text{apr}}'(A) &= \bigcup\{X|X \in \mathbb{C}, X \subseteq A\} \\ &= \{x|x \in U, \exists X \in \mathbb{C}[x \in X, X \subseteq A]\}, \\ \overline{\text{apr}}'(A) &= (\underline{\text{apr}}'(A^c))^c \\ &= \{x|x \in U, \forall X \in \mathbb{C}[x \in X \Rightarrow X \cap A \neq \emptyset]\}. \end{aligned}\tag{25.5}$$

and

$$\begin{aligned}\underline{\text{apr}}''(A) &= (\overline{\text{apr}}''(A^c))^c \\ &= \{x|x \in U, \forall X \in \mathbb{C}[x \in X \Rightarrow X \subseteq A]\}, \\ \overline{\text{apr}}''(A) &= \bigcup\{X|X \in \mathbb{C}, X \cap A \neq \emptyset\} \\ &= \{x|x \in U, \exists X \in \mathbb{C}[x \in X, X \cap A \neq \emptyset]\}. \end{aligned}\quad (25.6)$$

We may define two pairs of dual approximation operators for each covering. Both of pairs are consistent with the Pawlak definition. The following relationships hold for the above approximation operators [25.4, 25]

$$\underline{\text{apr}}''(A) \subseteq \underline{\text{apr}}'(A) \subseteq A \subseteq \overline{\text{apr}}'(A) \subseteq \overline{\text{apr}}''(A). \quad (25.7)$$

Therefore, the pair  $(\underline{\text{apr}}'(A), \overline{\text{apr}}'(A))$  is called a pair of tighter approximation and the pair  $(\underline{\text{apr}}''(A), \overline{\text{apr}}''(A))$  is called a looser approximation [25.25]. Furthermore, any approximation produced by other authors are bounded by

$$(\underline{\text{apr}}'(A), \overline{\text{apr}}'(A))$$

and

$$(\underline{\text{apr}}''(A), \overline{\text{apr}}''(A))$$

if

$$\underline{\text{apr}}(A) \subseteq A \subseteq \overline{\text{apr}}(A).$$

In addition to this fundamental generalization of a rough set to a covering, more than 20 different approximation pairs have been defined [25.4, 39]. Their properties were studied in [25.39], where the inclusion relationship occurring among two sets and their approximations was considered. All these approaches were categorized in a recent study [25.4].

We recall some notions that will be useful in Sect. 25.2.2 when dealing with the topological characterization of approximations.

#### **Definition 25.1 [25.39]**

Let  $\mathbb{C}$  be a covering on a universe  $U$  and  $x \in U$ . We define:

- The neighborhood of  $x$ :  $\gamma(x) = \bigcap\{C \in \mathbb{C} : x \in C\}$ .
- The friends of  $x$ :  $\delta(x) = \bigcup\{C \in \mathbb{C} : x \in C\}$ .
- The partition generated by a covering:  $\Pi_{\mathbb{C}}(x) = \{y \in U : \forall C \in \mathbb{C}, (x \in C \Leftrightarrow y \in C)\}$ .

Using the above operators, the following approximation pairs are introduced

$$L_1(A) = \bigcup\{\delta(x) : \delta(x) \subseteq A\}, \quad (25.8)$$

$$U_1(A) = L_1(A^c)^c, \quad (25.8)$$

$$L_2(A) = \bigcup\{C \subseteq A\},$$

$$U_2(A) = L_2(A^c)^c = \bigcap\{C^c : C \in \mathbb{C}, C \cap A = \emptyset\}, \quad (25.9)$$

$$L_3(A) = L_2(A),$$

$$U_3(A) = \bigcup\{C : C \cap A \neq \emptyset\} \setminus L_3(A^c), \quad (25.10)$$

$$L_4(A) = \bigcup\{\Pi_{\mathbb{C}}(x) \subseteq A\},$$

$$U_4(A) = \bigcup\{\Pi_{\mathbb{C}}(x) \cap A \neq \emptyset\}, \quad (25.11)$$

$$L_5(A) = \{x \in U : \gamma(x) \subseteq A\},$$

$$U_5(A) = \{x \in U : \gamma(x) \cap A \neq \emptyset\}, \quad (25.12)$$

$$L_6(A) = U_6(A^c)^c,$$

$$U_6(A) = \bigcup\{\gamma(x) : x \in A\}. \quad (25.13)$$

These approximation pairs have been introduced and studied in several papers: approximation pair 1 (25.8) can be found in [25.40], approximation pair 2 (25.9) in [25.5, 40–43], approximation pair 3 (25.10) in [25.42], approximation pair 4 (25.11) in many papers starting from [25.44], approximation pair 5 (25.12) in [25.41, 45], and approximation pair 6 (25.13) in [25.45, 46]. As we will discuss, they all show nice topological properties.

By simply replacing a partition with a covering, a generalized mathematical structure of a partition, in the granule-based definition, we form new rough sets. The lower and upper approximation operators are not necessary dual. We may redefine one of them to obtain the dual approximation operators. There are two types of approximation, a tight pair and a loose pair. The two pairs provide the boundary when new approximation operators are introduced.

#### **25.1.4 Subsystem-Based Rough Sets**

In the Pawlak rough set model, the same subsystem is used to define lower and upper approximation operators. When generalizing the subsystem-based definition, two subsystems may be used, one for the lower approximation, which is closed under union, and the other for the upper approximation, which is closed under intersection [25.4, 7, 47]. To ensure duality of approximation operators, the two subsystems should be dual systems with respect to set complement [25.4]. Given a closure system  $\bar{S}$ , its dual system  $\underline{S}$  can be con-

structed as  $\underline{S} = \{\sim X | X \in \bar{S}\}$ . The system  $\bar{S}$  contains the universe  $U$  and is closed under set intersection. The system  $\underline{S}$  contains the empty set  $\emptyset$  and is closed under set union [25.4]. A pair of lower and upper approximation operators with respect to  $S$  is defined as [25.4]

$$\begin{aligned}\underline{\text{apr}}(A) &= \bigcup\{X | X \in \underline{S}, X \subseteq A\}, \\ \overline{\text{apr}}(A) &= \bigcap\{X | X \in \bar{S}, A \subseteq X\}.\end{aligned}\quad (25.14)$$

In the Pawlak rough set model, the two systems  $\underline{S}$  and  $\bar{S}$  are the same, namely,  $\underline{S} = \bar{S}$ , which is closed under set complement, union, and intersection. That is, it is a Boolean algebra. The subsystem-based definition provides a way to approximate any set in  $2^U$  by a pair of sets in  $\underline{S}$  and  $\bar{S}$ , respectively [25.4]. The subsystem-based definition can be generalized by using different mathematical structures, such as topological spaces [25.7, 47, 48], closure systems [25.7, 47], lattices [25.7, 49], and posets [25.7, 50].

For an arbitrary topological space, the family of open sets is different from the family of closed sets. Let  $(U, O(U))$  be a topological space, where  $O(U) \subseteq 2^U$  is a family of subsets of  $U$  called open sets. The family of (topological) open sets contains  $\emptyset$  and  $U$ . The family of open sets is closed under union and finite intersection. The family of all (topological) closed sets  $C(U) = \{\neg X | X \in O(U)\}$  contains  $\emptyset$  and  $U$ , and is closed under intersection and finite union. A pair of generalized approximation operators can be defined by replacing  $B(U/E)$  with  $O(U)$  for the lower approximation operator, and  $B(U/E)$  with  $C(U)$  for the upper approximation operator [25.5]. The definitions of approximation operators are [25.5, 7, 50]

$$\begin{aligned}\underline{\text{apr}}(A) &= \bigcup\{X | X \in O(U), X \subseteq A\}, \\ \overline{\text{apr}}(A) &= \bigcap\{X | X \in C(U), A \subseteq X\}.\end{aligned}\quad (25.15)$$

The rough set model can be generalized by using closure systems. A family of subsets of  $U$ ,  $C(U)$ , is called a closure system if it contains  $U$  and is closed under intersection. By collecting the complements of members of  $C(U)$ , we can obtain another system  $O(U) = \{\neg X | X \in C(U)\}$ , which contains the empty set  $\emptyset$  and is closed under union. In this case, a pair of approximation operators in a closure system can be defined by replacing  $B(U/E)$  with  $O(U)$  for the lower approximation operator, and  $B(U/E)$  with  $C(U)$  for the upper approximation operator. The definitions of

approximation operators are [25.5, 7]

$$\begin{aligned}\underline{\text{apr}}(A) &= \bigcup\{X | X \in O(U), X \subseteq A\}, \\ \overline{\text{apr}}(A) &= \bigcap\{X | X \in C(U), A \subseteq X\}.\end{aligned}\quad (25.16)$$

The power set of the universe is a special lattice. Suppose  $(\mathcal{B}, \neg, \wedge, \vee, 0, 1)$  is a finite Boolean algebra and  $(\mathcal{B}_0, \neg, \wedge, \vee, 0, 1)$  is a sub-Boolean algebra. One may approximate an element of  $\mathcal{B}$  by using elements of  $\mathcal{B}_0$  [25.7]

$$\begin{aligned}\underline{\text{apr}}(x) &= \bigvee\{y | y \in \mathcal{B}_0, y \leq x\}, \\ \overline{\text{apr}}(x) &= \bigwedge\{y | y \in \mathcal{B}_0, x \leq y\}.\end{aligned}\quad (25.17)$$

We consider a more generalized definition in which the Boolean algebra  $\mathcal{B}$  is replaced by a completely distributive lattice [25.51], and one subsystem is used. A subsystem  $O(\mathcal{B})$  of  $\mathcal{B}$  satisfies the following axioms [25.7]:

- (O1)  $0 \in O(\mathcal{B}), 1 \in O(\mathcal{B})$ ;
- (O2) for any subsystem  $\mathcal{D} \subseteq O(\mathcal{B})$ , if there exists a least upper bound  $LUB(\mathcal{D}) = \bigvee \mathcal{D}$ , it belongs to  $O(\mathcal{B})$ ;
- (O3)  $O(\mathcal{B})$  is closed under finite meets.

Elements of  $O(\mathcal{B})$  are referred to as inner definable elements. The complement of an inner definable element is called an outer definable element. The set of outer definable elements  $C(\mathcal{B}) = \{\neg x | x \in O(\mathcal{B})\}$  is characterized by the following axioms [25.7]:

- (C1)  $0 \in C(\mathcal{B}), 1 \in C(\mathcal{B})$ ;
- (C2) for any subsystem  $\mathcal{D} \subseteq C(\mathcal{B})$ , if there exists a greatest lower bound  $GLB(\mathcal{D}) = \bigwedge \mathcal{D}$ , it belongs to  $C(\mathcal{B})$ ;
- (C3)  $C(\mathcal{B})$  is closed under finite joins.

From the sets of inner and outer definable elements, we define the following approximation operators [25.7]

$$\begin{aligned}\underline{\text{apr}}(x) &= \bigvee\{y | y \in O(\mathcal{B}), y \leq x\}, \\ \overline{\text{apr}}(x) &= \bigwedge\{y | y \in C(\mathcal{B}), x \leq y\}.\end{aligned}\quad (25.18)$$

Let  $(L, \leq, 0, 1)$  be a bounded lattice. Suppose  $O(L)$  is a subset of  $L$  such that it contains 0 and is closed under join, and  $C(L)$  a subset of  $L$  such that it contains 1 and is closed under meets. They are complete lattices,

although the meet of  $O(L)$  and the join of  $C(L)$  may be different from those of  $L$ . Based on these two systems, we can define two other approximation operators as follows [25.7]

$$\begin{aligned}\underline{\text{apr}}(x) &= \bigvee\{y \mid y \in O(L), y \leq x\}, \\ \overline{\text{apr}}(x) &= \bigwedge\{y \mid y \in C(L), x \leq y\}.\end{aligned}\quad (25.19)$$

The operator  $\overline{\text{apr}}$  is a closure operator [25.7].  $C(L)$  corresponds to the closure system in the set-theoretic framework. However, since a lattice may not be complemented, we must explicitly consider both  $O(L)$

and  $C(L)$ . That is, the system  $(L, O(L), C(L))$ , or equivalently the system  $(L, \underline{\text{apr}}, \overline{\text{apr}})$ , is used for the generalization of Pawlak approximation operators.

The subsystem-based formulation provides an important interpretation of rough set theory. It allows us to study rough set theory in the contexts of many algebraic systems [25.47]. This naturally leads to the generalization of rough set approximations. With the subsystem-based definition, we examine the generalized approximation operators by using topological space, closure systems, lattices, and posets in this subsection.

## 25.2 Theoretical Approaches

In this section, we further develop the previously outlined links with modal logics and topology.

### 25.2.1 Logical Setting

The *minimal modal system K* [25.52] is at the basis of any modal logic. Its language  $\mathcal{L}$  is the usual one of propositional logic plus necessity  $\Box$  and possibility  $\Diamond$ . That is,  $\mathcal{L} = a \in \mathcal{V} \mid \neg \alpha \mid \alpha \wedge \beta \mid \Box(\alpha)$ , where  $\mathcal{V} = \{a, b, c, \dots\}$  is the set of propositional variables and  $\neg, \wedge, \Box$  are the negation, conjunction, and necessity connectives. As usual, other connectives can be derived: disjunction  $\alpha \vee \beta$  stands for  $(\alpha' \wedge \beta')'$ , implication  $\alpha \rightarrow \beta$  stands for  $\alpha' \vee \beta$ , and possibility is  $\Diamond \alpha = \neg \Box(\neg \alpha)$ .

The axioms are those of Boolean logic plus the axioms to characterize the modal connectives:

- (B1)  $\alpha \rightarrow (\beta \rightarrow \alpha)$
- (B2)  $(\beta \rightarrow (\alpha \rightarrow \mu)) \rightarrow ((\beta \rightarrow \alpha) \rightarrow (\beta \rightarrow \gamma))$
- (B3)  $(\alpha' \rightarrow \beta') \rightarrow (\beta \rightarrow \alpha)$
- (K)  $\Box(\alpha \rightarrow \beta) \rightarrow (\Box \alpha \rightarrow \Box \beta)$ .

The rules are modus ponens: *If  $\vdash \alpha$  and  $\vdash \alpha \rightarrow \beta$  then  $\vdash \beta$*  and necessitation: *If  $\vdash \alpha$  then  $\vdash \Box \alpha$* .

In our context, the semantics is given through a model  $M = (X, R, v)$ , where  $(X, R)$  is an approximation space (that is, a universe with a binary relation) and  $v$  is the interpretation that given a variable returns a subset of elements of the universe:  $v(a) \subseteq X$ . Using the standard modal logic terminology,  $X$  is the set of possible worlds,  $R$  the accessibility relation, and  $v(a)$  represents the set of possible worlds where  $a$  holds. The

interpretation  $v$  can recursively be extended to any formula  $\alpha$  as

$$\begin{aligned}v(\neg \alpha) &= v(\alpha)^c, \\ v(\alpha_1 \wedge \alpha_2) &= v(\alpha_1) \cap v(\alpha_2), \\ v(\alpha_1 \vee \alpha_2) &= v(\alpha_1) \cup v(\alpha_2),\end{aligned}$$

and modal operators are mapped to lower and upper approximations according to Definition 25.4

$$\begin{aligned}v(\Box \alpha) &= \underline{\text{apr}}_n(v(\alpha)), \\ v(\Diamond \alpha) &= \overline{\text{apr}}_n(v(\alpha)).\end{aligned}$$

It is well known from modal logic [25.52] that, once the basic axioms (B1)–(B3) and (K) are fixed, then a different modal axiom according to Table 25.1 corresponds to any relation property.

Clearly, these axioms reflect the properties on rough approximations given in Sect. 25.1.2 and can be used to generate all the logics given in Fig. 25.2.

Other kinds of generalized rough sets models have been studied in the literature under the framework of modal logic. In particular, nondeterministic information

**Table 25.1** Correspondence between modal axioms and relation properties

Name	Axiom	Property
T	$\Box \alpha \rightarrow \alpha$	Reflexive
4	$\Box \alpha \rightarrow \Box \Box(\alpha)$	Transitive
5	$\Diamond \alpha \rightarrow \Box(\Diamond(\alpha))$	Euclidean
D	$\Box \alpha \rightarrow \Diamond \alpha$	Serial
B	$\alpha \rightarrow \Box \Diamond \alpha$	Symmetric

logic (**NIL**) [25.53] is defined to capture those information tables in which more than one value can correspond to each pair (object, attribute). For instance, if we have a feature *color* then it is allowed that to each object can be assigned more than one color. Given this extended definition, several new relations can be introduced; these were studied in the *Orłowska–Pawlak* seminal paper [25.53] and some subsequent studies [25.54–56]. Some of these relations are:

- *Similarity (connection)*  
 $xSy$  iff  $f(x, a) \cap f(y, a) \neq \emptyset$  for all  $a \in A$ .
- *Inclusion*  
 $xIy$  iff  $f(x, a) \subseteq f(y, a)$  for all  $a \in A$ .
- *Indiscernibility*  
 $xIndy$  iff  $f(x, a) = f(y, a)$  for all  $a \in A$ .
- *Weak indiscernibility*  
 $xW_iy$  iff  $f(x, a) = f(y, a)$  for some  $a \in A$ .
- *Weak similarity*  
 $xW_sy$  iff  $f(x, a) \cap f(y, a) \neq \emptyset$  for some  $a \in A$ .
- *Complementarity*  
 $xComy$  iff  $f(x, a) = VAL_a \setminus f(y, a)$ .

We also mention the logic for data analysis (**DAL**) [25.57], which is meant to deal with approximation spaces with more than one equivalence relation  $(X, R_i)$ .

Besides modal logic, in standard rough set theory based on one equivalence relation, several authors have dealt with a many-valued logic approach [25.58, 59], also with some criticism from the point of view of the interpretation of results [25.60]. On the other hand, there have been only a few attempts to link generalized rough sets and many-valued logic. One of the reasons is the intrinsic difficulty that arises when trying to define intersection and union of rough sets (in an algebraic context defining a lattice and not only a poset) without imposing some restrictions (see, for example, [25.61, 62]).

A recent work [25.63] deals with many-valued logic in coverings and in particular the  $\underline{apr}''$ ,  $\overline{apr}''$  approximations defined in (25.6). The novelty of the approach in the introduction of a *subordination relation* among objects

$$x \preceq y \quad \text{iff} \quad \forall C \in C (y \in C \implies x \in C),$$

which is strictly linked to the notion of neighborhood. Indeed,

$$x \preceq y \quad \text{iff} \quad x \in \gamma(y).$$

We also remark that a similar preorder relation defined by a topology is used in the bitopological approach to dominance-based rough sets [25.64]. This link could bring new insight into the many-valued approach to covering-based rough sets.

The syntax of the logic in [25.63] consists of two types of variables: *object variables*  $x, y, \dots$  and *set variables*  $A, B, \dots$  Atomic formulae are  $x \preceq y$  and  $x \in A$  (where  $A$  can be a set variable or a composition of set variables) and compound formulae are obtained with the usual logical connectives  $\neg, \wedge, \vee$ . The axioms are given in the form of sequent calculus, and the interpretation mapping  $I$  is given with respect to a covering  $C$  in atomic formulae as

$$I(x \preceq y) = \begin{cases} t & \text{if } v(x) \preceq v(y) \\ f & \text{otherwise} \end{cases},$$

where  $v$  maps each object variable to an object in the universe  $U$  and

$$I(x \in A) = \begin{cases} t & \text{if } v(x) \in \underline{apr}''(w(A)) \\ f & \text{if } v(x) \in \overline{apr}''(w(A)^c) \\ u & \text{otherwise} \end{cases},$$

where  $w$  maps each set variable and set formula to a subset of objects and  $u$  is a third truth value representing the unknown. The interpretation extends to compound formulae by truth functional application of Kleene three-valued logic. The logic is proven to be sound but complete only with respect to the sublanguage of atomic formulae.

We remark that this logic suffers from the problems of using three-valued logic to capture an epistemic notion such as is the case of Kleene-valued logics with respect to uncertainty. For instance, even if we are not sure if an element  $x \in A$ , we can undoubtedly say that  $(x \in A) \vee \neg(x \in A)$  (*tertium non datur*). On the contrary, with the above interpretation we can obtain that  $I((x \in A) \wedge \neg(x \in A)) = u$ , whenever  $x$  is in the boundary of  $A$ , that is  $I(x \in A) = u$ .

## 25.2.2 Topology

We saw in Sect. 25.1.4 that the subsystem approach can be generalized by the help of topological notions. Here, we further develop this topic and show which covering-based approximations have a topological behavior.

Let us consider a lattice structure and define on it a notion of closure [25.65, 66].

**Definition 25.2**

Given a lattice  $\mathcal{L}$ , a map  $c : \mathcal{L} \mapsto \mathcal{L}$  is a *closure operator* if for all  $x, y \in \mathcal{L}$ :

$$(C1op) \quad x \leq c(x)$$

$$(C2op) \quad \text{If } x \leq y \text{ then } c(x) \leq c(y)$$

$$(C3op) \quad c(c(x)) = c(x)$$

The map  $c$  is a *topological closure* if in addition (C1op)–(C3op) satisfies

$$(C4op) \quad c(a) \vee c(b) = c(a \vee b).$$

The map  $c$  is an *Alexandroff closure* if in addition (C1op)–(C3op) satisfies

$$(C5op) \quad \vee_j c(a_j) = c(\vee_j a_j).$$

Of course, any Alexandroff closure is a topological one and on a finite universe, the two notions coincide.

On a complemented lattice, an interior operator is defined by duality as  $i(x) = c(x')'$  and properties dual to (C1op)–(C5op) hold. On the other hand, if the lattice is not complemented, an interior operator must be explicitly defined, as discussed in Sect. 25.1.4.

To the above algebraic definition of a closure operator there corresponds an equivalent one based on closed sets as we saw in Sect. 25.1.4. More precisely:

**Definition 25.3**

Let  $\mathcal{L}$  be a lattice and  $C \subseteq \mathcal{L}$  a subset of elements which is closed under arbitrary intersections, that is, axioms (C1)–(C3) are satisfied. Then, a *closure oper-*

*ator* satisfying properties (C1op–C3op) is defined as  $c(a) = \wedge\{u \in C : a \leq u\}$ .

A *topological closure* is such that the union of a finite family of closed elements is closed, i. e.,  $(\vee_{i \in I} c_i) \in C$  with  $I$  a finite set of indexes and an *Alexandroff topology* if closed under arbitrary union.

Now, if the subsystem rough sets are naturally based on a topological ground, also covering rough sets can be classified with respect to topological properties. First of all, let us consider the approximations  $\text{apr}'(A)$ ,  $\overline{\text{apr}}'(A)$  defined in (25.5). They are an interior and a closure operator, respectively. On the other hand, approximation  $\overline{\text{apr}}''(A)$  in (25.6) is not a closure, since in general, it does not satisfy condition (C3).

Moreover, let us consider a covering  $\mathbb{C}(X)$  of a universe and the neighborhood of an element  $x \in X$  with respect to  $\mathbb{C}(X)$  defined as  $\gamma(x)$  in Definition 25.1. It is well known that an Alexandroff closure operator is induced as the map  $c_\gamma : \mathcal{P}(X) \mapsto \mathcal{P}(X)$  defined as  $c_\gamma(A) = \cup\{\gamma(a) : a \in A\}$ , which correspond to the upper approximation  $U_6$  in (25.13), and consequently the dual operator  $L_6$  is an interior operator.

More generally, all the upper approximations  $U_1$ – $U_6$  are closure operators. In particular  $U_4$ – $U_6$  are also topological closures, and since duality holds with respect to all approximation pairs but  $(L_3, U_3)$  and since  $L_3 = L_2$ , then all lower approximations are interior operators. This result can be easily established by checking that the properties satisfied by the approximations include those of Definition 25.2 (see Table 25.1 in [25.39]).

## 25.3 Conclusion

Three equivalent approaches to Pawlak rough sets can be given based on an equivalence relation, a partition of the universe, or a Boolean algebra. These different views generate three different possible generalizations of the classical model: binary relation, covering, and subsystem-based rough sets. We have reviewed these models and given the definitions of rough approximations in the different contexts. It can be seen that different models show interesting mathematical properties. In particular, binary relations-based rough sets have their roots in modal logic, whereas covering and subsystem-based rough sets are linked to topology.

Nowadays, generalized rough sets are continuously defined and we can encounter, for instance, more than 20 definitions of approximations based on coverings [25.4]. There is, however, a lack of interpretation in this collection. Efforts should be made to understand the meaning and usefulness of the already defined approximations. This should also be considered when defining new approximations. Besides an intrinsic theoretical interest, a logical approach could also be useful in this direction. Indeed, if in the case of binary relations-based rough sets we have a clear logical framework, the same cannot be said about covering and subsystem-based rough sets, where only few results are known.

# Fuzzy-Rough

Masahiro Inuiguchi, Wei-Zhi Wu, Chris Cornelis, Nele Verbiest

Fuzzy sets and rough sets are known as uncertainty models. They are proposed to treat different aspects of uncertainty. Therefore, it is natural to combine them to build more powerful mathematical tools for treating problems under uncertainty. In this chapter, we describe the state-of-the-art in the combinations of fuzzy and rough sets dividing into three parts.

In the first part, we describe two kinds of models of fuzzy rough sets: one is classification-oriented model and the other is approximation-oriented model. We describe the fundamental properties and show the relations of those models. Moreover, because those models use logical connectives such as conjunction and implication functions, the selection of logical connectives can sometimes be a question. Then we propose a logical connective-free model of fuzzy rough sets.

In the second part, we develop a generalized fuzzy rough set model. We first introduce general types of belief structures and their induced dual pairs of belief and plausibility functions in the fuzzy environment. We then build relationships between belief and plausibility functions in the Dempster-Shafer theory of evidence and the lower and upper approximations in rough set theory in various situations. We also provide the potential applications of the main results to intelligent information systems.

In the third part, we give an overview of the practical applications of fuzzy rough sets. The main focus will be on the machine-learning domain. In

## 26.1 Introduction to Fuzzy-Rough Hybridization

Rough set approaches [26.1, 2] have been successfully applied to various fields related to data analysis, knowledge discovery, decision analysis, and so on. In order to expand the application area and to develop its theory

further, rough sets have been generalized under various settings. There are two different generalizations. One relaxes the precision so that the sizes of lower and upper approximations are controlled by a precision parameter.

This generalized rough set is called a variable precision rough set. The other generalizes the approximation space, i.e., the structure of background knowledge. Many researchers generalized an equivalence relation which is often referred to as an indiscernibility relation to a general binary relation or a family. Many other researchers [26.3–23] generalized an equivalence relation to a fuzzy binary relation or a family of fuzzy sets.

In this chapter, we describe the generalizations of rough sets in the latter sense. More precisely, we concentrate on the fuzzy generalizations of rough set approaches called fuzzy rough hybridizations. Fuzzy rough sets were originally proposed by *Nakamura* [26.3] and by *Dubois* and *Prade* [26.4, 5]. The fundamental properties of fuzzy rough sets have been investigated by *Dubois* and *Prade* [26.4, 5] and *Radzikowska* and *Kerre* [26.9]. In those studies, an equivalence relation of approximation space in the original rough sets is generalized to a fuzzy equivalence relation. *Greco* et al. [26.7] proposed fuzzy rough sets under a fuzzy dominance relation. Those fuzzy rough sets are based on possibility and necessity measures directly. Moreover, this type of fuzzy rough sets is defined under more generalized settings [26.11, 15] and different types of fuzzy rough sets were proposed based on certainty qualifications by *Inuiguchi* and *Tanino* [26.10, 12] and also based on modifier functions by *Greco* et al. [26.24, 25]. The fuzzy rough set model can be used to deal with attribute reduction in information systems with fuzzy decision while the fuzzy rough set model can be employed in reasoning and knowledge acquisition with decision tables with real-valued conditional attributes or quantitative data (see, for example, [26.26–36]).

In the first part of this chapter, we introduce three models of fuzzy rough sets. Those fuzzy sets are classified into two groups, i.e., classification-oriented fuzzy rough set models and approximation-oriented fuzzy rough set models proposed by *Inuiguchi* [26.37] originally in the crisp settings. In the classification-oriented models, we are interested in a set to which objects belong. We evaluate each object whether its membership to a set  $X$  is consistent with all information we have at hand or not. The positive region of  $X$  is defined by collecting all objects whose memberships to  $X$  are consistent with whole information. The possible region of  $X$  is defined by collecting all objects whose memberships to  $X$  are conceivable from some part of information but not consistent with all information. Then the fuzzy rough set of  $X$  is defined by a pair of the positive and possible regions of  $X$ . On

the contrary, in approximation-oriented models, we are interested in the approximations of a set by using elementary sets of a family. We approximate a set  $X$  by unions of the elementary sets and by intersections of the complementary sets of the elementary sets. The lower and upper approximations are defined by the inner and outer approximations of  $X$ , respectively. A rough set of  $X$  is defined by a pair of the lower and upper approximations. We describe that one of the three models belongs to the group of classification-oriented models and the remaining two models belong to the group of approximation-oriented models.

Another important method used to deal with uncertainty in intelligent systems is the Dempster–Shafer theory of evidence [26.38]. Shafer's belief and plausibility functions are constructed under the assumption that the focal elements in the belief structure are all crisp. In some situations, it seems to be quite natural that the evidence mass may be assigned to a fuzzy subset of the universe of discourse. In fact, combining the Dempster–Shafer theory and fuzzy set theory has been suggested to be a way to deal with different kinds of uncertain information in intelligent systems in a number of studies. It is demonstrated that the lower and upper approximation operators in rough set theory have strong relationship with the belief and plausibility functions in the Dempster–Shafer theory of evidence [26.21, 23, 39–44]. The Dempster–Shafer theory of evidence may be used to analyze knowledge acquisition in information systems (see, for example, [26.45–49]).

In the second part of this chapter, we will explore the relationships between belief and plausibility functions in the Dempster–Shafer theory of evidence and the lower and upper approximations in rough set theory with their potential applications to intelligent information systems.

Both fuzzy set and rough set theories have fostered broad research communities and have been applied in a wide range of settings. More recently, this has also extended to the hybrid fuzzy rough set models. The third part of this chapter tries to give a sample of those applications, which are in particular numerous for machine learning but which also cover many other fields, like image processing, decision making, and information retrieval.

Note that we do not consider applications that simply involve a joint application of fuzzy sets and rough sets, like for instance a rough classifier that induces fuzzy rules. Rather, we focus on applications that specifically involve one of the fuzzy rough set models discussed in the previous sections.

This chapter is organized as follows. In the next section, three models of fuzzy rough sets are explained dividing into two groups. In Sect. 26.3, we introduce generalized fuzzy belief structures with ap-

plication in fuzzy information systems. In Sect. 26.4, we give an overview of the practical applications of fuzzy rough sets focusing on the machine-learning domain.

## 26.2 Classification- Versus Approximation-Oriented Fuzzy Rough Set Models

In this section, we review three kinds of fuzzy rough sets from classification-oriented and approximation-oriented points of view. Focusing on the membership of an object to a set  $X$  under the indiscernibility relation, the classical rough set defined by a pair of lower and upper approximations of a set  $X$  can be seen as a classifier of objects into three disjoint regions: positive, negative, and boundary regions of a set  $X$ . Namely, the lower approximation defines the positive region, the complement of the upper approximation defines the negative region and the difference between upper and lower approximations defines the boundary region. On the other hand, focusing on the approximations of  $X$  by means of elementary sets of the partition, the rough set of  $X$  defines the inner and outer approximations of  $X$ . Namely, the lower approximation defines the inner approximation and the upper approximation defines the outer approximation. Those two different views of rough sets give different definitions of rough sets in the generalized settings (see Inuiguchi [26.50]). In this section, we describe fuzzy rough sets in a generalized setting from those points of view and show the fundamental properties, differences, and similarities.

### 26.2.1 Classification-Oriented Fuzzy Rough Sets

#### Definitions in Crisp Setting

In this subsection, we define fuzzy rough sets under the interpretation of rough sets as classification of objects into positive, negative, and boundary regions of a set and describe their properties. As the introduction, we first describe the definitions of positive and possible regions of a set in the crisp setting. Let  $U$  be a set of all objects. Assume that we do not know objects which fit with a particular concept  $C$  but we have pieces of information that tell some objects fit with  $C$  and that the other objects do not fit. Let  $X \subseteq U$  be the set of objects which are supposed to fit with  $C$  in the information and  $U - X$  the set of objects which are sup-

posed not to fit with  $C$  in the information. On the other hand, there is knowledge about  $C$  expressed by a binary relation  $P \subseteq U \times U$ . Under the binary relation  $P$ , we presume  $y$  fits with  $C$  from facts  $(y, x) \in P$  and  $x$  fits with  $C$ .

Under this circumstance, we investigate credible members of  $X$  and plausible members of  $X$ . Objects whose membership to  $X$  is consistent with the knowledge can be understood as credible members of  $X$ , while objects whose membership to  $X$  is presumable from the information and the knowledge can be understood as plausible members. For convenience, we define  $P(x) = \{y \in U \mid (y, x) \in P\}$  which is the set of objects whose membership to  $X$  is presumed from the fact  $x \in X$ . Therefore, if  $x \in X$  satisfies  $\forall y \in P(x), y \in X$  or simply,  $P(x) \subseteq X$ ,  $x$  can be considered a credible member of  $X$ . Thus, the set of credible members of  $X$  is defined by

$$\begin{aligned} P_*(X) &= \{x \in X \mid P(x) \subseteq X\} \\ &= X \cap \{x \in U \mid P(x) \subseteq X\}. \end{aligned} \quad (26.1)$$

On the other hand, we may presume  $x \in X$  if  $x \in X$  or  $\exists y \in X, x \in P(y)$  under the information and the knowledge. Then the set of plausible members of  $X$  can be defined by

$$P^*(X) = X \cup \{x \in U \mid \exists y \in X, x \in P(y) \neq \emptyset\}. \quad (26.2)$$

$P_*(X)$  is called the positive region of  $X$  and  $P^*(X)$  is called the possible region of  $X$ . Moreover, we do not assume the reflexivity of  $P$ , i.e.,  $\forall x \in U, (x, x) \in P$ . This is why we take the intersection with  $X$  in the definition of  $P_*(X)$  and the union with  $X$  in the definition of  $P^*(X)$ . Those intersection and union can be dropped when  $P$  is reflexive.

When there is knowledge about  $C$  expressed by a binary relation  $Q \subseteq U \times U$  instead of  $P$ . Under the binary relation  $Q$ , we presume  $y$  does not fit with  $C$  from facts

$(y, x) \in Q$  and  $x$  does not fit with  $C$ . In this case, we directly obtain positive and possible regions of  $U - X$ , respectively, by

$$\begin{aligned} Q_*(U - X) &= \{x \in U - X \mid Q(x) \subseteq U - X\} \\ &= (U - X) \cap \{x \in U \mid Q(x) \subseteq U - X\}, \end{aligned} \quad (26.3)$$

$$\begin{aligned} Q^*(U - X) &= (U - X) \cup \{x \in U \mid \exists y \in U - X, \\ &\quad x \in Q(y) \neq \emptyset\}. \end{aligned} \quad (26.4)$$

Because an object that is not a member of  $Q_*(U - X)$  can be seen as a plausible member of  $X$  and an object which is not a member of  $Q^*(U - X)$  can be seen as a credible member of  $X$ , we may define positive and possible regions of  $X$  by

$$\begin{aligned} \bar{Q}_*(X) &= U - Q^*(U - X), \\ \bar{Q}^*(X) &= U - Q_*(U - X). \end{aligned} \quad (26.5)$$

Inuiguchi [26.50] investigated the properties of those positive and possible regions.

### Definitions in Fuzzy Setting and Their Properties

We now extend those definitions of positive and possible regions into the fuzzy setting. First, we assume a fuzzy set  $X \subseteq U$  and a fuzzy binary relation  $P \subseteq U \times U$  are given. Their membership functions  $\mu_X(x)$  and  $\mu_P(y, x)$  show the membership degree of  $x \in U$  to a fuzzy set  $X$  and the degree to what extent we presume that  $y$  is a member of  $X$  from the fact  $x$  is a member of a fuzzy set  $X$ , where  $\mu_X: U \rightarrow [0, 1]$  and  $\mu_P: U \times U \rightarrow [0, 1]$ . We define  $P(x)$  by its membership function  $\mu_{P(x)}(y) = \mu_P(y, x)$ .

To define the positive region under this circumstance, we should consider the consistency degree of the information that  $x$  is a member of  $X$  to membership degree  $\mu_X(x)$  with the knowledge  $P$ . This can be measured by the truth value of statement  $y \in P(x)$  implies  $y \in X$  under fuzzy sets  $P(x)$  and  $X$ . The truth value of this statement can be defined by a necessity measure  $\inf_{y \in U} I(\mu_{P(x)}(y), \mu_X(y))$  with an implication function  $I: [0, 1] \times [0, 1] \rightarrow [0, 1]$  such that  $I(0, 0) = I(0, 1) = I(1, 1) = 1$ ,  $I(1, 0) = 0$ ,  $I(\cdot, a)$  is decreasing for any  $a \in [0, 1]$  and  $I(a, \cdot)$  is increasing for any  $a \in [0, 1]$ . Therefore, in the analogy to (26.1), the membership function of the positive region  $P_*(X)$  of  $X$  can be

defined by

$$\begin{aligned} \mu_{P_*(X)}(x) &= \min \left( \mu_X(x), \inf_{y \in U} I(\mu_{P(x)}(y), \mu_X(y)) \right) \\ &= \min \left( \mu_X(x), \inf_{y \in U} I(\mu_P(y, x), \mu_X(y)) \right), \end{aligned} \quad (26.6)$$

where we note the intersection  $C \cap D$  of two fuzzy sets  $C, D \subseteq U$  is normally defined by  $\mu_{C \cap D}(x) = \min(\mu_C(x), \mu_D(x))$ ,  $\forall x \in U$ .  $\mu_{C \cap D}$ ,  $\mu_C$  and  $\mu_D$  are membership functions of  $C \cap D$ ,  $C$  and  $D$ . However, some researchers use  $t$ -norms [26.51] instead of the min operation. A  $t$ -norm  $t$  is a conjunction function  $t: [0, 1] \times [0, 1] \rightarrow [0, 1]$  such that (t1)  $\forall a \in [0, 1]$ ,  $t(a, 1) = t(1, a) = a$  (boundary condition), (t2)  $\forall a, b \in [0, 1]$ ,  $t(a, b) = t(b, a)$  (commutativity) and (t3)  $\forall a, b, c \in [0, 1]$ ,  $t(a, t(b, c)) = t(t(a, b), c)$  (associativity).

Now let us define the possible region when  $X$  and  $P$  are a fuzzy set and a fuzzy binary relation, respectively. To do this, we should define the truth value of statement *there exists*  $y \in X$  such that  $x \in P(y)$  under fuzzy sets  $X$  and  $P(x)$ . The truth value of this statement can be obtained by a possibility measure  $\sup_{y \in U} T(\mu_{P(y)}(x), \mu_X(y))$  with a conjunction function  $T: [0, 1] \times [0, 1] \rightarrow [0, 1]$  such that  $T(1, 1) = 1$ ,  $T(0, 0) = T(0, 1) = T(1, 0) = 0$  and  $T$  is increasing in both arguments. Therefore, in the analogy to (26.2), the membership function of the possible region  $P^*(X)$  of  $X$  can be defined by

$$\begin{aligned} \mu_{P^*(X)}(x) &= \max \left( \mu_X(x), \sup_{y \in U} T(\mu_{P(y)}(x), \mu_X(y)) \right) \\ &= \max \left( \mu_X(x), \sup_{y \in U} T(\mu_P(y, x), \mu_X(y)) \right), \end{aligned} \quad (26.7)$$

where we note the union  $C \cup D$  of two fuzzy sets  $C, D \subseteq U$  is normally defined by  $\mu_{C \cup D}(x) = \max(\mu_C(x), \mu_D(x))$ ,  $\forall x \in U$ .  $\mu_{C \cup D}$  is a membership functions of  $C \cup D$ . However, some researchers use  $t$ -conorms [26.51] instead of the max operation. A  $t$ -conorm  $s$  is a function  $s: [0, 1] \times [0, 1] \rightarrow [0, 1]$  such that (s1)  $\forall a \in [0, 1]$ ,  $s(a, 0) = s(0, a) = a$  (boundary condition), (s2)  $\forall a, b \in [0, 1]$ ,  $s(a, b) = s(b, a)$  (commutativity), (s3)  $\forall a, b, c \in [0, 1]$ ,  $s(a, s(b, c)) = s(s(a, b), c)$  (associativity), and (s4)  $\forall a, b, c, d$  such that  $a \geq c$  and  $b \geq d$ ;  $s(a, b) \geq s(c, d)$  (monotonicity).

Note that we do not assume the reflexivity of  $P$ , i.e.,  $\mu_P(x, x) = 1$ ,  $\forall x \in U$  so that we take the

minimum between  $\mu_X$  and  $\inf_{y \in U} I(\mu_{P(x)}(y), \mu_X(y))$  in Eq. (26.6) and the maximum between  $\mu_X$  and  $\sup_{y \in U} T(\mu_{P(y)}(x), \mu_X(y))$  in (26.7). When  $P$  is reflexive,  $I(1, a) \leq a$  and  $T(1, a) \geq a$  for all  $a \in [0, 1]$ , we have

$$\begin{aligned}\mu_{P^*(X)}(x) &= \inf_{y \in U} I(\mu_{P(x)}(y), \mu_X(y)), \\ \mu_{P^*(X)}(x) &= \sup_{y \in U} T(\mu_{P(y)}(x), \mu_X(y)).\end{aligned}\quad (26.8)$$

Those definitions of lower and upper approximations have been proposed by *Dubois* and *Prade* [26.4, 5] and *Radzikowska* and *Kerre* [26.9]. They assumed the reflexivity of  $P$  and  $I(1, a) = T(1, a) = a$ , for all  $a \in [0, 1]$ . Moreover, the definitions of (26.8) are used even when  $P$  is not reflexive and neither  $I$  nor  $T$  satisfy the boundary conditions  $I(1, a) = T(1, a) = a$ , for all  $a \in [0, 1]$  [26.15, 52]. In such generalized situation, we may loose the inclusiveness of  $P_*(X)$  in  $X$  and that of  $X$  in  $P^*(X)$  for  $P_*(X)$  and  $P^*(X)$  defined by (26.8). The definitions of  $P_*(X)$  and  $P^*(X)$  by (26.6) and (26.7) obtained from the interpretations of positive and possible regions of  $X$  satisfy the inclusiveness of  $P_*(X)$  in  $X$  and that of  $X$  in  $P^*(X)$  even in the generalized situation.

Using the positive region  $P_*(X)$  and the possible region  $P^*(X)$ , we can define a fuzzy rough set of  $X$  as a pair  $(P_*(X), P^*(X))$ . We can call such fuzzy rough sets as classification-oriented fuzzy rough sets under a positively extensive relation  $P$  of  $X$  (for short CP-fuzzy rough sets). Note that the relation  $P$  depends on the meaning of a set  $X$ . Thus, we cannot always define the CP-rough set of  $U - X$  by the same relation  $P$ .

To define a CP-rough set of  $U - X$ , we should introduce another fuzzy relation  $Q \subseteq U \times U$  such that  $\mu_{Q(x)}(y) = \mu_Q(y, x)$  represents the degree to what extent we presume an object  $y$  as a member of  $U - X$  from the fact  $x$  is a member of  $U - X$ , where  $\mu_Q: U \times U \rightarrow [0, 1]$  is a membership function of a fuzzy relation  $Q$ . In the same way, we define positive and possible regions of  $U - X$  under fuzzy relation  $Q$  by the following membership functions

$$\begin{aligned}\mu_{Q^*(U-X)}(x) &= \min \left( n(\mu_X(x)), \inf_{y \in U} I(\mu_Q(y, x), n(\mu_X(y))) \right), \\ (26.9)\end{aligned}$$

$$\begin{aligned}\mu_{Q^*(U-X)}(x) &= \max \left( n(\mu_X(x)), \sup_{y \in U} T(\mu_Q(x, y), n(\mu_X(y))) \right), \\ (26.10)\end{aligned}$$

where  $U - X$  is defined by a membership function  $n(\mu_X(\cdot))$  and  $n: [0, 1] \rightarrow [0, 1]$  is a strong negation which is a decreasing function such that  $n(n(a)) = a$ ,  $a \in [0, 1]$  (involutive). The involution implies the continuity of  $n$ .

Using  $Q_*(X)$  and  $Q^*(X)$ , in analogy to (26.5), we can define the positive region  $\bar{Q}_*(X)$  and the possible region  $\bar{Q}^*(X)$  of  $X$  by the following membership functions

$$\begin{aligned}\mu_{\bar{Q}_*(X)}(x) &= \min \left( \mu_X(x), \inf_{y \in U} n(T(\mu_Q(x, y), n(\mu_X(y)))) \right), \\ (26.11)\end{aligned}$$

$$\begin{aligned}\mu_{\bar{Q}^*(X)}(x) &= \max \left( \mu_X(x), \sup_{y \in U} n(I(\mu_Q(y, x), n(\mu_X(y)))) \right). \\ (26.12)\end{aligned}$$

We can define a fuzzy rough set of  $X$  as a pair  $(\bar{Q}_*(X), \bar{Q}^*(X))$  with the positive region  $\bar{Q}_*(X)$  and the possible region  $\bar{Q}^*(X)$ . We can call this type of rough sets as classification-oriented fuzzy rough sets under a negatively extensive relation  $Q$  of  $X$  (for short CN-fuzzy rough sets).

Let us discuss the properties of CP- and CN-fuzzy rough sets. By definition, we have

$$\begin{aligned}P_*(X) &\subseteq X \subseteq P^*(X), \\ \bar{Q}_*(X) &\subseteq X \subseteq \bar{Q}^*(X),\end{aligned}\quad (26.13)$$

$$P_*(\emptyset) = P^*(\emptyset) = \bar{Q}_*(\emptyset) = \bar{Q}^*(\emptyset) = \emptyset,\quad (26.14)$$

$$P_*(U) = P^*(U) = \bar{Q}_*(U) = \bar{Q}^*(U) = U,\quad (26.15)$$

$$P_*(X \cap Y) = P_*(X) \cap P_*(Y),\quad (26.16)$$

$$P^*(X \cup Y) = P^*(X) \cup P^*(Y),\quad (26.17)$$

$$\bar{Q}_*(X \cap Y) = \bar{Q}_*(X) \cap \bar{Q}_*(Y),\quad (26.18)$$

$$\bar{Q}^*(X \cup Y) = \bar{Q}^*(X) \cup \bar{Q}^*(Y),\quad (26.19)$$

$$X \subseteq Y \text{ implies } P_*(X) \subseteq P_*(Y),$$

$$X \subseteq Y \text{ implies } P^*(X) \subseteq P^*(Y),\quad (26.20)$$

$$X \subseteq Y \text{ implies } \bar{Q}_*(X) \subseteq \bar{Q}_*(Y),$$

$$X \subseteq Y \text{ implies } \bar{Q}^*(X) \subseteq \bar{Q}^*(Y),\quad (26.21)$$

where the inclusion relation between two fuzzy sets  $A$  and  $B$  is defined by  $\mu_A(x) \leq \mu_B(x)$ , for all  $x \in U$ .

The properties satisfied under some conditions are listed as follows (see *Inuiguchi* [26.37]):

- (1) When  $I(a, b) = n(T(a, n(b)))$ , for all  $a, b \in [0, 1]$  and  $Q$  is the converse of  $P$ , i.e.,  $\mu_Q(x, y) = \mu_P(y, x)$ , for all  $x, y \in U$ , we have

$$P_*(X) = U - Q^*(U - X) = \bar{Q}_*(X), \quad (26.22)$$

$$P^*(X) = U - Q_*(U - X) = \bar{Q}^*(X). \quad (26.23)$$

- (2) When  $T(a, I(a, b)) \leq b$  holds for all  $a, b \in [0, 1]$ , we have

$$X \supseteq P^*(P_*(X)) \supseteq P_*(X) \supseteq P_*(P_*(X)), \quad (26.24)$$

$$X \subseteq \bar{Q}_*(\bar{Q}^*(X)) \subseteq \bar{Q}^*(X) \subseteq \bar{Q}^*(\bar{Q}^*(X)). \quad (26.25)$$

- (3) When  $I(a, T(a, b)) \geq b$  holds for all  $a, b \in [0, 1]$ , we have

$$X \subseteq P_*(P^*(X)) \subseteq P^*(X) \subseteq P^*(P^*(X)), \quad (26.26)$$

$$X \supseteq \bar{Q}^*(\bar{Q}_*(X)) \supseteq \bar{Q}_*(X) \supseteq \bar{Q}_*(\bar{Q}_*(X)). \quad (26.27)$$

- (4) Let  $P$  and  $Q$  be  $T'$ -transitive. The following assertions are valid:

- (a) When  $I$  is upper semicontinuous and satisfies  $I(a, I(b, c)) = I(T'(b, a), c)$  for all  $a, b, c \in [0, 1]$ , we have

$$P_*(P_*(X)) = P_*(X), \quad \bar{Q}^*(\bar{Q}^*(X)) = \bar{Q}^*(X). \quad (26.28)$$

- (b) When  $T = T'$  is lower semicontinuous and satisfies  $T(a, T(b, c)) = T(T(a, b), c)$  for all  $a, b, c \in [0, 1]$  (associativity), we have

$$P^*(P^*(X)) = P^*(X), \quad \bar{Q}_*(\bar{Q}_*(X)) = \bar{Q}_*(X). \quad (26.29)$$

- (5) When  $P$  and  $Q$  are reflexive and  $T$ -transitive, the following assertions are valid:

- (a) If  $I(a, \cdot)$  is upper semicontinuous,  $I(1, a) \leq a$ , and  $T = \xi[I]$  is associative, then we have

$$P^*(P_*(X)) = P_*(X), \quad \bar{Q}_*(\bar{Q}^*(X)) = \bar{Q}^*(X). \quad (26.30)$$

- (b) If  $I(a, b) = n(\xi[I](a, n(b)))$  and the conditions of (a) are satisfied, then we have

$$P_*(P^*(X)) = P^*(X), \quad \bar{Q}^*(\bar{Q}_*(X)) = \bar{Q}_*(X). \quad (26.31)$$

Here a fuzzy relation  $P$  is said to be  $T'$ -transitive, if and only if  $P$  satisfies  $\mu_P(x, z) \geq T'(\mu_P(x, y), \mu_P(y, z))$  for all  $x, y, z \in U$  and for a conjunction function  $T'$ . We can generate a function  $\xi[I]: [0, 1] \times [0, 1] \rightarrow [0, 1]$  by  $\xi[I](a, b) = \inf\{s \in [0, 1] \mid I(a, s) \geq b\}$  when a function  $I: [0, 1] \times [0, 1] \rightarrow [0, 1]$  is given.  $\xi[I]$  is a conjunction function when  $I$  satisfies  $I(1, a) < 1$  for all  $a \in [0, 1]$ .

Concerning to the assumption of (1), it is known that a function  $I'$  defined by  $I'(a, b) = n(T(a, n(b)))$  is an implication function and that a function  $T'$  defined by  $T'(a, b) = n(I(a, n(b)))$  is a conjunction function (see, for example, *Inuiguchi* and *Sakawa* [26.51, 53]). The assumption of (2) corresponds to modus ponens, i.e.,  $A$  and  $(A \rightarrow B)$  implies  $B$ . Therefore, it is a natural assumption. However, this cannot hold for any implication and conjunction functions. For example, consider functions  $T(a, b) = \min(a, b)$  and  $I(a, b) = \max(1 - a, b)$  which are often used in possibility theory.  $T(a, I(a, b)) \leq b$  does not always hold. On the other hand, the assumption holds for any  $T$  and  $I$  such that  $T(a, b) \leq \min(a, b)$  for all  $a, b \in [0, 1]$  and  $I(a, b) \leq b$  for all  $a, b \in [0, 1]$  satisfying  $a > b$ . Thus, a  $t$ -norm  $T$  and a residual implication  $I$  of a  $t$ -norm satisfies the assumption, i.e.,  $I$  is defined by  $I(a, b) = \sup\{s \in [0, 1] \mid t(a, s) \leq b\}$ , for  $a, b \in [0, 1]$ . The assumption of (3) is dual with that of (2). Namely, for any implication function  $I$ , there exists a conjunction function  $T'$  such that  $I(a, b) = n(T'(a, n(b)))$ , and for any conjunction function  $T$ , there exists an implication function  $I'$  such that  $T(a, b) = n(I'(a, n(b)))$ . Using  $T'$  and  $I'$ , the assumption  $I(a, T(a, b)) \geq b$  is equivalent to  $T'(a, I'(a, b)) \leq b$  which is the same as the assumption of (2).

The assumption of (3) is satisfied with  $I$  and  $T$  such that  $I(a, b) \geq \max(n(a), b)$  for all  $a, b \in [0, 1]$  and  $T(a, b) \geq b$  for all  $a, b \in [0, 1]$  satisfying  $a > n(b)$ . The assumption of (4)-(a) is satisfied with residual implication functions of lower semicontinuous  $t$ -norms  $T'$  and S-implication functions with respect to lower semicontinuous  $t$ -norms  $T'$ , where an S-implication function  $I$  with respect to the  $t$ -norm  $T'$  is defined by  $I(a, b) = n(T'(a, n(b)))$ ,  $a, b \in [0, 1]$  with a strong negation  $n$ . The assumption of (4)-(b) is satisfied with lower semicontinuous  $t$ -norms  $T$ . These assumptions are satisfied with a lot of famous implication and conjunction functions.

## 26.2.2 Approximation-Oriented Fuzzy Rough Sets

### Definitions in Crisp Setting

In this section, we define fuzzy rough sets under the interpretation of rough sets as approximation of sets and describe their properties. We first describe the definitions of lower and upper approximations in the crisp setting. We assume a family of subsets in  $U$ ,  $\mathcal{F} = \{F_i \mid i = 1, 2, \dots, p\}$  is given. Each elementary set  $F_i$  is a meaningful set of objects such as a set of objects satisfying some properties.  $F_i$ s can be seen as information granules with which we would like to express a set of objects. Given a set  $X \subseteq U$ , an understated expression of  $X$ , or in other words, an inner approximation of  $X$  by means of unions of  $F_i$ s is obtained by

$$\mathcal{F}_*^{\cup}(X) = \bigcup \{F_i \in \mathcal{F} \mid F_i \subseteq X\}. \quad (26.32)$$

On the other hand, an overstated expression of  $X$ , or in other words, an outer approximation of  $X$  by means of unions of  $F_i$ s is obtained by

$$\begin{aligned} \mathcal{F}_*^{\cup}(X) &= \bigcap \left\{ \bigcup_{i \in J} F_i \mid \bigcup_{i \in J} F_i \supseteq X, \right. \\ &\quad \left. J \subseteq \{1, 2, \dots, p, \circ\} \right\}, \end{aligned} \quad (26.33)$$

where we define  $F_\circ = U$ . We add  $F_\circ$  considering cases where there is no  $J \subseteq \{1, 2, \dots, p\}$  such that  $\bigcup_{i \in J} F_i \supseteq X$ . In such cases, we obtain  $\mathcal{F}_*^{\cup}(X) = U$  owing to the existence of  $F_\circ = U$ .  $\mathcal{F}_*^{\cup}(X)$  and  $\mathcal{F}_*^{\cup}(X)$  are called lower and upper approximations of  $X$ , respectively.

Applying those approximations to  $U - X$ , we obtain  $\mathcal{F}_*^{\cup}(U - X)$  and  $\mathcal{F}_*^{\cup}(U - X)$ . From those, we obtain

$$\begin{aligned} \mathcal{F}_*^{\cap}(X) &= U - \mathcal{F}_*^{\cup}(U - X) \\ &= \bigcup \left\{ U - \bigcup_{i \in J} F_i \mid \bigcup_{i \in J} F_i \supseteq U - X, \right. \\ &\quad \left. J \subseteq \{1, 2, \dots, p, \circ\} \right\}, \end{aligned} \quad (26.34)$$

$$\begin{aligned} \mathcal{F}_*^{\cap}(X) &= U - \mathcal{F}_*^{\cup}(U - X) \\ &= \bigcap \{U - F_i \mid F_i \subseteq U - X, \\ &\quad i \in \{1, 2, \dots, p, \bullet\}\}, \end{aligned} \quad (26.35)$$

where we define  $F_\bullet = \emptyset$ . We note that  $\mathcal{F}_*^{\cap}(X)$  and  $\mathcal{F}_*^{\cap}(X)$  are not always the same as  $\mathcal{F}_*^{\cup}(X)$  and  $\mathcal{F}_*^{\cup}(X)$ ,

respectively. The properties of those lower and upper approximations are studied by Inuiguchi [26.50].

### Definitions by Certainty Qualifications in Fuzzy Setting

We extend those lower and upper approximations to cases where  $\mathcal{F}$  is a family of fuzzy sets in  $U$  and  $X$  is a fuzzy set in  $U$ . To do this, we extend the intersection, union, complement, and the inclusion relation into the fuzzy setting. The intersection, union, and complement are defined by the min operation, the max operation and a strong negation  $n$ , i. e.,  $C \cap D$ ,  $C \cup D$  and  $U - C$  for fuzzy sets  $C$  and  $D$  are defined by membership functions  $\mu_{C \cap D}(x) = \min(\mu_C(x), \mu_D(x))$ ,  $\forall x \in C$ ,  $\mu_{C \cup D}(x) = \max(\mu_C(x), \mu_D(x))$ ,  $\forall x \in C$ ,  $\mu_{U - C}(x) = n(\mu_C(x))$ ,  $\forall x \in C$ , respectively. The inclusion relation  $C \subseteq D$  is extended to inclusion relation with degree  $Inc(C, D) = \inf_x I(\mu_C(x), \mu_D(x))$ , where  $I$  is an implication function.

First let us define a lower approximation by extending (26.32). In (26.32), before applying the union, we collect  $F_i$  such that  $F_i \subseteq X$ . This procedure cannot be extended simply into the fuzzy setting, because the inclusion relation has a degree showing to what extent the inclusion holds in the fuzzy setting. Namely, each  $F_i$  has a degree  $q_i = Inc(F_i, X)$ . This means that  $X$  includes  $F_i$  to a degree  $q_i$ . Therefore, by using  $F_i$ ,  $X$  is expressed as a fuzzy set including  $F_i$  to a degree  $q_i$ . In other words,  $X$  is a fuzzy set  $Y$  satisfying

$$Inc(F_i, Y) = \inf_x I(\mu_{F_i}(x), \mu_Y(x)) = q_i. \quad (26.36)$$

We note that there exists a solution satisfying (26.36) because  $q_i$  is defined by  $Inc(F_i, X)$ . There can be many solutions  $Y$  satisfying (26.36) and the intersection and union of those solutions can be seen as inner and outer approximations of  $X$  by  $F_i$ . Because we are now extending (26.32) and interested in the lower approximation, we consider the intersection of fuzzy sets including  $F_i$  to a degree  $q_i$ . Let us consider

$$Inc(F_i, Y) = \inf_x I(\mu_{F_i}(x), \mu_Y(x)) \geq q_i, \quad (26.37)$$

instead of (26.36). Equation (26.37) is called a converse-certainty qualification [26.10] (or possibility-qualification). Because  $I(a, \cdot)$  is increasing for any  $a \in [0, 1]$  for an implication function  $I$  and (26.36) has a solution, the intersection of solutions of (26.36) is the same as the intersection of solutions of (26.37). Moreover, because  $I$  is upper semicontinuous, we obtain the intersection of solutions of (26.37) as the smallest solution  $\check{Y}$  of (26.37) defined by the following membership

function

$$\begin{aligned}\mu_{\tilde{Y}}(x) &= \inf\{s \in [0, 1] \mid I(\mu_{F_i}(x), s) \geq q_i\} \\ &= \xi[I](\mu_{F_i}(x), q_i).\end{aligned}\quad (26.38)$$

We have  $\tilde{Y} \subseteq X$ . Because we have many  $F_i \in \mathcal{F}$ , the lower approximation  $\mathcal{F}_*^\xi(X)$  of  $X$  is defined by the following membership function

$$\begin{aligned}\mu_{\mathcal{F}_*^\xi(X)}(x) &= \sup_{F \in \mathcal{F}} \xi[I]\left(\mu_F(x), \inf_{y \in U} I(\mu_F(y), \mu_X(y))\right),\end{aligned}\quad (26.39)$$

where  $\mathcal{F}$  can have infinitely many elementary fuzzy sets  $F$ .

Because (26.32) is extended to (26.39), (26.35) is extended to the following equation in the sense that  $\mathcal{F}_*^\xi(X) = U - F_*^\xi(U - X)$

$$\begin{aligned}\mu_{\mathcal{F}_*^\xi(X)}(x) &= \inf_{F \in \mathcal{F}} n\left(\xi[I]\left(\mu_F(x), \inf_{y \in U} I(\mu_F(y), n(\mu_X(y)))\right)\right),\end{aligned}\quad (26.40)$$

where  $\mu_{\mathcal{F}_*^\xi(X)}$  is the membership function of the upper approximation  $\mathcal{F}_*^\xi(X)$  of  $X$ .

Now let us consider the extension of (26.33). In this case, before applying the intersection, we collect  $\bigcup_{i \in J} F_i$  such that  $\bigcup_{i \in J} F_i \supseteq X$ . In the fuzzy setting, each  $\bigcup_{i \in J} F_i$  has a degree  $r_J = \text{Inc}(X, \bigcup_{i \in J} F_i)$ . This means that  $X$  is included in  $\bigcup_{i \in J} F_i$  to a degree  $r_J$ . Therefore, by using  $F_i$ ,  $i \in J$ ,  $X$  is expressed as a fuzzy set included in  $\bigcup_{i \in J} F_i$  to a degree  $r_J$ . In other words,  $X$  is a fuzzy set  $Y$  satisfying

$$\begin{aligned}\text{Inc}\left(Y, \bigcup_{i \in J} F_i\right) &= \inf_x I\left(\mu_Y(x), \max_{i \in J} \mu_{F_i}(x)\right) \\ &= r_J.\end{aligned}\quad (26.41)$$

We note that there exists a solution satisfying (26.41) because  $r_J$  is defined by  $\text{Inc}(X, \bigcup_{i \in J} F_i)$ . There can be many solutions  $Y$  satisfying (26.41) and the intersection and union of those solutions can be seen as inner and outer approximations of  $X$  by  $\bigcup_{i \in J} F_i$ . Because we are now extending (26.33) and interested in the upper approximation, we consider the union of fuzzy sets in-

cluding  $\bigcup_{i \in J} F_i$  to a degree  $r_J$ . Let us consider

$$\begin{aligned}\text{Inc}\left(Y, \bigcup_{i \in J} F_i\right) &= \inf_x I\left(\mu_Y(x), \max_{i \in J} \mu_{F_i}(x)\right) \\ &\geq r_J,\end{aligned}\quad (26.42)$$

instead of (26.41). Equation (26.42) is called a certainty qualification [26.10, 54]. Because  $I(\cdot, a)$  is decreasing for any  $a \in [0, 1]$  for an implication function  $I$  and (26.41) has a solution, the union of solutions of (26.41) is the same as the union of solutions of (26.42). Moreover, because  $I$  is upper semicontinuous, we obtain the union of solutions of (26.42) as the greatest solution  $\hat{Y}$  of (26.42) defined by the following membership function

$$\begin{aligned}\mu_{\hat{Y}}(x) &= \sup\left\{s \in [0, 1] \mid I\left(s, \max_{i \in J} \mu_{F_i}(x)\right) \geq q_i\right\} \\ &= \sigma[I]\left(r_J, \max_{i \in J} \mu_{F_i}(x)\right),\end{aligned}\quad (26.43)$$

where we define  $\sigma[I](a, b) = \sup\{s \in [0, 1] \mid I(s, b) \geq a\}$  for  $a, b \in [0, 1]$ . We have  $X \subseteq \hat{Y}$ . Because we have many  $\bigcup_{i \in J} F_i$ , the upper approximation  $\mathcal{F}_*^\sigma(X)$  of  $X$  is defined by the following membership function

$$\begin{aligned}\mu_{\mathcal{F}_*^\sigma(X)}(x) &= \inf_{\mathcal{T} \subseteq \mathcal{F}} \sigma[I]\left(\inf_{y \in U} I\left(\mu_X(y), \sup_{F \in \mathcal{T}} \mu_F(y)\right),\right. \\ &\quad \left.\sup_{F \in \mathcal{T}} \mu_F(x)\right),\end{aligned}\quad (26.44)$$

where  $\mathcal{F}$  can have infinitely many elementary fuzzy sets  $F$ . We note that  $\sigma[I]$  becomes an implication function.

Because (26.33) is extended to (26.44), (26.34) is extended to the following equation in the sense that  $\mathcal{F}_*^\sigma(X) = U - F_*^\sigma(U - X)$

$$\begin{aligned}\mu_{\mathcal{F}_*^\sigma(X)}(x) &= \sup_{\mathcal{T} \subseteq \mathcal{F}} n\left(\sigma[I]\left(\inf_{y \in U} I\left(n(\mu_X(y)), \sup_{F \in \mathcal{T}} \mu_F(y)\right),\right.\right. \\ &\quad \left.\left.\sup_{F \in \mathcal{T}} \mu_F(x)\right)\right),\end{aligned}\quad (26.45)$$

where  $\mu_{\mathcal{F}_*^\sigma(X)}$  is the membership function of the upper approximation  $\mathcal{F}_*^\sigma(X)$  of  $X$ .

These four approximations were originally proposed by *Inuiguchi* and *Tanino* [26.10]. They selected a pair  $(\mathcal{F}_*^\xi(X), \mathcal{F}_*^*(X))$  to define a rough set of  $X$ . However, in connection with the crisp case, *Inuiguchi* [26.37] selected pairs  $(\mathcal{F}_*^\xi(X), \mathcal{F}_*^*(X))$  and  $(\mathcal{F}_*^\sigma(X), \mathcal{F}_*^*(X))$  for the definitions of rough sets of  $X$ . In this chapter, a pair  $(\mathcal{F}_*^\xi(X), \mathcal{F}_*^*(X))$  is called a  $\xi$ -fuzzy rough set and a pair  $(\mathcal{F}_*^\sigma(X), \mathcal{F}_*^*(X))$  a  $\sigma$ -fuzzy rough set.

### Properties

First, we show properties about the representations of lower and upper approximations defined by (26.39), (26.40), (26.44), and (26.45). We have the following equalities (see *Inuiguchi* [26.37])

$$\mu_{\mathcal{F}_*^\xi(X)}(x) = \sup\{\xi[I](\mu_F(x), h) \mid F \in \mathcal{F}, h \in [0, 1]\}$$

such that

$$\xi[I](\mu_F(y), h) \leq \mu_X(y), \forall y \in U, \quad (26.46)$$

$$\mu_{\mathcal{F}_*^\sigma(X)}(x) = \sup \left\{ n \left( \sigma[I] \left( h, \sup_{F \in \mathcal{T}} \mu_F(x) \right) \right) \mid \right.$$

$$\mathcal{T} \subseteq \mathcal{F}, h \in [0, 1]$$

such that

$$\sigma[I] \left( h, \sup_{F \in \mathcal{T}} \mu_F(y) \right) \geq n(\mu_X(y)), \forall y \in U \}, \quad (26.47)$$

$$\mu_{\mathcal{F}_*^*(X)}(x) = \inf \{ n(\xi[I](\mu_F(x), h)) \mid$$

$$F \in \mathcal{F}, h \in [0, 1]\}$$

such that

$$\xi[I](\mu_F(y), h) \leq n(\mu_X(y)), \forall y \in U \}, \quad (26.48)$$

$$\mu_{\mathcal{F}_*^*(X)}(x)$$

$$= \inf \left\{ \sigma[I] \left( h, \sup_{F \in \mathcal{T}} \mu_F(x) \right) \mid \mathcal{T} \subseteq \mathcal{F}, h \in [0, 1] \right\}$$

such that

$$\sigma[I] \left( h, \sup_{F \in \mathcal{T}} \mu_F(y) \right) \geq \mu_X(y), \forall y \in U \}. \quad (26.49)$$

Using these equations, the following properties can be easily obtained:

$$\mathcal{F}_*^\xi(X) \subseteq X \subseteq \mathcal{F}_*^*(X),$$

$$\mathcal{F}_*^\sigma(X) \subseteq X \subseteq \mathcal{F}_*^*(X), \quad (26.50)$$

$$\mathcal{F}_*^\xi(\emptyset) = \mathcal{F}_*^*(\emptyset) = \emptyset,$$

$$\mathcal{F}_*^*(U) = \mathcal{F}_*^\sigma(U) = U, \quad (26.51)$$

$$X \subseteq Y \text{ implies } \mathcal{F}_*^\xi(X) \subseteq \mathcal{F}_*^\xi(Y),$$

$$X \subseteq Y \text{ implies } \mathcal{F}_*^\sigma(X) \subseteq \mathcal{F}_*^\sigma(Y), \quad (26.52)$$

$$X \subseteq Y \text{ implies } \mathcal{F}_*^*(X) \subseteq \mathcal{F}_*^*(Y),$$

$$X \subseteq Y \text{ implies } \mathcal{F}_*^\sigma(X) \subseteq \mathcal{F}_*^*(Y), \quad (26.53)$$

$$\mathcal{F}_*^\xi(X \cup Y) \supseteq \mathcal{F}_*^\xi(X) \cup \mathcal{F}_*^\xi(Y),$$

$$\mathcal{F}_*^\sigma(X \cup Y) \supseteq \mathcal{F}_*^\sigma(X) \cup \mathcal{F}_*^\sigma(Y), \quad (26.54)$$

$$\mathcal{F}_*^*(X \cap Y) \subseteq \mathcal{F}_*^*(X) \cap \mathcal{F}_*^*(Y),$$

$$\mathcal{F}_*^\sigma(X \cap Y) \subseteq \mathcal{F}_*^\sigma(X) \cap \mathcal{F}_*^\sigma(Y), \quad (26.55)$$

$$\mathcal{F}_*^\xi(U - X) = U - \mathcal{F}_*^*(X),$$

$$\mathcal{F}_*^\sigma(U - X) = U - \mathcal{F}_*^*(X). \quad (26.56)$$

Furthermore, we can prove the following properties (see *Inuiguchi* [26.37]):

(7) The following assertions are valid:

(a) If  $a > 0, b < 1$  imply  $I(a, b) < 1$  and

$$\inf_{x \in U} \sup_{F \in \mathcal{F}} \mu_F(x) > 0,$$

then we have

$$\mathcal{F}_*^\xi(U) = U \text{ and } \mathcal{F}_*^*(\emptyset) = \emptyset.$$

(b) If  $b < 1$  implies  $I(1, b) < 1$  and

$$\inf_{x \in U} \sup_{F \in \mathcal{F}} \mu_F(x) = 1,$$

then we have

$$\mathcal{F}_*^*(U) = U \text{ and } \mathcal{F}_*^\xi(\emptyset) = \emptyset.$$

(c) If  $a > 0, b < 1$  imply  $I(a, b) < 1$  and  $\forall x \in U, \exists F \in \mathcal{F}$  such that  $\mu_F(x) < 1$ , then we have  $\mathcal{F}_*^\sigma(U) = U$  and  $\mathcal{F}_*^*(\emptyset) = \emptyset$ .

(d) If  $a > 0$  implies  $I(a, 0) < 1$  and  $\forall x \in U, \exists F \in \mathcal{F}$  such that  $\mu_F(x) = 0$ , then we have  $\mathcal{F}_*^\sigma(U) = U$  and  $\mathcal{F}_*^*(\emptyset) = \emptyset$ .

(8) We have

$$\mathcal{F}_*^\sigma(X \cap Y) = \mathcal{F}_*^\sigma(X) \cap \mathcal{F}_*^\sigma(Y),$$

$$\mathcal{F}_*^*(X \cup Y) = \mathcal{F}_*^*(X) \cup \mathcal{F}_*^*(Y). \quad (26.57)$$

Moreover, if  $\forall a \in [0, 1], I(a, a) = 1$  and  $\forall F_i, F_j \in \mathcal{F}, F_i \neq F_j, F_i \cap F_j = \emptyset$ , we have

$$\mathcal{F}_*^\xi(X \cap Y) = \mathcal{F}_*^\xi(X) \cap \mathcal{F}_*^\xi(Y),$$

$$\mathcal{F}_*^*(X \cup Y) = \mathcal{F}_*^*(X) \cup \mathcal{F}_*^*(Y). \quad (26.58)$$

(9) We have

$$\begin{aligned}\mathcal{F}_*^\xi(\mathcal{F}_*^\xi(X)) &= \mathcal{F}_*^\xi(X), \\ \mathcal{F}_*^\sigma(\mathcal{F}_*^\sigma(X)) &= \mathcal{F}_*^\sigma(X),\end{aligned}\quad (26.59)$$

$$\begin{aligned}\mathcal{F}_*^*(\mathcal{F}_*^*(X)) &= \mathcal{F}_*^*(X), \\ \mathcal{F}_*^*(\mathcal{F}_*^\sigma(X)) &= \mathcal{F}_*^\sigma(X).\end{aligned}\quad (26.60)$$

*Inuiguchi and Tanino* [26.10] first proposed this type of fuzzy rough sets. They demonstrated the advantage in approximation when  $P$  is reflexive and symmetric,  $I$  is Dienes implication, and  $T$  is minimum operation. *Inuiguchi and Tanino* [26.55] showed that by selection of a necessity measure expressible various inclusion situations, the approximations become better, i.e., the differences between lower and upper approximations satisfying (26.58) become smaller. Moreover, *Inuiguchi and Tanino* [26.56] applied these fuzzy rough sets to function approximation.

### 26.2.3 Relations Between Two Kinds of Fuzzy Rough Sets

Under the given fuzzy relations  $P$  and  $Q$  described in Sect. 26.2.1, we discuss the relations between two kinds of fuzzy rough sets. Families of fuzzy sets are defined by  $\mathcal{P} = \{P(x) \mid x \in U\}$  and  $\mathcal{Q} = \{Q(x) \mid x \in U\}$ . We have the following assertions:

(10) When  $P$  and  $Q$  are reflexive,  $I(1, a) = a$ , we have

$$P_*(X) \subseteq P_*^\xi(X), \quad Q_*^*(X) \subseteq \bar{Q}^*(X). \quad (26.61)$$

(11) When  $P$  and  $Q$  are reflexive,  $X$  is a crisp set,  $a \leq b$  if and only if  $I(a, b) = 1$  and  $T(a, 1) = a$  for all  $a \in [0, 1]$ , we have

$$P_\sigma^*(X) \subseteq P^*(X), \quad \bar{Q}_*(X) \subseteq Q_*^\sigma(X). \quad (26.62)$$

(12) When  $P$  and  $Q$  are  $T$ -transitive, the following assertions are valid:

(a) When  $T = \xi[I]$  is associative, we have

$$P_*^\xi(X) \subseteq P_*(X), \quad \bar{Q}^*(X) \subseteq Q_*^*(X). \quad (26.63)$$

(b) When  $T = \xi[\sigma[I]]$  and  $\sigma[I](a, \sigma[I](b, c)) = \sigma[I](b, \sigma[I](a, c))$  for all  $a, b, c \in [0, 1]$ , we have

$$P^*(X) \subseteq P_\sigma^*(X), \quad Q_*^\sigma(X) \subseteq \bar{Q}_*(X). \quad (26.64)$$

Here we define

$$\zeta[T](a, b) = \sup\{s \in [0, 1] \mid T(a, s) \leq b\}.$$

This functional  $\zeta$  can produce an implication function from a conjunction function  $T$ . Note that  $\zeta[\xi[I]] = I$  and  $\xi[\zeta[T]] = I$  for upper semicontinuous  $I$  and lower semicontinuous  $T$  (see *Inuiguchi and Sakawa* [26.53]).

### 26.2.4 The Other Approximation-Oriented Fuzzy Rough Sets

*Greco et al.* [26.24, 25] proposed fuzzy rough sets corresponding to a gradual rule [26.57], *the more an object is in  $G$ , the more it is in  $X$*  with fuzzy sets  $G$  and  $X$ . Corresponding to this gradual rule, we may define the lower approximation  $G_*^+(X)$  of  $X$  and the upper approximation  $G_*^-(X)$  of  $X$ , respectively, by the following membership functions

$$\mu_{G_*^+(X)}(x) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) \geq \mu_G(x)\}, \quad (26.65)$$

$$\mu_{G_*^-(X)}(x) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) \leq \mu_G(x)\}. \quad (26.66)$$

When we have a gradual rule, *the less an object is in  $G$ , the more it is in  $X$* , we define the lower approximation  $G_*^-(X)$  of  $X$  and the upper approximation  $G_*^+(X)$  of  $X$ , respectively, by the following membership functions

$$\mu_{G_*^-(X)}(x) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) \leq \mu_G(x)\}, \quad (26.67)$$

$$\mu_{G_*^+(X)}(x) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) \geq \mu_G(x)\}. \quad (26.68)$$

Moreover, when a complex gradual rule, *the more an object is in  $G^+$  and the less it is in  $G^-$ , the more it is in  $X$*  is given, the lower approximation  $G_*^\pm(X)$  and upper approximation  $G_*^\pm(X)$  are defined, respectively, by the following equations

$$\begin{aligned}\mu_{G_*^\pm(X)}(x) &= \inf\{\mu_X(z) \mid z \in U, \mu_G^+(z) \geq \mu_G^+(x), \\ \mu_G^-(z) &\leq \mu_G^-(x)\},\end{aligned}\quad (26.69)$$

$$\begin{aligned}\mu_{G_*^\pm(X)}(x) &= \sup\{\mu_X(z) \mid z \in U, \mu_G^+(z) \leq \mu_G^+(x), \\ \mu_G^-(z) &\geq \mu_G^-(x)\},\end{aligned}\quad (26.70)$$

where we define  $G = \{G^+, G^-\}$ .

The fuzzy rough sets are defined by pairs of those lower and upper approximations. This approach is advantageous in (i) no logical connectives such as implication function, conjunction function, etc., are used

and (ii) the fuzzy rough sets correspond to gradual rules (see Greco et al. [26.24, 25]). However, we need a background knowledge about the monotone properties between  $G$  (or  $\mathcal{G}$ ) and  $X$ .

This approach can be seen from a viewpoint of modifier functions of fuzzy sets. A modifier function  $\varphi$  is generally a function from  $[0, 1]$  to  $[0, 1]$  [26.58]. Functions defined by  $\varphi_1(x) = x^2$ ,  $\varphi_2(x) = \sqrt{x}$  and  $\varphi_3(x) = 1 - x$  are known as modifier functions corresponding to modifying words *very*, *more*, *or less* and *not*. Namely, given a fuzzy set  $A$ , we may define fuzzy sets *very A*, *more or less A* and *not-A* by the following membership functions

$$\begin{aligned}\mu_{\text{very } A}(x) &= (\mu_A(x))^2, \\ \mu_{\text{more or less } A}(x) &= \sqrt{\mu_A(x)}, \\ \mu_{\text{not-}A}(x) &= 1 - \mu_A(x).\end{aligned}\quad (26.71)$$

Such modifier functions are often used in approximate/fuzzy reasoning [26.59, 60], especially in the indirect method of fuzzy reasoning which is called also, truth value space method.

Namely, we may define the lower approximation  $\Phi_*(X)$  of  $X$  and the upper approximation  $\Phi^*(X)$  of  $X$  by means of a fuzzy set  $G$  by the following membership functions

$$\begin{aligned}\mu_{\Phi_*(X)}(x) &= \varphi_*^{G \rightarrow X}(\mu_G(x)), \\ \mu_{\Phi^*(X)}(x) &= \varphi_{G \rightarrow X}^*(\mu_G(x)),\end{aligned}\quad (26.72)$$

where  $\Phi = \{\varphi_*^{G \rightarrow X}, \varphi_{G \rightarrow X}^*\}$  and modifier functions  $\varphi_*^{G \rightarrow X}$  and  $\varphi_{G \rightarrow X}^*$  are selected to satisfy

$$\begin{aligned}\varphi_*^{G \rightarrow X}(\mu_G(x)) &\leq \mu_X(x), \\ \varphi_{G \rightarrow X}^*(\mu_G(x)) &\geq \mu_X(x), \quad \forall x \in U.\end{aligned}\quad (26.73)$$

Indeed,

$$\xi[I](\cdot, \inf_{y \in U} I(\mu_G(y), \mu_X(y)))$$

and

$$\sigma[I](\inf_{y \in U} I(\mu_X(y), \mu_G(y)), \cdot)$$

are modifier functions satisfying (26.73) and these are used to define  $\mathcal{F}_*^\xi(X)$  and  $\mathcal{F}_\sigma^*(X)$  in (26.39) and (26.44), respectively. We note that we consider multiple fuzzy sets  $G = F \in \mathcal{F}$  in (26.39) and apply the union because we have

$$\xi[I](\mu_G, \inf_{y \in U} I(\mu_G(y), \mu_X(y))) \leq \mu_X(x),$$

$\forall x \in U$  for all  $G \in \mathcal{F}$ .

Similarly we consider multiple fuzzy sets  $G$  defined by  $\mu_G(x) = \sup_{F \in \mathcal{F} \subseteq \mathcal{F}} \mu_F(x)$ ,  $x \in U$  in (26.44) and we apply the intersection because we have  $\sigma[I](\inf_{y \in U} I(\mu_G(y), \mu_X(y)), \mu_G(x)) \geq \mu_X(x)$ ,  $\forall x \in U$  for all those fuzzy sets  $G$ .

In the definitions of (26.65)–(26.68), the following modifier functions are used, respectively

$$\varphi_*^+(\alpha) = \sup\{\psi_*^+(\beta) \mid \beta \in [0, \alpha]\},$$

$$\varphi_+^*(\alpha) = \inf\{\psi_+^*(\beta) \mid \beta \in [\alpha, 1]\}, \quad (26.74)$$

$$\varphi_*^-(\alpha) = \sup\{\psi_*^-(\beta) \mid \beta \in [\alpha, 1]\},$$

$$\varphi_-^*(\alpha) = \inf\{\psi_-^*(\beta) \mid \beta \in [0, \alpha]\}, \quad (26.75)$$

where we define

$$\psi_*^+(\alpha) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) \geq \alpha\}, \quad (26.76)$$

$$\psi_+^*(\alpha) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) \leq \alpha\}, \quad (26.77)$$

$$\psi_*^-(\alpha) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) \leq \alpha\}, \quad (26.78)$$

$$\psi_-^*(\alpha) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) \geq \alpha\}, \quad (26.79)$$

with  $\inf \emptyset = 0$  and  $\sup \emptyset = 1$ . We note that  $\varphi_*^+$  and  $\varphi_+^*$  are monotonically increasing which  $\varphi_*^-$  and  $\varphi_-^*$  are monotonically decreasing. These monotonicities are imposed in order to fit the supposed gradual rules. However, such monotonicities do not hold for functions  $\psi_*^+$ ,  $\psi_+^*$ ,  $\psi_*^-$  and  $\psi_-^*$ . In the cases of (26.69) and (26.70), we should extend the modifier function to a generalized modifier function which is a function from  $[0, 1] \times [0, 1]$  to  $[0, 1]$  because we have two fuzzy sets in the premise of the corresponding gradual rule. The associated generalized modifier functions with (26.69) and (26.70) are obtained as

$$\begin{aligned}\varphi_*^\pm(\alpha_1, \alpha_2) &= \sup\{\psi_*^\pm(\beta_1, \beta_2) \mid \beta_1 \in [0, \alpha_1], \beta_2 \in [\alpha_2, 1]\}, \\ \varphi_\pm^*(\alpha_1, \alpha_2) &= \sup\{\psi_\pm^*(\beta_1, \beta_2) \mid \beta_1 \in [\alpha_1, 1], \beta_2 \in [0, \alpha_2]\},\end{aligned}\quad (26.80)$$

$$\begin{aligned}\varphi_\pm^*(\alpha_1, \alpha_2) &= \sup\{\psi_\pm^*(\beta_1, \beta_2) \mid \beta_1 \in [\alpha_1, 1], \beta_2 \in [0, \alpha_2]\},\end{aligned}\quad (26.81)$$

where we define

$$\begin{aligned}\psi_*^\pm(\beta_1, \beta_2) &= \inf\{\mu_X(z) \mid z \in U, \mu_G^+(\beta_1) \geq \beta_1, \mu_G^-(\beta_2) \leq \beta_2\}, \\ \psi_\pm^*(\beta_1, \beta_2) &= \sup\{\mu_X(z) \mid z \in U, \mu_G^+(\beta_1) \leq \beta_1, \mu_G^-(\beta_2) \geq \beta_2\},\end{aligned}\quad (26.82)$$

$$\begin{aligned}\psi_\pm^*(\beta_1, \beta_2) &= \sup\{\mu_X(z) \mid z \in U, \mu_G^+(\beta_1) \leq \beta_1, \mu_G^-(\beta_2) \geq \beta_2\},\end{aligned}\quad (26.83)$$

with  $\inf \emptyset = 0$  and  $\sup \emptyset = 1$ . We note  $\varphi_{\pm}^{\pm}$  and  $\varphi_{\pm}^*$  are monotonically increasing in the first argument and monotonically decreasing in the second argument.

Moreover, when we do not have any background knowledge about the relation between  $G$  and  $X$  which is expressed by a gradual rule. We may define the lower approximation  $G_*(X)$  and the upper approximation  $G^*(X)$  by the following membership functions

$$\mu_{G_*(X)}(x) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) = \mu_G(x)\}, \quad (26.84)$$

$$\mu_{G^*(X)}(x) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) = \mu_G(x)\}. \quad (26.85)$$

The modifier functions associate with these approximations are obtained as

$$\varphi_*(\alpha) = \inf\{\mu_X(z) \mid z \in U, \mu_G(z) = \alpha\}, \quad (26.86)$$

$$\varphi^*(\alpha) = \sup\{\mu_X(z) \mid z \in U, \mu_G(z) = \alpha\}, \quad (26.87)$$

where we define  $\inf \emptyset = 0$  and  $\sup \emptyset = 1$ . Equation (26.87) is same as the inverse truth qualification [26.59, 60] of  $X$  based on  $G$ .

We describe the properties of the approximations defined by (26.65) to (26.68). However, the other approximations defined by (26.69), (26.70), (26.84), and (26.85) have the similar results. We have the following properties for the approximations defined by (26.65) to (26.68) (see Greco et al. [26.25] for a part of these properties):

$$\begin{aligned} G_*^+(X) &\subseteq X \subseteq G_*^*(X), \\ G_*^-(X) &\subseteq X \subseteq G_*^*(X), \end{aligned} \quad (26.88)$$

$$G_*^+(\emptyset) = G_*^*(\emptyset) = G_*^-(\emptyset) = G_-^*(\emptyset) = \emptyset, \quad (26.89)$$

$$G_*^+(U) = G_*^*(U) = G_*^-(U) = G_-^*(U) = U, \quad (26.90)$$

$$\begin{aligned} G_*^+(X \cap Y) &= G_*^+(X) \cap G_*^+(Y), \\ G_*^-(X \cap Y) &= G_*^-(X) \cap G_*^-(Y), \end{aligned} \quad (26.91)$$

$$\begin{aligned} G_*^+(X \cup Y) &= G_*^+(X) \cup G_*^+(Y), \\ G_*^-(X \cup Y) &= G_*^-(X) \cup G_*^-(Y), \end{aligned} \quad (26.92)$$

$$X \subseteq Y \text{ implies } G_*^+(X) \subseteq G_*^+(Y), \quad (26.93)$$

$$X \subseteq Y \text{ implies } G_*^-(X) \subseteq G_*^-(Y), \quad (26.93)$$

$$X \subseteq Y \text{ implies } G_-^-(X) \subseteq G_-^-(Y), \quad (26.93)$$

$$X \subseteq Y \text{ implies } G_*(X) \subseteq G_*(Y), \quad (26.94)$$

$$G_*^+(X \cup Y) \supseteq G_*^+(X) \cup G_*^+(Y), \quad (26.95)$$

$$G_*^+(X \cap Y) \subseteq G_*^+(X) \cap G_*^+(Y), \quad (26.96)$$

$$G_*^-(X \cup Y) \supseteq G_*^-(X) \cup G_*^-(Y), \quad (26.97)$$

$$G_*^-(X \cap Y) \subseteq G_*^-(X) \cap G_*^-(Y), \quad (26.98)$$

$$G_*^+(U \setminus X) = U \setminus G_*^+(X) = U \setminus (U \setminus G)_+^*(X) \quad (26.99)$$

$$= (U \setminus G)_+^+(U \setminus X), \quad (26.99)$$

$$G_*^+(G_*^+(X)) = G_*^+(G_*^+(X)) = G_*^+(X), \quad (26.99)$$

$$G_*^+(G_*^+(X)) = G_*^+(G_*^+(X)) = G_*^+(X), \quad (26.99)$$

$$G_*^-(G_*^-(X)) = G_*^-(G_*^-(X)) = G_*^-(X), \quad (26.100)$$

$$G_*^-(G_*^-(X)) = G_*^-(G_*^-(X)) = G_*^-(X), \quad (26.100)$$

where  $U \setminus X$  is a fuzzy set defined by its membership function  $\mu_{U \setminus X}(x) = N(\mu_X(x))$ ,  $\forall x \in U$  with a strictly decreasing function  $N: [0, 1] \rightarrow [0, 1]$ . We found that all fundamental properties [26.2] of the classical rough set are preserved.

## 26.2.5 Remarks

Three types of fuzzy rough set models have been described, divided into two groups: classification-oriented and approximation-oriented models. The classification-oriented fuzzy rough set models are much more investigated by many researchers. However, the approximation-oriented fuzzy rough set models would be more important because they are associated with rules. While approximation-oriented fuzzy rough set models based on modifiers are strongly related to the gradual rules, approximation-oriented fuzzy rough set models based on certainty qualification have relations to uncertain generation rule (uncertain qualification rule: certainty rule and possibility rule) [26.54], i.e., a rule such as *the more an object is in A, the more certain (possible) it is in B*. While approximation-oriented fuzzy rough set models based on modifiers need a modifier function for each granule  $G$ , the approximation-oriented fuzzy rough set models based on certainty qualification need only a degree of inclusion for each granule  $F$ . Therefore, the latter may work well for data compression such as image compression, speech compression, and so on.

## 26.3 Generalized Fuzzy Belief Structures with Application in Fuzzy Information Systems

In rough set theory there exists a pair of approximation operators, the lower and upper approximations, whereas in the Dempster–Shafer theory of evidence there exists a dual pair of uncertainty measures, the belief and plausibility functions. In this section, general types of belief structures and their induced dual pairs of belief and plausibility functions are first introduced. Relationships between belief and plausibility functions in the Dempster–Shafer theory of evidence and the lower and upper approximations in rough set theory are then established. It is shown that the probabilities of lower and upper approximations induced from an approximation space yield a dual pair of belief and plausibility functions. And for any belief structure there must exist a probability approximation space such that the belief and plausibility functions defined by the given belief structure are, respectively, the lower and upper probabilities induced by the approximation space. The pair of lower and upper approximations of a set capture the non-numeric aspect of uncertainty of the set which can be interpreted as the qualitative representation of the set, whereas the pair of the belief and plausibility measures of the set capture the numeric aspect of uncertainty of the set which can be treated as the quantitative characterization of the set. Finally, the potential applications of the main results to intelligent information systems are explored.

### 26.3.1 Belief Structures and Belief Functions

In this section, we recall some basic notions related to belief structures with their induced belief and plausibility functions.

#### Belief and Plausibility Functions Derived from a Crisp Belief Structure

Throughout this section,  $U$  will be a nonempty set called the universe of discourse. The class of all subsets (respectively, fuzzy subsets) of  $U$  will be denoted by  $\mathcal{P}(U)$  (respectively, by  $\mathcal{F}(U)$ ). For any  $A \in \mathcal{F}(U)$ , the complement of  $A$  will be denoted by  $\approx A$ , i. e.,

$$(\approx A)(x) = 1 - A(x) \text{ for all } x \in U.$$

The basic representational structure in the Dempster–Shafer theory of evidence is a belief structure.

#### Definition 26.1

Let  $U$  be a nonempty set which may be infinite, a set function  $m: \mathcal{P}(U) \rightarrow [0, 1]$  is referred to as a crisp basic probability assignment if it satisfies axioms (M1) and (M2)

$$(M1) m(\emptyset) = 0, \quad (M2) \sum_{X \subseteq U} m(X) = 1.$$

A set  $X \in \mathcal{P}(U)$  with nonzero basic probability assignment is referred to as a focal element of  $m$ . We denote by  $\mathcal{M}$  the family of all focal elements of  $m$ . The pair  $(\mathcal{M}, m)$  is called a crisp belief structure on  $U$ .

#### Lemma 26.1

Let  $(\mathcal{M}, m)$  be a crisp belief structure on  $U$ . Then the focal elements of  $m$  constitute a countable set.

*Proof:* For any  $n \in \{1, 2, \dots\}$ , let

$$H_n = \{A \in \mathcal{M} \mid m(A) > 1/n\}.$$

By axiom (M2) we can see that for each  $n \in \{1, 2, \dots\}$ ,  $H_n$  is a finite set. Since  $\mathcal{M} = \bigcup_{n=1}^{\infty} H_n$ , we conclude that  $\mathcal{M}$  is countable. ■

Associated with each belief structure, a pair of belief and plausibility functions can be defined.

#### Definition 26.2

Let  $(\mathcal{M}, m)$  be a crisp belief structure on  $U$ . A set function  $\text{Bel}: \mathcal{P}(U) \rightarrow [0, 1]$  is called a CC-belief function on  $U$  if

$$\text{Bel}(X) = \sum_{M \subseteq X} m(M), \quad \forall X \in \mathcal{P}(U). \quad (26.101)$$

A set function  $\text{Pl}: \mathcal{P}(U) \rightarrow [0, 1]$  is called a CC-plausibility function on  $U$  if

$$\text{Pl}(X) = \sum_{M \cap X \neq \emptyset} m(M), \quad \forall X \in \mathcal{P}(U). \quad (26.102)$$

#### Remark 26.1

Since  $\mathcal{M}$  is a countable set, the change of convergence may not change the values of the infinite (countable) sums in (26.101) and (26.102). Therefore, Definition 26.2 is reasonable.

The CC-belief function and CC-plausibility function based on the same belief structure are connected by the dual property

$$\text{Pl}(X) = 1 - \text{Bel}(\approx X), \quad \forall X \in \mathcal{P}(U) \quad (26.103)$$

and moreover,

$$\text{Bel}(X) \leq \text{Pl}(X), \quad \forall X \in \mathcal{P}(U). \quad (26.104)$$

When  $U$  is finite, a CC-belief function can be equivalently defined as a monotone *Choquet* capacity [26.61] on  $U$  which satisfies the following properties [26.38]:

- (MC1)  $\text{Bel}(\emptyset) = 0$ ,
- (MC2)  $\text{Bel}(U) = 1$ ,
- (MC3) for all  $X_i \in \mathcal{P}(U), i = 1, 2, \dots, k$ ,

$$\begin{aligned} \text{Bel}\left(\bigcup_{i=1}^k X_i\right) &\geq \\ &\sum_{\emptyset \neq J \subseteq \{1, 2, \dots, k\}} (-1)^{|J|+1} \text{Bel}\left(\bigcap_{i \in J} X_i\right). \end{aligned} \quad (26.105)$$

Similarly, a CC-plausibility function can be equivalently defined as an alternating Choquet capacity on  $U$  which satisfies the following properties:

- (AC1)  $\text{Pl}(\emptyset) = 0$ ,
- (AC2)  $\text{Pl}(U) = 1$ ,
- (AC3) for all  $X_i \in \mathcal{P}(U), i = 1, 2, \dots, k$ ,

$$\begin{aligned} \text{Pl}\left(\bigcap_{i=1}^k X_i\right) &\leq \\ &\sum_{\emptyset \neq J \subseteq \{1, 2, \dots, k\}} (-1)^{|J|+1} \text{Pl}\left(\bigcup_{i \in J} X_i\right). \end{aligned} \quad (26.106)$$

A monotone Choquet capacity is a belief function in which the basic probability assignment can be calculated by using the Möbius transform

$$m(X) = \sum_{Y \subseteq X} (-1)^{|X \setminus Y|} \text{Bel}(Y), \quad X \in \mathcal{P}(U). \quad (26.107)$$

A crisp belief structure can also be induced by a dual pair of fuzzy belief and plausibility functions.

### Definition 26.3

Let  $(\mathcal{M}, m)$  be a crisp belief structure on  $U$ . A fuzzy set

function  $\text{Bel}: \mathcal{F}(U) \rightarrow [0, 1]$  is called a CF-belief function on  $U$  if

$$\text{Bel}(X) = \sum_{A \in \mathcal{M}} m(A) N_A(X), \quad \forall X \in \mathcal{F}(U). \quad (26.108)$$

A fuzzy set function  $\text{Pl}: \mathcal{F}(U) \rightarrow [0, 1]$  is called a CF-plausibility function on  $U$  if

$$\text{Pl}(X) = \sum_{A \in \mathcal{M}} m(A) \Pi_A(X), \quad \forall X \in \mathcal{F}(U), \quad (26.109)$$

where  $N_A: \mathcal{F}(U) \rightarrow [0, 1]$  and  $\Pi_A: \mathcal{F}(U) \rightarrow [0, 1]$  are, respectively, the necessity measure and the possibility measure determined by the crisp set  $A$  defined as follows

$$N_A(X) = \bigwedge_{u \in A} X(u), \quad X \in \mathcal{F}(U), \quad (26.110)$$

$$\Pi_A(X) = \bigvee_{u \in A} X(u), \quad X \in \mathcal{F}(U). \quad (26.111)$$

### Belief and Plausibility Functions Derived from a Fuzzy Belief Structure

#### Definition 26.4

Let  $U$  be a nonempty set which may be infinite. A set function  $m: \mathcal{F}(U) \rightarrow [0, 1]$  is referred to as a fuzzy basic probability assignment, if it satisfies axioms (FM1) and (FM2)

$$(FM1) m(\emptyset) = 0,$$

$$(FM2) \sum_{X \in \mathcal{F}(U)} m(X) = 1.$$

A fuzzy set  $X \in \mathcal{F}(U)$  with  $m(X) > 0$  is referred to as a focal element of  $m$ . We denote by  $\mathcal{M}$  the family of all focal elements of  $m$ . The pair  $(\mathcal{M}, m)$  is called a fuzzy belief structure.

#### Lemma 26.2

[26.62] Let  $(\mathcal{M}, m)$  be a fuzzy belief structure on  $W$ . Then the focal elements of  $m$  constitute a countable set.

In the discussion to follow, all the focal elements are supposed to be normal, i. e., for any  $A \in \mathcal{M}$ , there exists an  $x \in U$  such that  $A(x) = 1$ . Associated with the fuzzy belief structure  $(\mathcal{M}, m)$ , two pairs of fuzzy belief and plausibility functions can be derived.

**Definition 26.5**

Let  $U$  be a nonempty set which may be infinite, and  $(\mathcal{M}, m)$  a fuzzy belief structure on  $U$ . A crisp set function  $\text{Bel}: \mathcal{P}(U) \rightarrow [0, 1]$  is referred to as a FC-belief function on  $U$  if

$$\text{Bel}(X) = \sum_{A \in \mathcal{M}} m(A)N_A(X), \quad \forall X \in \mathcal{P}(U). \quad (26.112)$$

A crisp set function  $\text{Pl}: \mathcal{P}(U) \rightarrow [0, 1]$  is called a FC-plausibility function on  $U$  if

$$\text{Pl}(X) = \sum_{A \in \mathcal{M}} m(A)\Pi_A(X), \quad \forall X \in \mathcal{P}(U), \quad (26.113)$$

where  $N_A: \mathcal{P}(U) \rightarrow [0, 1]$  and  $\Pi_A: \mathcal{P}(U) \rightarrow [0, 1]$  are, respectively, the necessity measure and the possibility measure determined by the fuzzy set  $A$  defined as follows

$$N_A(X) = \bigwedge_{u \notin X} (1 - A(u)), X \in \mathcal{P}(U) \quad (26.114)$$

$$\Pi_A(X) = \bigvee_{u \in X} A(u), X \in \mathcal{P}(U). \quad (26.115)$$

**Definition 26.6**

Let  $U$  be a nonempty set which may be infinite, and  $(\mathcal{M}, m)$  a fuzzy belief structure on  $U$ . A fuzzy set function  $\text{Bel}: \mathcal{F}(U) \rightarrow [0, 1]$  is referred to as a FF-belief function on  $U$  if

$$\text{Bel}(X) = \sum_{A \in \mathcal{M}} m(A)N_A(X), \quad \forall X \in \mathcal{F}(U). \quad (26.116)$$

A fuzzy set function  $\text{Pl}: \mathcal{F}(U) \rightarrow [0, 1]$  is called a FF-plausibility function on  $U$  if

$$\text{Pl}(X) = \sum_{A \in \mathcal{M}} m(A)\Pi_A(X), \quad \forall X \in \mathcal{F}(U). \quad (26.117)$$

Where  $N_A: \mathcal{F}(U) \rightarrow [0, 1]$  and  $\Pi_A: \mathcal{F}(U) \rightarrow [0, 1]$  are, respectively, the necessity measure and the possibility measure determined by the fuzzy set  $A$  defined as follows

$$N_A(X) = \bigwedge_{u \in U} (X(u) \vee (1 - A(u))), X \in \mathcal{F}(U), \quad (26.118)$$

$$\Pi_A(X) = \bigvee_{u \in U} (X(u) \wedge A(u)), X \in \mathcal{F}(U). \quad (26.119)$$

It can be proved that the belief and plausibility functions derived from the same fuzzy belief structure  $(\mathcal{M}, m)$  are dual, that is,

$$\text{Bel}(X) = 1 - \text{Pl}(\approx X), \quad \forall X \in \mathcal{F}(U). \quad (26.120)$$

And

$$\text{Bel}(X) \leq \text{Pl}(X), \quad \forall X \in \mathcal{F}(U). \quad (26.121)$$

Moreover,  $\text{Bel}$  is a fuzzy monotone Choquet capacity of infinite order on  $U$  which satisfies axioms (FMC1)–(FMC3),

(FMC1)  $\text{Bel}(\emptyset) = 0$ ,

(FMC2)  $\text{Bel}(U) = 1$ ,

(FMC3) For  $X_i \in \mathcal{F}(U)$ ,  $i = 1, 2, \dots, n$ ,  $n \in \mathbb{N}$ ,

$$\begin{aligned} \text{Bel}\left(\bigcup_{i=1}^n X_i\right) &\geq \\ \sum_{\emptyset \neq J \subseteq \{1, 2, \dots, n\}} (-1)^{|J|+1} \text{Bel}\left(\bigcap_{j \in J} X_j\right). \end{aligned} \quad (26.122)$$

And  $\text{Pl}$  is a fuzzy alternating Choquet capacity of infinite order on  $U$  which obeys axioms (FAC1)–(FAC3),

(FAC1)  $\text{Pl}(\emptyset) = 0$ ,

(FAC2)  $\text{Pl}(U) = 1$ ,

(FAC3) For  $X_i \in \mathcal{F}(U)$ ,  $i = 1, 2, \dots, n$ ,  $n \in \mathbb{N}$ ,

$$\text{Pl}\left(\bigcap_{i=1}^n X_i\right) \leq \sum_{\emptyset \neq J \subseteq \{1, 2, \dots, n\}} (-1)^{|J|+1} \text{Pl}\left(\bigcup_{i \in J} X_i\right). \quad (26.123)$$

### 26.3.2 Belief Structures of Rough Approximations

In this section, we show relationships between various belief and plausibility functions in Dempster–Shafer theory of evidence and the lower and upper approximations in rough set theory with potential applications.

#### Belief Functions versus Crisp Rough Approximations

**Definition 26.7**

Let  $U$  and  $W$  be two nonempty universes of discourse. A subset  $R \in \mathcal{P}(U \times W)$  is referred to as a binary relation from  $U$  to  $W$ . The relation  $R$  is referred to as serial if

for any  $x \in U$  there exists  $y \in W$  such that  $(x, y) \in R$ . If  $U = W$ ,  $R \in \mathcal{P}(U \times U)$  is called a binary relation on  $U$ ,  $R \in \mathcal{P}(U \times U)$  is referred to as reflexive if  $(x, x) \in R$  for all  $x \in U$ ;  $R$  is referred to as symmetric if  $(x, y) \in R$  implies  $(y, x) \in R$  for all  $x, y \in U$ ;  $R$  is referred to as transitive if for any  $x, y, z \in U$ ,  $(x, y) \in R$  and  $(y, z) \in R$  imply  $(x, z) \in R$ ;  $R$  is referred to as Euclidean if for any  $x, y, z \in U$ ,  $(x, y) \in R$  and  $(x, z) \in R$  imply  $(y, z) \in R$ ;  $R$  is referred to as an equivalence relation if  $R$  is reflexive, symmetric and transitive.

Assume that  $R$  is an arbitrary binary relation from  $U$  to  $W$ . One can define a set-valued mapping  $R_s: U \rightarrow \mathcal{P}(W)$  by

$$R_s(x) = \{y \in W | (x, y) \in R\}, \quad x \in U. \quad (26.124)$$

$R_s(x)$  is called the successor neighborhood of  $x$  with respect to  $R$  [26.63]. Obviously, any set-valued mapping  $F$  from  $U$  to  $W$  defines a binary relation from  $U$  to  $W$  by setting  $R = \{(x, y) \in U \times W | y \in F(x)\}$ . For  $A \in \mathcal{P}(W)$ , let  $j(A) = R_s^{-1}(A)$  be the counter-image of  $A$  under the set-valued mapping  $R_s$ , i. e.,

$$j(A) = \begin{cases} R_s^{-1}(A) = \{u \in U | R_s(u) = A\}, & \text{if } A \in \{R_s(x) | x \in U\}, \\ \emptyset, & \text{otherwise.} \end{cases} \quad (26.125)$$

Then it is well known that  $j$  satisfies the properties (J1) and (J2)

$$(J1) A \neq B \implies j(A) \cap j(B) = \emptyset,$$

$$(J2) \bigcup_{A \in \mathcal{P}(W)} j(A) = U.$$

### Definition 26.8

If  $R$  is an arbitrary relation from  $U$  to  $W$ , then the triple  $(U, W, R)$  is referred to as a generalized approximation space. For any set  $A \subseteq W$ , a pair of lower and upper approximations,  $\underline{R}(A)$  and  $\overline{R}(A)$ , are, respectively, defined by

$$\begin{aligned} \underline{R}(A) &= \{x \in U | R_s(x) \subseteq A\}, \\ \overline{R}(A) &= \{x \in U | R_s(x) \cap A \neq \emptyset\}. \end{aligned} \quad (26.126)$$

The pair  $(\underline{R}(A), \overline{R}(A))$  is referred to as a generalized crisp rough set and  $\underline{R}$  and  $\overline{R}: \mathcal{P}(W) \rightarrow \mathcal{P}(U)$  are called the lower and upper generalized approximation operators, respectively.

If  $U$  is countable set,  $P$  a normalized probability measure on  $U$ , i. e.,  $P(\{x\}) > 0$  for all  $x \in U$ , and  $R$  an arbitrary relation from  $U$  to  $W$ , then  $((U, P), W, R)$  is referred to as a probability approximation space.

### Theorem 26.1 [26.43]

Assume that  $((U, P), W, R)$  is a serial probability approximation space, for  $X \in \mathcal{P}(W)$ , define

$$\begin{aligned} m(X) &= P(j(X)), \\ \text{Bel}(X) &= P(\underline{R}(X)), \\ \text{Pl}(X) &= P(\overline{R}(X)). \end{aligned} \quad (26.127)$$

Then  $m: \mathcal{P}(W) \rightarrow [0, 1]$  is a basic probability assignment on  $W$  and  $\text{Bel}: \mathcal{P}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{P}(W) \rightarrow [0, 1]$  are, respectively, the CC-belief and CC-plausibility functions on  $W$ .

Conversely, for any crisp belief structure  $(\mathcal{M}, m)$  on  $W$  which may be infinite. If  $\text{Bel}: \mathcal{P}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{P}(W) \rightarrow [0, 1]$  are, respectively, the CC-belief and CC-plausibility functions defined in Definition 26.2, then there exists a countable set  $U$ , a serial relation  $R$  from  $U$  to  $W$ , and a normalized probability measure  $P$  on  $U$  such that

$$\begin{aligned} \text{Bel}(X) &= P(\underline{R}(X)), \\ \text{Pl}(X) &= P(\overline{R}(X)), \quad \forall X \in \mathcal{P}(W). \end{aligned} \quad (26.128)$$

The notion of information systems (sometimes called data tables, attribute-value systems, knowledge representation systems etc.) provides a convenient tool for the representation of objects in terms of their attribute values.

An information system is a pair  $(U, A)$ , where  $U = \{x_1, x_2, \dots, x_n\}$  is a nonempty, finite set of objects called the universe of discourse and  $A = \{a_1, a_2, \dots, a_m\}$  is a nonempty, finite set of attributes, such that  $a: U \rightarrow V_a$  for any  $a \in A$ , where  $V_a$  is called the domain of  $a$ .

Each nonempty subset  $B \subseteq A$  determines an indiscernibility relation as follows

$$R_B = \{(x, y) \in U \times U | a(x) = a(y), \forall a \in B\}. \quad (26.129)$$

Since  $R_B$  is an equivalence relation on  $U$ , it forms a partition  $U/R_B = \{[x]_B | x \in U\}$  of  $U$ , where  $[x]_B$  denotes the equivalence class determined by  $x$  with respect to (w.r.t.)  $B$ , i. e.,  $[x]_B = \{y \in U | (x, y) \in R_B\}$ .

Let  $(U, A)$  be an information system,  $B \subseteq A$ , for any  $X \subseteq U$ , denote

$$\begin{aligned} R_B(X) &= \{x \in U | [x]_B \subseteq X\}, \\ \overline{R}_B(X) &= \{x \in U | [x]_B \cap X \neq \emptyset\}, \end{aligned} \quad (26.130)$$

where  $R_B(X)$  and  $\overline{R}_B(X)$  are, respectively, referred to as the lower and upper approximations of  $X$  w.r.t.  $(U, R_B)$ , the knowledge generated by  $B$ . Objects in  $R_B(X)$  can be certainty classified as elements of  $X$  on the basis of knowledge in  $(U, R_B)$ , whereas objects in  $\overline{R}_B(X)$  can only be classified possibly as elements of  $X$  on the basis of knowledge in  $(U, R_B)$ .

For  $B \subseteq A$  and  $X \subseteq U$ , denote  $\text{Bel}_B(X) = P(R_B(X))$  and  $\text{Pl}_B(X) = P(\overline{R}_B(X))$ , where  $P(Y) = |Y|/|U|$  and  $|Y|$  is the cardinality of a set  $Y$ . Then  $\text{Bel}_B$  and  $\text{Pl}_B$  are CC-belief function and CC-plausibility function on  $U$ , respectively, and the corresponding mass distribution is

$$m_B(Y) = \begin{cases} P(Y), & \text{if } Y \in U/R_B, \\ 0, & \text{otherwise.} \end{cases}$$

A decision system (sometimes called decision table) is a pair  $(U, C \cup \{d\})$  where  $(U, C)$  is an information system, and  $d$  is a distinguished attribute called the decision; in this case  $C$  is called the conditional attribute set,  $d$  is a map  $d: U \rightarrow V_d$  of the universe  $U$  into the value set  $V_d$ , we assume, without any loss of generality, that  $V_d = \{1, 2, \dots, r\}$ . Define

$$R_d = \{(x, y) \in U \times U \mid d(x) = d(y)\}. \quad (26.131)$$

Then we obtain the partition  $U/R_d = \{D_1, D_2, \dots, D_r\}$  of  $U$  into decision classes, where  $D_j = \{x \in U \mid d(x) = j\}, j \leq r$ . If  $R_C \subseteq R_d$ , then the decision system  $(U, C \cup \{d\})$  is consistent, otherwise it is inconsistent. One can acquire certainty decision rules from consistent decision systems and uncertainty decision rules from inconsistent decision systems.

### Belief Functions versus Rough Fuzzy Approximations

#### Definition 26.9

Let  $(U, W, R)$  be a generalized approximation space, for a fuzzy set  $A \in \mathcal{F}(W)$ , the lower and upper approximations of  $A$ ,  $\underline{RF}(A)$  and  $\overline{RF}(A)$ , with respect to the approximation space  $(U, W, R)$  are fuzzy sets of  $U$  whose membership functions, for each  $x \in U$ , are defined, respectively, by

$$\overline{RF}(A)(x) = \bigvee_{y \in R_s(x)} A(y), \quad x \in U, \quad (26.132)$$

$$\underline{RF}(A)(x) = \bigwedge_{y \in R_s(x)} A(y), \quad x \in U. \quad (26.133)$$

The pair  $(\underline{RF}(A), \overline{RF}(A))$  is referred to as a generalized rough fuzzy set, and  $\underline{RF}$  and  $\overline{RF}: \mathcal{F}(W) \rightarrow \mathcal{F}(U)$  are

referred to as lower and upper generalized rough fuzzy approximation operators, respectively.

In the discussion to follow, we always assume that  $(U, \mathcal{A}, P)$  is a probability space, i.e.,  $U$  is a nonempty set,  $\mathcal{A} \subseteq \mathcal{P}(U)$  a  $\sigma$ -algebra on  $U$ , and  $P$  a probability measure on  $U$ .

#### Definition 26.10

A fuzzy set  $A \in \mathcal{F}(U)$  is said to be measurable w.r.t.  $(U, \mathcal{A})$  if  $A: U \rightarrow [0, 1]$  is a measurable function w.r.t.  $\mathcal{A} - \mathcal{B}([0, 1])$ , where  $\mathcal{B}([0, 1])$  is the family of Borel sets on  $[0, 1]$ . We denote by  $\mathcal{F}(U, \mathcal{A})$  the family of all measurable fuzzy sets of  $U$  w.r.t.  $\mathcal{A} - \mathcal{B}([0, 1])$ .

For any measurable fuzzy set  $A \in \mathcal{F}(U, \mathcal{A})$ , since  $A_\alpha \in \mathcal{A}$  for all  $\alpha \in [0, 1]$ ,  $A_\alpha$  is a measurable set on the probability space  $(U, \mathcal{A}, P)$  and then  $P(A_\alpha) \in [0, 1]$ . Note that  $f(\alpha) = P(A_\alpha)$  is monotone decreasing and left continuous, it can be seen that  $f(\alpha)$  is integrable, we denote the integrand as  $\int_0^1 P(A_\alpha) d\alpha$ .

#### Definition 26.11

If a fuzzy set  $A$  is measurable w.r.t.  $(U, \mathcal{A})$ , and  $P$  is a probability measure on  $(U, \mathcal{A})$ . Denote

$$P(A) = \int_0^1 P(A_\alpha) d\alpha, \quad (26.134)$$

$P(A)$  is called the probability of  $A$ .

For a singleton set  $\{x\}$ , we will write  $P(x)$  instead of  $P(\{x\})$  for short.

#### Proposition 26.1

[26.21, 64] The fuzzy probability measure  $P$  in Definition 26.11 satisfies the following properties:

- (1)  $P(A) \in [0, 1]$  and  $P(A) + P(\approx A) = 1$ , for all  $A \in \mathcal{F}(U, \mathcal{A})$ .
- (2)  $P$  is countably additive, i.e., for  $A_i \in \mathcal{F}(U, \mathcal{A})$ ,  $i = 1, 2, \dots$ ,  $A_i \cap A_j = \emptyset$ ,  $\forall i \neq j$ , then

$$P\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} P(A_i). \quad (26.135)$$

- (3)  $A, B \in \mathcal{F}(U, \mathcal{A})$ ,  $A \subseteq B \implies P(A) \leq P(B)$ .

- (4) If  $U = \{u_i | i = 1, 2, \dots\}$  is an infinite countable set and  $\mathcal{A} = \mathcal{P}(U)$ , then for all  $A \in \mathcal{F}(U)$ ,

$$P(A) = \int_0^1 P(A_\alpha) d\alpha = \sum_{x \in U} A(x) P(x). \quad (26.136)$$

- (5) If  $U$  is a finite set with  $|U| = n$ ,  $\mathcal{A} = \mathcal{P}(U)$ , and  $P(u) = 1/n$ , then  $P(A) = \int_0^1 P(A_\alpha) d\alpha = |A|/n$  for all  $A \in \mathcal{P}(U)$ .

### Theorem 26.2

Assume that  $((U, P), W, R)$  is a serial probability approximation space, for  $X \in \mathcal{F}(W)$ , define

$$\begin{aligned} m(X) &= P(j(X)), \\ \text{Bel}(X) &= P(\underline{RF}(X)), \\ \text{Pl}(X) &= P(\overline{RF}(X)). \end{aligned} \quad (26.137)$$

Then  $m: \mathcal{P}(W) \rightarrow [0, 1]$  is a basic probability assignment on  $W$  and  $\text{Bel}: \mathcal{F}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{F}(W) \rightarrow [0, 1]$  are, respectively, the CF-belief and CF-plausibility functions on  $W$ .

Conversely, for any crisp belief structure  $(\mathcal{M}, m)$  on  $W$  which may be infinite. If  $\text{Bel}: \mathcal{F}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{F}(W) \rightarrow [0, 1]$  are, respectively, the CF-belief and CF-plausibility functions defined in Definition 26.3, then there exists a countable set  $U$ , a serial relation  $R$  from  $U$  to  $W$ , and a normalized probability measure  $P$  on  $U$  such that

$$\begin{aligned} \text{Bel}(X) &= P(\underline{RF}(X)), \\ \text{Pl}(X) &= P(\overline{RF}(X)), \quad \forall X \in \mathcal{F}(W). \end{aligned} \quad (26.138)$$

For a decision table  $((U, C \cup \{d\}), V_d = \{d_1, d_2, \dots, d_r\})$ , where  $d$  is called a fuzzy decision if, for each  $x \in U$ ,  $d(x)$  is a fuzzy subset of  $V_d$ , i.e.,  $d: U \rightarrow \mathcal{F}(V_d)$ , with no loss of generality, we represent  $d$  as follows

$$\begin{aligned} d(x_i) &= d_{i1}/d_1 + d_{i2}/d_2 + \dots + d_{ir}/d_r, i \\ &= 1, 2, \dots, n, \end{aligned} \quad (26.139)$$

where  $d_{ij} \in [0, 1]$ . In this case,  $((U, C \cup \{d\})$  is called an information system with fuzzy decision. For the fuzzy decision  $d$ , we define a fuzzy indiscernibility binary relation  $R_d$  on  $U$  as follows: For  $i, k = 1, 2, \dots, n$

$$R_d(x_i, x_k) = \min\{1 - |d_{ij} - d_{kj}| | j = 1, 2, \dots, r\}. \quad (26.140)$$

Then, we obtain a fuzzy similarity class  $S_d(x)$  of  $x \in U$  in the system  $((U, C \cup \{d\})$  as follows

$$S_d(x)(y) = R_d(x, y), \quad y \in U. \quad (26.141)$$

Since  $S_d(x)(x) = R_d(x, x) = 1$ , we see that  $S_d(x): U \rightarrow [0, 1]$  is a normalized fuzzy set of  $U$ . Denote by  $U/R_d$  the fuzzy similarity classes induced by the fuzzy decision  $d$ , i.e.

$$U/R_d = \{S_d(x) | x \in U\}. \quad (26.142)$$

For  $B \subseteq C$  and  $X \in \mathcal{F}(U)$ , we define the lower and upper approximations of  $X$  w.r.t.  $(U, R_B)$  as follows

$$\begin{aligned} \underline{RF}_B(X)(x) &= \bigwedge_{y \in S_B(x)} X(y), \quad x \in U, \\ \overline{RF}_B(X)(x) &= \bigvee_{y \in S_B(x)} X(y), \quad x \in U. \end{aligned} \quad (26.143)$$

### Theorem 26.3

Let  $((U, C \cup \{d\})$  be an information system with fuzzy decision. For  $B \subseteq C$  and  $X \in \mathcal{F}(U)$ , if  $\underline{RF}_B(X)$  and  $\overline{RF}_B(X)$  are, respectively, the lower and upper approximations of  $X$  w.r.t.  $(U, R_B)$  defined by Definition 26.9, denote

$$\begin{aligned} \text{Bel}_B(X) &= P(\underline{RF}_B(X)), \\ \text{Pl}_B(X) &= P(\overline{RF}_B(X)), \end{aligned} \quad (26.144)$$

where  $P(X) = \sum_{x \in U} X(x)/|U|$  for  $X \in \mathcal{F}(U)$ , then  $\text{Bel}_B: \mathcal{F}(U) \rightarrow [0, 1]$  and  $\text{Pl}_B: \mathcal{F}(U) \rightarrow [0, 1]$  are, respectively, a CF-belief function and a CF-plausibility function on  $U$ , and the corresponding basic probability assignment  $m_B$  is

$$m_B(Y) = \begin{cases} P(Y) = |Y|/|U|, & \text{if } Y \in U/R_B, \\ 0, & \text{otherwise.} \end{cases} \quad (26.145)$$

### Belief Functions versus Fuzzy Rough Approximations

#### Definition 26.12

Let  $U$  and  $W$  be two nonempty universes of discourse. A fuzzy subset  $R \in \mathcal{F}(U \times W)$  is referred to as a binary relation from  $U$  to  $W$ ,  $R(x, y)$  is the degree of relation between  $x$  and  $y$ , where  $(x, y) \in U \times W$ . The fuzzy relation  $R$  is referred to as serial if for each  $x \in U$ ,  $\bigvee_{y \in W} R(x, y) = 1$ . If  $U = W$ ,  $R \in \mathcal{F}(U \times U)$  is called

a fuzzy binary relation on  $U$ ,  $R$  is referred to as a reflexive fuzzy relation if  $R(x, x) = 1$  for all  $x \in U$ ;  $R$  is referred to as a symmetric fuzzy relation if  $R(x, y) = R(y, x)$  for all  $x, y \in U$ ;  $R$  is referred to as a transitive fuzzy relation if  $R(x, z) \geq \vee_{y \in U} (R(x, y) \wedge R(y, z))$  for all  $x, z \in U$ ;  $R$  is referred to as an equivalence fuzzy relation if it is reflexive, symmetric, and transitive.

### Definition 26.13

Let  $U$  and  $W$  be two nonempty universes of discourse and  $R$  a fuzzy relation from  $U$  to  $W$ . The triple  $(U, W, R)$  is called a generalized fuzzy approximation space. For any set  $A \in \mathcal{F}(W)$ , the lower and upper approximations of  $A$ ,  $\underline{FR}(A)$  and  $\overline{FR}(A)$ , with respect to the approximation space  $(U, W, R)$  are fuzzy sets of  $U$  whose membership functions, for each  $x \in U$ , are defined, respectively, by

$$\begin{aligned}\overline{FR}(A)(x) &= \bigvee_{y \in W} [R(x, y) \wedge A(y)], \quad x \in U, \\ \underline{FR}(A)(x) &= \bigwedge_{y \in W} [(1 - R(x, y)) \vee A(y)], \quad x \in U.\end{aligned}\tag{26.146}$$

The pair  $(\underline{FR}(A), \overline{FR}(A))$  is referred to as a generalized fuzzy rough set, and  $\underline{FR}$  and  $\overline{FR}: \mathcal{F}(W) \rightarrow \mathcal{F}(U)$  are referred to as lower and upper generalized fuzzy rough approximation operators, respectively.

### Theorem 26.4

Let  $(U, W, R)$  be a serial fuzzy approximation space in which  $U$  is a countable set and  $P$  a probability measure on  $U$ . If  $\underline{FR}$  and  $\overline{FR}$  are the fuzzy rough approximation operators defined in Definition 26.13, denote

$$\begin{aligned}\text{Bel}(X) &= P(\underline{FR}(X)), \\ \text{Pl}(X) &= P(\overline{FR}(X)), \quad X \in \mathcal{F}(W).\end{aligned}\tag{26.147}$$

Then  $\text{Bel}: \mathcal{F}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{F}(W) \rightarrow [0, 1]$  are, respectively, FF-fuzzy belief and FF-plausibility functions on  $W$ .

Conversely, if  $(\mathcal{M}, m)$  is a fuzzy belief structure on  $W$ ,  $\text{Bel}: \mathcal{F}(W) \rightarrow [0, 1]$  and  $\text{Pl}: \mathcal{F}(W) \rightarrow [0, 1]$  are the pair of FF-fuzzy belief function and FF-plausibility function defined in Definition 26.6, then there exists a countable set  $U$ , a serial fuzzy relation  $R$  from  $U$  to  $W$ , and a probability measure  $P$  on  $U$  such that for all

$X \in \mathcal{F}(W)$ ,

$$\text{Bel}(X) = P(\underline{FR}(X)) = \sum_{x \in U} \underline{FR}(X)(x)P(x),\tag{26.148}$$

$$\text{Pl}(X) = P(\overline{FR}(X)) = \sum_{x \in U} \overline{FR}(X)(x)P(x).\tag{26.149}$$

A pair  $(U, A)$  is called a fuzzy information system if each  $a \in A$  is a fuzzy attribute, i.e., for each  $x \in U$ ,  $a(x)$  is a fuzzy subset of  $V_d$ , that is,  $a: U \rightarrow \mathcal{F}(V_a)$ . Similar to (26.140), we can define a reflexive fuzzy binary relation  $R_a$  on  $U$ , and consequently, for any attribute subset  $B \subseteq A$  one can define a reflexive fuzzy relation  $R_B$  as follows

$$R_B = \bigcap_{a \in B} R_a.\tag{26.150}$$

For  $X \in \mathcal{F}(U)$ , denote

$$\text{Bel}_B(X) = P(\underline{FR}_B(X)), \quad \text{Pl}_B(X) = P(\overline{FR}_B(X)),\tag{26.151}$$

where  $P(X) = \sum_{x \in U} X(x)/|U|$  for  $X \in \mathcal{F}(U)$ . Then, according to Theorem 26.4,  $\text{Bel}_B: \mathcal{F}(U) \rightarrow [0, 1]$  and  $\text{Pl}_B: \mathcal{F}(U) \rightarrow [0, 1]$  are respectively, FF-fuzzy belief function and FF-plausibility function on  $U$ . More specifically, if  $X$  in (26.151) is crisp subset of  $U$ , then  $\text{Bel}_B: \mathcal{P}(U) \rightarrow [0, 1]$  and  $\text{Pl}_B: \mathcal{P}(U) \rightarrow [0, 1]$  defined by (26.151) are, respectively, FC-fuzzy belief functions and FC-plausibility functions on  $U$ . Based on these observations, we believe that FF-fuzzy belief functions and FF-plausibility functions can be used to analyze uncertainty fuzzy information systems with fuzzy decision and whereas FC-fuzzy belief functions and FC-plausibility functions can be employed to deal with knowledge discovery in fuzzy information systems with crisp decision.

### 26.3.3 Conclusion of This Section

The lower and upper approximations of a set capture the non-numeric aspect of uncertainty of the set which can be interpreted as the qualitative representation of the set, whereas the pair of the belief and plausibility measures of the set characterize the numeric aspect of uncertainty of the set which can be treated as the quantitative characterization of the set. In this section, we have introduced some generalized belief and plausibility and belief functions on the Dempster–Shafer

theory of evidence. We have shown that the fuzzy belief and plausibility functions can be interpreted as the lower and upper approximations in rough set theory. That is, the belief and plausibility functions in the Dempster–Shafer theory of evidence can be represented as the probabilities of lower and upper approximations

in rough set theory; thus, rough set theory may be regarded as the basis of the Dempster–Shafer theory of evidence. Also the Dempster–Shafer theory of evidence in the fuzzy environment provides a potentially useful tool for reasoning and knowledge acquisition in fuzzy systems and fuzzy decision systems.

## 26.4 Applications of Fuzzy Rough Sets

Both fuzzy set and rough set theories have fostered broad research communities and have been applied in a wide range of settings. More recently, this has also extended to the hybrid fuzzy rough set models. This section tries to give a sample of those applications, which are in particular numerous for machine learning but which also cover many other fields, like image processing, decision making, and information retrieval.

Note that we do not consider applications that simply involve a joint application of fuzzy sets and rough sets, like for instance a rough classifier that induces fuzzy rules. Rather, we focus on applications that specifically involve one of the fuzzy rough set models discussed in the previous sections.

### 26.4.1 Applications in Machine Learning

#### Feature Selection

The most prominent application of classical rough set theory is undoubtedly semantics-preserving data dimensionality reduction: the removal of attributes (features) from information systems (An information system  $(U, A)$  consists of a nonempty set  $U$  of objects which are described by a set of attributes  $A$ ) without sacrificing the ability to discern between different objects. A minimal attribute subset  $B \subseteq A$  that maintains objects' discernibility is called a *reduct*. For classification tasks, it is sufficient to be able to discern between objects belonging to different classes, in which case a *decision reduct*, also called *relative reduct*, is sought.

The traditional rough set model sets forth a crisp notion of discernibility, where two objects are either discernible or not w.r.t. a set of attributes  $B$  based on their values for all attributes in  $B$ . To be able to handle numerical data, discretization is required. Fuzzy-rough feature selection avoids this external preprocessing step by incorporating graded indiscernibility between objects directly into the data reduction process. On the other hand, by the use of fuzzy partitions, such that ob-

jects can belong to different classes to varying degrees, a more flexible data representation is obtained.

Chronologically, the oldest proposal to apply fuzzy rough sets to feature selection is due to *Kuncheva* [26.26] in 1992. However, rather than using Dubois and Prade's definition, she proposed her own notion of a fuzzy rough set based on an inclusion measure. Based on this, she defined a quality measure for evaluating attribute subsets w.r.t. their ability to approximate a predetermined fuzzy partition on the data, and illustrated its usefulness on a medical data set.

*Jensen* and *Shen* [26.27, 29] were the first to propose a reduction method that generalizes the classical rough set positive region and dependency function. In particular, the dependency degree  $\gamma_B$ , with  $B \subseteq A$ , is used to guide a hill-climbing search in which, starting from  $B = \emptyset$ , in each step an attribute  $a$  is added such that  $\gamma_{B \cup \{a\}}$  is maximal. The search ends when there is no further increase in the measure. This is the Quick Reduct algorithm. In [26.65] they replaced this simple greedy search heuristic by a more complex one based on ant colony optimization.

*Hu* et al. [26.66] formally defined the notions of reduct and decision reduct in the fuzzy-rough case, referring to the invariance of the fuzzy partition induced by the data, and of the fuzzy positive region, respectively. They also showed that minimal subsets that are invariant w.r.t. (conditional) entropy are (decision) reducts.

*Tsang* et al. [26.67] proposed a method based on the discernibility matrix and function to find all decision reducts where invariance of the fuzzy positive region defined using Dubois and Prade's definition is imposed, and proved its correctness. In [26.68], an extension of this method is defined that finds all decision reducts where the approximations are defined using a lower semicontinuous  $t$ -norm  $\mathcal{T}$  and its R-implicator. The particular case using Łukasiewicz connectives was studied in [26.69]. Later, *Zhao* and *Tsang* [26.31] studied relationships that exist between different kinds of

decision reducts, defined using different types of fuzzy connectives.

In [26.70], *Jensen* and *Shen* introduced three different quality measures for evaluating attribute subsets: the first one is a revised version of their previously defined degree of dependency, the second one is based on the fuzzy boundary region, and the third one on the satisfaction of the clauses of the fuzzy discernibility function. On the other hand, in [26.71], *Cornelis* et al. proposed the definition of fuzzy  $\mathcal{M}$ -decision reducts, where  $\mathcal{M}$  is an increasing,  $[0, 1]$ -valued quality measure. They studied two measures based on the fuzzy positive region and two more based on the fuzzy discernibility function, and applied them to classification and regression problems.

In [26.33], *Chen* and *Zhao* studied the concept of local reduction: instead of looking for a global reduction, where the whole positive region is considered as an invariant, they focus on subsets of decision classes and identify the conditional attributes that provide minimal descriptions for them.

Over the past few years, there has also been considerable interest in the application of noise-tolerant fuzzy rough set models to feature selection, where the aim is to make the reduction more robust in the presence of noisy or erroneous data. For instance, *Hu* et al. [26.72] defined fuzzy rough sets as an extension of variable precision rough sets, and used a corresponding notion of positive region to guide a greedy search algorithm. In [26.73], *Cornelis* and *Jensen* evaluated the vaguely quantified rough set (VQRS) approach to feature selection. They found that because the model does not satisfy monotonicity w.r.t. the fuzzy relation  $R$ , adding more attributes does not always lead to an expansion of the fuzzy positive region, and the hill-climbing search sometimes runs into troubles. Furthermore, in [26.74] *Hu* et al., inspired by the idea of soft margin support vector machines, introduced soft fuzzy rough sets and applied them to feature selection.

*He* et al. [26.75] consider the problem of fuzzy-rough feature selection for decision systems with fuzzy decisions, that is, where the decision attribute is characterized by a fuzzy  $T$ -similarity relation instead of a crisp one. This is the case of regression problems. They give an algorithm for finding all decision reducts and another one for finding a single reduction.

The relatively high complexity of fuzzy-rough feature selection algorithms somewhat limits its applicability to large datasets. In view of this, *Chen* et al. [26.76] propose a fast algorithm to obtain one reduct, based on a procedure to find the minimal elements of the

discernibility matrix of [26.67]. The algorithm is compared w.r.t. execution time with the proposals in [26.70] and [26.67], and turns out to be a lot faster. On the other hand, *Qian* et al. [26.77] implement an efficient version of feature selection using the model of *Hu* et al. [26.72].

The use of kernel functions as fuzzy similarity relations in feature selection algorithms has also sparked researchers' interest. In particular, *Du* et al. [26.78] apply fuzzy-rough feature selection with kernelized fuzzy rough sets to yawn detection, while *Chen* et al. [26.79] propose parameterized attribute reduction with Gaussian kernel-based fuzzy rough sets. *He* and *Wu* [26.80] develop a new method to compute membership for fuzzy support vector machines (FSVMs) by using a Gaussian kernel-based fuzzy rough set, and employ a technique of attribute reduction using Gaussian kernel-based fuzzy rough sets to perform feature selection for FSVMs.

Finally, *Derrac* et al. [26.81] combine fuzzy-rough feature selection with evolutionary instance selection.

### Instance Selection

Instance selection can be seen as the orthogonal task to feature selection: here the goal is to reduce an information system  $(U, A)$  by removing objects from  $U$ . The first work on instance selection using fuzzy rough set theory was presented in [26.82]. The main idea is that instances for which the fuzzy rough lower approximation membership is lower than a certain threshold are removed. This idea was improved in [26.83], where the selection threshold is optimized. This method has been applied in combination with evolutionary feature selection in [26.84] and for imbalanced classification problems in [26.85, 86], in combination with resampling methods.

### Classification

Fuzzy rough sets have been widely used for classification purposes, either by means of rule induction or by plugging them into existing classifiers like nearest neighbor classifiers, decision trees, and support vector machines (SVM).

The earliest work on rule induction using fuzzy rough set theory can be found in [26.25]. In this paper, the authors propose a fuzzy rough framework to induce fuzzy decision rules that does not use any fuzzy logical connectives. Later, in [26.30], an approach that generates rules from data using fuzzy reducts was presented, with a fuzzy rough feature selection preprocessing step. In [26.87], the authors noticed that using feature selection as a preprocessing step often leads to

too specific rules, and proposed an algorithm for simultaneous feature selection and rule induction. In [26.88, 89], a rule-based classifier is built using the so-called consistency degree as a critical value to keep the discernibility information invariant in the rule-induction process. Another approach to fuzzy rough rule induction can be found in [26.90], where rules are found from training data with hierarchical and quantitative attribute values. The most recent work can be found in [26.91], where fuzzy equivalence relations are used to model different types of attributes in order to obtain small rule sets from hybrid data, and in [26.92] where a harmony search algorithm is proposed to generate emerging rule sets.

In [26.93], the  $K$  nearest neighbor method was improved using fuzzy set theory. So far, three different fuzzy-rough-based approaches have been used to improve this fuzzy nearest neighbor (**FNN**) classifier. In [26.94], the author introduces a fuzzy rough ownership function and plugs it into the **FNN** algorithm. In [26.95–98], the extent to which the nearest neighbors belong to the fuzzy lower and upper approximations of a certain class are used to predict the class of the target instance, these techniques are applied in [26.99] for mammographic risk analysis. Finally, in [26.100], the **FNN** algorithm is improved using the fuzzy rough positive regions as weights for the nearest neighbors.

During the last decade, several authors have worked on fuzzy rough improvements of decision trees. The common idea of these methods is that during the construction phase of the decision tree, the feature significances are measured using fuzzy rough techniques [26.101–104]. In [26.105–107], the kernel functions of the **SVM** are redefined using fuzzy rough sets, to take into account the inconsistency between conditional attributes and the decision class. In [26.80], this approach is combined with fuzzy rough feature selection. In [26.108], **SVMs** are reformulated by plugging in the fuzzy rough memberships of all training samples into the constraints of the **SVMs**.

### Clustering

Many authors have worked on clustering methods that use both fuzzy set theory and rough set theory, but to the best of our knowledge, only two approaches use fuzzy rough sets for clustering. In [26.109], fuzzy rough sets are used to measure the intracluster similarity, in order to estimate the optimal number of clusters. In [26.110], a fuzzy rough measure is used to measure the similarity between genes in microarray analysis, in order to generate clusters such that genes within a cluster are highly

correlated to the sample categories, while those in different clusters are as dissimilar as possible.

### Neural Networks

There are many approaches to incorporate fuzzy rough set theory in neural networks. One option is to use fuzzy rough set theory to reduce the problem that samples in the same input clusters can have different classes. The resulting fuzzy rough neural networks are designed such that they work as fuzzy rough membership functions [26.111–114]. A related approach is to use fuzzy rough set theory to find the importance of each subset of information sources of subnetworks [26.115]. Other approaches use fuzzy rough set theory to measure the importance of each feature in the input layer of the neural network [26.116–118].

### 26.4.2 Other Applications

#### Image Processing

Fuzzy rough sets have been used in several domains of image processing. They are especially suitable for these tasks because they can capture both indiscernibility and vagueness, which are two important aspects of image processing.
