In [26.119, 120], fuzzy-rough-based image segmenting methods are proposed and applied in a traditional Chinese medicine tongue image segmentation experiment. Often, fuzzy rough attribute reduction methods are proposed for image processing problems, as in [26.121] or in [26.122], where the methods are applied for face recognition. In [26.123], a method for edge detection is proposed by building a hierarchy of rough-fuzzy sets to exploit the uncertainty and vagueness at different image resolutions. Another aspect of image processing is texture segmentation, this problem is tackled in [26.124] using rough-fuzzy sets. In [26.125], the authors solve the image classification problem using a nearest neighbor clustering algorithm based on fuzzy rough set theory, and apply their algorithm to hand gesture recognition. In [26.126], a combined approach of neural network classification systems with a fuzzy rough sets based feature reduction method is presented. In [26.127], fuzzy rough feature reduction techniques are applied to a large-scale Mars McMurdo panorama image.

#### Decision Making

Fuzzy rough set theory has many applications in decision making. In [26.128], the authors calculate the fuzzy rough memberships of software components in

previous projects and decide based on these values which ones to reuse in a new program. In [26.129, 130], a multiobjective decision-making model based on fuzzy rough set theory is used to solve the inventory problem. In [26.131], variable precision fuzzy rough sets are used to develop a decision making model, that is applied for IT offshore outsourcing risk evaluation. Another approach can be found in [26.132] where the decision corresponds to the decision corresponding with the instance with maximal sum of lower and upper soft fuzzy rough approximation. Recent work can be found in [26.133], where a fuzzy rough set model over two universes is defined to develop a general decision-making framework in an uncertainty environment for solving a medical diagnosis problem.

### Information Retrieval, Data Mining, and the Web

Fuzzy rough sets have been used to model imprecision and vagueness in databases. In [26.134], the au-

thors develop a fuzzy rough relational database, while in [26.135], a fuzzy rough extension of a rough object classifier for relational database mining is studied. In [26.136], fuzzy rough set theory is used to mine from incomplete datasets, while in [26.137], fuzzy rough sets are incorporated in mining agents for predicting stock prices. More recently, fuzzy rough sets have been applied to identify imprecision in temporal database models [26.138, 139].

In [26.140, 141], fuzzy rough set theory is used to approximate document queries. In the context of the semantic web, a lot of work has been done on fuzzy rough description logics. The first paper on this topic can be found in [26.142], where a fuzzy rough ontology was proposed. Later, in [26.143], the authors propose a fuzzy rough extension of the descriptive logic  $S\mathcal{H}\mathcal{I}\mathcal{N}$ . A fuzzy rough extension of the descriptive logic  $\mathcal{ALC}$  can be found in [26.144]. In [26.145, 146], an improved and more general approach is presented.

# Artificial Neural Network Models

Peter Tino, Lubica Benuskova, Alessandro Sperduti

We outline the main models and developments in the broad field of artificial neural networks ([ANN](#)). A brief introduction to biological neurons motivates the initial formal neuron model – the perceptron. We then study how such formal neurons can be generalized and connected in network structures. Starting with the biologically motivated layered structure of [ANN](#) (feed-forward [ANN](#)), the networks are then generalized to include feedback loops (recurrent [ANN](#)) and even more abstract generalized forms of feedback connections (recursive neuronal networks) enabling processing of structured data, such as sequences, trees, and graphs. We also introduce [ANN](#) models capable of forming topographic lower-dimensional maps of data (self-organizing maps). For each [ANN](#) type we out-

line the basic principles of training the corresponding [ANN](#) models on an appropriate data collection.

The human brain is arguably one of the most exciting products of evolution on Earth. It is also the most powerful information processing tool so far. Learning based on examples and parallel signal processing lead to emergent macro-scale behavior of neural networks in the brain, which cannot be easily linked to the behavior of individual micro-scale components (neurons). In this chapter, we will introduce *artificial neural network* ([ANN](#)) models motivated by the brain that can learn in the presence of a *teacher*. During the course of learning the teacher specifies what the right responses to input examples should be. In addition, we will also mention [ANNs](#) that can learn without a teacher, based on principles of self-organization.

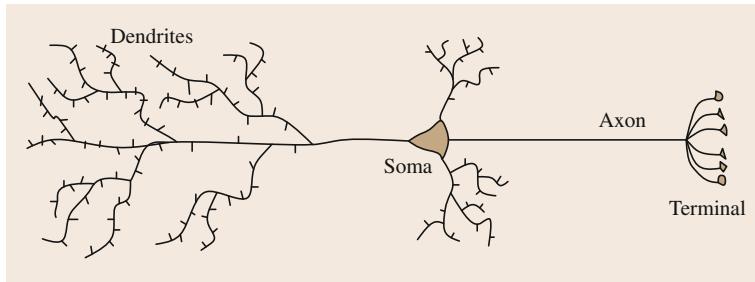

To set the context, we will begin by introducing basic neurobiology. We will then describe the *perceptron* model, which, even though rather old and simple, is an

important building block of more complex *feed-forward ANN* models. Such models can be used to approximate complex non-linear functions or to learn a variety of association tasks. The feed-forward models are capable of processing patterns without temporal association. In the presence of temporal dependencies, e.g., when learning to predict future elements of a time series (with certain prediction horizon), the feed-forward [ANN](#) needs to be extended with a memory mechanism to account for temporal structure in the data. This will naturally lead us to *recurrent neural network* models ([RNN](#)), which besides feed-forward connections also contain feedback loops to preserve, in the form of the information processing state, information about the past. [RNN](#) can be further extended to *recursive ANNs* ([RecNN](#)), which can process structured data such as trees and acyclic graphs.

## 27.1 Biological Neurons

It is estimated that there are about  $10^{12}$  neural cells (*neurons*) in the human brain. Two-thirds of the neurons

form a 4–6 mm thick cortex that is assumed to be the center of cognitive processes. Within each neuron com-

**Fig. 27.1** Schematic illustration of the basic information processing structure of the biological neuron

plex biological processes take place, ensuring that it can process signals from other neurons, as well as send its own signals to them. The signals are of electro-chemical nature. In a simplified way, signals between the neurons can be represented by real numbers quantifying the *intensity* of the incoming or outgoing signals. The point of signal transmission from one neuron to the other is called the *synapse*. Within synapse the incoming signal can be reinforced or damped. This is represented by the *weight* of the synapse. A single neuron can have up to  $10^3$ – $10^5$  such *points of entry* (synapses). The input to the neuron is organized along *dendrites* and the *soma* (Fig. 27.1). Thousands of dendrites form a rich tree-like structure on which most synapses reside.

Signals from other neurons can be either excitatory (positive) or inhibitory (negative), relayed via excitatory or inhibitory synapses. When the sum of the positive and negative contributions (signals) from other neurons, weighted by the synaptic weights, becomes greater than a certain excitation threshold, the neuron will generate an electric spike that will be transmitted over the output channel called the *axon*. At the end of

axon, there are thousands of output branches whose terminals form synapses on other neurons in the network. Typically, as a result of input excitation, the neuron can generate a series of spikes of some average frequency – about  $1$ – $10^2$  Hz. The frequency is proportional to the overall stimulation of the neuron.

The first principle of information coding and representation in the brain is *redundancy*. It means that each piece of information is processed by a redundant set of neurons, so that in the case of partial brain damage the information is not lost completely. As a result, and crucially – in contrast to conventional computer architectures, gradually increasing damage to the computing substrate (neurons plus their interconnection structure) will only result in gradually decreasing processing capabilities (*graceful degradation*). Furthermore, it is important what set of neurons participate in coding a particular piece of information (*distributed representation*). Each neuron can participate in coding of many pieces of information, in conjunction with other neurons. The information is thus associated with patterns of distributed activity on sets of neurons.

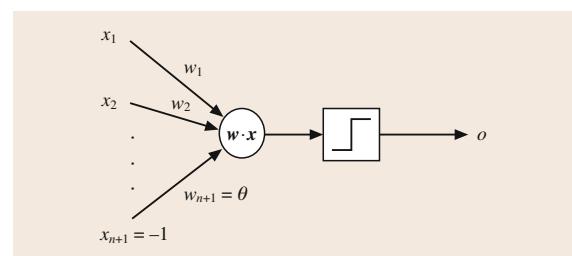

## 27.2 Perceptron

The perceptron is a simple neuron model that takes input signals (patterns) coded as (real) *input* vectors  $\bar{x} = (x_1, x_2, \dots, x_{n+1})$  through the associated (real) vector of synaptic *weights*  $\bar{w} = (w_1, w_2, \dots, w_{n+1})$ . The output  $o$  is determined by

$$o = f(\text{net}) = f(\bar{w} \cdot \bar{x}) = f\left(\sum_{j=1}^{n+1} w_j x_j\right) = f\left(\sum_{j=1}^n w_j x_j - \theta\right), \quad (27.1)$$

where *net* denotes the weighted sum of inputs, (i.e., dot product of weight and input vectors), and  $f$  is the *activation function*. By convention, if there are  $n$  inputs to

the perceptron, the input  $(n+1)$  will be fixed to  $-1$  and the associated weight to  $w_{n+1} = \theta$ , which is the value of the *excitation threshold*.

**Fig. 27.2** Schematic illustration of the perceptron model

In 1958 Rosenblatt [27.1] introduced a discrete perceptron model with a bipolar activation function (Fig. 27.2)

$$f(\text{net}) = \text{sign}(\text{net})$$

$$= \begin{cases} +1 & \text{if net} \geq 0 \Leftrightarrow \sum_{j=1}^n w_j x_j \geq \theta \\ -1 & \text{if net} < 0 \Leftrightarrow \sum_{j=1}^n w_j x_j < \theta. \end{cases} \quad (27.2)$$

The *boundary* equation

$$\sum_{j=1}^n w_j x_j - \theta = 0, \quad (27.3)$$

parameterizes a hyperplane in  $n$ -dimensional space with normal vector  $\bar{w}$ .

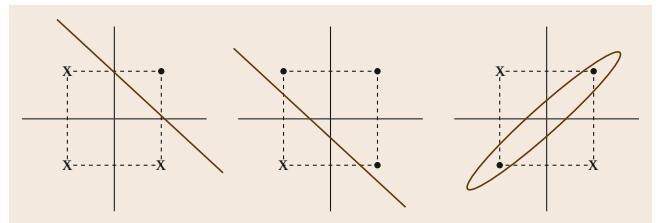

The perceptron can classify input patterns into two classes, if the classes can indeed be separated by an  $(n-1)$ -dimensional hyperplane (27.3). In other words, the perceptron can deal with *linearly-separable problems* only, such as logical functions AND or OR. XOR, on the other hand, is not linearly separable (Fig. 27.3). Rosenblatt showed that there is a simple training rule that will find the separating hyperplane, provided that the patterns are linearly separable.

As we shall see, a general rule for training many ANN models (not only the perceptron) can be formulated as follows: the weight vector  $\bar{w}$  is changed proportionally to the product of the input vector and a *learning signal*  $s$ . The learning signal  $s$  is a function of  $\bar{w}$ ,  $\bar{x}$ , and possibly a teacher feedback  $d$

$$s = s(\bar{w}, \bar{x}, d) \quad \text{or} \quad s = s(\bar{w}, \bar{x}). \quad (27.4)$$

In the former case, we talk about *supervised learning* (with direct guidance from a teacher); the latter case is known as *unsupervised learning*. The update of the  $j$ -th weight can be written as

$$w_j(t+1) = w_j(t) + \Delta w_j(t) = w_j(t) + \alpha s(t) x_j(t). \quad (27.5)$$

**Fig. 27.3** Linearly separable and non-separable problems

The positive constant  $0 < \alpha \leq 1$  is called the learning rate.

In the case of the perceptron, the learning signal is the disproportion (difference) between the desired (target) and the actual (produced by the model) response,  $s = d - o = \delta$ . The update rule is known as the  $\delta$  (delta) rule

$$\Delta w_j = \alpha(d - o)x_j. \quad (27.6)$$

The same rule can, of course, be used to update the activation threshold  $w_{n+1} = \theta$ .

Consider a training set

$$A_{\text{train}} = \{(\bar{x}^1, d^1)(\bar{x}^2, d^2) \dots (\bar{x}^p, d^p) \dots (\bar{x}^P, d^P)\}$$

consisting of  $P$  (input,target) couples. The perceptron training algorithm can be formally written as:

- **Step 1:** Set  $\alpha \in (0, 1)$ . Initialize the weights randomly from  $(-1, 1)$ . Set the counters to  $k = 1, p = 1$  ( $k$  indexes sweep through  $A_{\text{train}}$ ,  $p$  indexes individual training patterns).
- **Step 2:** Consider input  $\bar{x}^p$ , calculate the output  $o = \text{sign}(\sum_{j=1}^{n+1} w_j x_j^p)$ .
- **Step 3:** Weight update:  $w_j \leftarrow w_j + \alpha(d^p - o^p)x_j^p$ , for  $j = 1, \dots, n+1$ .
- **Step 4:** If  $p < P$ , set  $p \leftarrow p + 1$ , go to step 2. Otherwise go to step 5.
- **Step 5:** Fix the weights and calculate the cumulative error  $E$  on  $A_{\text{train}}$ .
- **Step 6:** If  $E = 0$ , finish training. Otherwise, set  $p = 1, k = k + 1$  and go to step 2. A new training epoch starts.

## 27.3 Multilayered Feed-Forward ANN Models

A breakthrough in our ability to construct and train more complex multilayered ANNs came in 1986, when Rumelhart et al. [27.2] introduced the error back-propagation method. It is based on making the transfer functions differentiable (hence the error functional to be minimized is differentiable as well) and finding a local minimum of the error functional by the gradient-based steepest descent method.

We will show derivation of the back-propagation algorithm for two-layer feed-forward ANN as demonstrated, e.g., in [27.3]. Of course, the same principles can be applied to a feed-forward ANN architecture with any (finite) number of layers. In feed-forward ANNs neurons are organized in layers. There are no connections among neurons within the same layer; connections only exist between successive layers. Each neuron from layer  $l$  has connections to each neuron in layer  $l+1$ .

As has already been mentioned, the *activation functions* need to be differentiable and are usually of the sigmoid *shape*. The most common activation functions are

- *Unipolar sigmoid:*

$$f(\text{net}) = \frac{1}{1 + \exp(-\lambda \text{net})} \quad (27.7)$$

- *Bipolar sigmoid* (hyperbolic tangent):

$$f(\text{net}) = \frac{2}{1 + \exp(-\lambda \text{net})} - 1. \quad (27.8)$$

The constant  $\lambda > 0$  determines steepness of the sigmoid curve and it is commonly set to 1. In the limit  $\lambda \rightarrow \infty$  the bipolar sigmoid tends to the sign function (used in the perceptron) and the unipolar sigmoid tends to the step function.

Consider the single-layer ANN in Fig. 27.4. The output and input vectors are  $\bar{y} = (y_1, \dots, y_j, \dots, y_J)$  and  $\bar{o} = (o_1, \dots, o_k, \dots, o_K)$ , respectively, where  $o_k = f(\text{net}_k)$  and

$$\text{net}_k = \sum_{j=1}^J w_{kj} y_j. \quad (27.9)$$

Set  $y_J = -1$  and  $w_{kJ} = \theta_k$ , a threshold for  $k = 1, \dots, K$  output neurons. The desired output is  $\bar{d} = (d_1, \dots, d_k, \dots, d_K)$ .

After training, we would like, for all training patterns  $p = 1, \dots, P$  from  $A_{\text{train}}$ , the model output to

closely resemble the desired values (target). The training problem is transformed to an optimization one by defining the error function

$$E_p = \frac{1}{2} \sum_{k=1}^K (d_{pk} - o_{pk})^2, \quad (27.10)$$

where  $p$  is the training point index.  $E_p$  is the sum of squares of errors on the output neurons. During learning we seek to find the weight setting that minimizes  $E_p$ . This will be done using the gradient-based steepest descent on  $E_p$ ,

$$\Delta w_{kj} = -\alpha \frac{\partial E_p}{\partial w_{kj}} = -\alpha \frac{\partial E_p}{\partial (\text{net}_k)} \frac{\partial (\text{net}_k)}{\partial w_{kj}} = \alpha \delta_{ok} y_j, \quad (27.11)$$

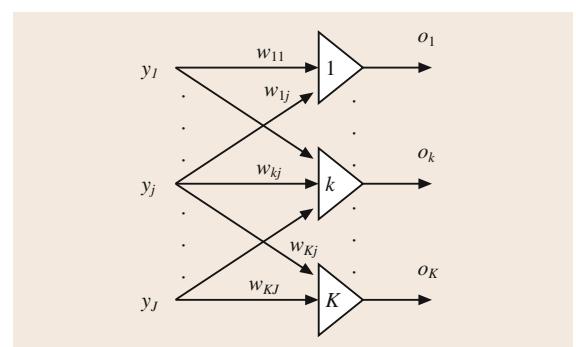

where  $\alpha$  is a positive learning rate. Note that  $-\partial E_p / \partial (\text{net}_k) = \delta_{ok}$ , which is the generalized training signal on the  $k$ -th output neuron. The partial derivative  $\partial (\text{net}_k) / \partial w_{kj}$  is equal to  $y_j$  (27.9). Furthermore,

$$\delta_{ok} = -\frac{\partial E_p}{\partial (\text{net}_k)} = -\frac{\partial E_p}{\partial o_k} \frac{\partial o_k}{\partial (\text{net}_k)} = (d_{pk} - o_{pk}) f'_k, \quad (27.12)$$

where  $f'_k$  denotes the derivative of the activation function with respect to  $\text{net}_k$ . For the unipolar sigmoid (27.7), we have  $f'_k = o_k(1 - o_k)$ . For the bipolar sigmoid (27.8),  $f'_k = (1/2)(1 - o_k^2)$ . The rule for updating the  $j$ -th weight of the  $k$ -th output neuron reads as

$$\Delta w_{kj} = \alpha (d_{pk} - o_{pk}) f'_k y_j, \quad (27.13)$$

where  $(d_{pk} - o_{pk}) f'_k = \delta_{ok}$  is *generalized error signal* flowing back through all connections ending in the  $k$ -th output neuron. Note that if we put  $f'_k = 1$ , we would obtain the perceptron learning rule (27.6).

**Fig. 27.4** A single-layer ANN

We will now extend the network with another layer, called the hidden layer (Fig. 27.5).

Input to the network is identical with the input vector  $\bar{x} = (x_1, \dots, x_i, \dots, x_I)$  for the hidden layer. The output neurons process as inputs the outputs  $\bar{y} = (y_1, \dots, y_j, \dots, y_J)$ ,  $y_j = f(\text{net}_j)$  from the hidden layer. Hence,

$$\text{net}_j = \sum_{i=1}^I v_{ji} x_i . \quad (27.14)$$

As before, the last (in this case the  $I$ -th) input is fixed to  $-1$ . Recall that the same holds for the output of the  $J$ -th hidden neuron. Activation thresholds for hidden neurons are  $v_{jl} = \theta_j$ , for  $j = 1, \dots, J$ .

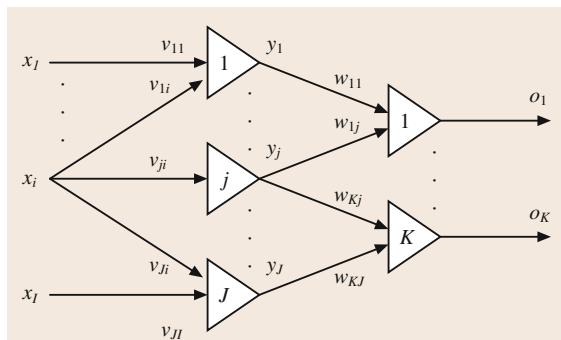

Equations (27.11)–(27.13) describe modification of weights from the hidden to the output layer. We will now show how to modify weights from the input to the hidden layer. We would still like to minimize  $E_p$  (27.10) through the steepest descent.

The hidden weight  $v_{ji}$  will be modified as follows

$$\Delta v_{ji} = -\alpha \frac{\partial E_p}{\partial v_{ji}} = -\alpha \frac{\partial E_p}{\partial (\text{net}_j)} \frac{\partial (\text{net}_j)}{\partial v_{ji}} = \alpha \delta_{yj} x_i . \quad (27.15)$$

Again,  $-\partial E_p / \partial (\text{net}_j) = \delta_{yj}$  is the generalized training signal on the  $j$ -th hidden neuron that should flow on the input weights. As before,  $\partial (\text{net}_j) / \partial v_{ji} = x_i$  (27.14). Furthermore,

$$\delta_{yj} = -\frac{\partial E_p}{\partial (\text{net}_j)} = -\frac{\partial E_p}{\partial y_j} \frac{\partial y_j}{\partial (\text{net}_j)} = -\frac{\partial E_p}{\partial y_j} f'_j , \quad (27.16)$$

**Fig. 27.5** A two-layer feed-forward ANN

where  $f'_j$  is the derivative of the activation function in the hidden layer with respect to  $\text{net}_j$ ,

$$\begin{aligned} \frac{\partial E_p}{\partial y_j} &= -\sum_{k=1}^K (d_{pk} - o_{pk}) \frac{\partial f(\text{net}_k)}{\partial y_j} \\ &= -\sum_{k=1}^K (d_{pk} - o_{pk}) \frac{\partial f(\text{net}_k)}{\partial (\text{net}_k)} \frac{\partial (\text{net}_k)}{\partial y_j} . \end{aligned} \quad (27.17)$$

Since  $f'_k$  is the derivative of the output neuron sigmoid with respect to  $\text{net}_k$  and  $\partial (\text{net}_k) / \partial y_j = w_{kj}$  (27.9), we have

$$\frac{\partial E_p}{\partial y_j} = -\sum_{k=1}^K (d_{pk} - o_{pk}) f'_k w_{kj} = -\sum_{k=1}^K \delta_{ok} w_{kj} . \quad (27.18)$$

Plugging this to (27.16) we obtain

$$\delta_{yj} = \left( \sum_{k=1}^K \delta_{ok} w_{kj} \right) f'_j . \quad (27.19)$$

Finally, the weights from the input to the hidden layer are modified as follows

$$\Delta v_{ji} = \alpha \left( \sum_{k=1}^K \delta_{ok} w_{kj} \right) f'_j x_i . \quad (27.20)$$

Consider now the general case of  $m$  hidden layers. For the  $n$ -th hidden layer we have

$$\Delta v_{ji}^n = \alpha \delta_{yj}^n x_i^{n-1} , \quad (27.21)$$

where

$$\delta_{yj}^n = \left( \sum_{k=1}^K \delta_{ok}^{n+1} w_{kj}^{n+1} \right) (f_j^n)' , \quad (27.22)$$

and  $(f_j^n)'$  is the derivative of the activation function of the  $n$ -layer with respect to  $\text{net}_j^n$ .

Often, the learning speed can be improved by using the so-called momentum term

$$\begin{aligned} \Delta w_{kj}(t) &\leftarrow \Delta w_{kj}(t) + \mu \Delta w_{kj}(t-1) , \\ \Delta v_{ji}(t) &\leftarrow \Delta v_{ji}(t) + \mu \Delta v_{ji}(t-1) , \end{aligned} \quad (27.23)$$

where  $\mu \in (0, 1)$  is the momentum rate.

Consider a training set

$$A_{\text{train}} = \{(\bar{x}^1, \bar{d}^1), (\bar{x}^2, \bar{d}^2), \dots, (\bar{x}^p, \bar{d}^p)\} .$$

The back-propagation algorithm for training feed-forward ANNs can be summarized as follows:

- *Step 1:* Set  $\alpha \in (0, 1)$ . Randomly initialize weights to *small* values, e.g., in the interval  $(-0.5, 0.5)$ . Counters and the error are initialized as follows:  $k = 1, p = 1, E = 0$ .  $E$  denotes the accumulated error across training patterns

$$E = \sum_{p=1}^P E_p, \quad (27.24)$$

where  $E_p$  is given in (27.10). Set a tolerance threshold  $\varepsilon$  for the error. The threshold will be used to stop the training process.

- *Step 2:* Apply input  $\bar{x}^p$  and compute the corresponding  $\bar{y}^p$  and  $\bar{o}^p$ .
- *Step 3:* For every output neuron, calculate  $\delta_{ok}$  (27.12), for hidden neuron determine  $\delta_{yj}$  (27.19).
- *Step 4:* Modify the weights  $w_{kj} \leftarrow w_{kj} + \alpha \delta_{ok} y_j$  and  $v_{ji} \leftarrow v_{ji} + \alpha \delta_{yj} x_i$ .
- *Step 5:* If  $p < P$ , set  $p = p + 1$  and go to step 2. Otherwise go to step 6.
- *Step 6:* Fixing the weights, calculate  $E$ . If  $E < \varepsilon$ , stop training, otherwise permute elements of  $A_{\text{train}}$ , set  $E = 0, p = 1, k = k + 1$ , and go to step 2.

Consider a feed-forward ANN with fixed weights and single output unit. It can be considered a real-valued function  $G$  on  $I$ -dimensional vectorial inputs,

$$G(\bar{x}) = f \left( \sum_{j=1}^J w_j f \left( \sum_{i=1}^I v_{ji} x_i \right) \right).$$

There has been a series of results showing that such a parameterized function class is *sufficiently rich* in the space of *reasonable* functions (see, e.g., [27.4]). For example, for any smooth function  $F$  over a compact domain and a precision threshold  $\varepsilon$ , for sufficiently large number  $J$  of hidden units there is a weight setting so that  $G$  is not further away from  $F$  than  $\varepsilon$  (in L-2 norm).

When training a feed-forward ANN a key decision must be made about how complex the model should be. In other words, how many hidden units  $J$  one should use. If  $J$  is too small, the model will be too rigid (high

bias) and it will not be able to sufficiently adapt to the data. However, under different samples from the same data generating process, the resulting trained models will vary relatively little (low variance). On the other hand, if  $J$  is too high, the model will be too complex, modeling even such irrelevant features of the data such as output noise. The particular data will be interpolated exactly (low bias), but the variability of fitted models under different training samples from the same process will be immense. It is, therefore, important to set  $J$  to an *optimal* value, reflecting the complexity of the data generating process. This is usually achieved by splitting the data into three disjoint sets – *training*, *validation*, and *test sets*. Models with different numbers of hidden units are trained on the training set, their performance is then checked on a held-out validation set. The *optimal* number of hidden units is selected based on the (smallest) validation error. Finally, the test set is used for independent comparison of selected models from different model classes.

If the data set is not large enough, one can perform such a *model selection* using *k-fold cross-validation*. The data for model construction (this data would be considered training and validation sets in the scenario above) is split into  $k$  disjoint folds. One fold is selected as the validation fold, the other  $k - 1$  will be used for training. This is repeated  $k$  times, yielding  $k$  estimates of the validation error. The validation error is then calculated as the mean of those  $k$  estimates.

We have described data-based methods for model selection. Other alternatives are available. For example, by turning an ANN into a probabilistic model (e.g., by including an appropriate output noise model), under some prior assumptions on weights (e.g., a-priori small weights are preferred), one can perform Bayesian model selection (through *model evidence*) [27.5].

There are several seminal books on feed-forward ANNs with well-documented theoretical foundations and practical applications, e.g., [27.3, 6, 7]. We refer the interested reader to those books as good starting points as the breadth of theory and applications of feed-forward ANNs is truly immense.

## 27.4 Recurrent ANN Models

Consider a situation where the associations in the training set we would like to learn are of the following (abstract) form:  $a \rightarrow \alpha, b \rightarrow \beta, b \rightarrow \alpha, b \rightarrow \gamma, c \rightarrow \alpha, c \rightarrow \gamma, d \rightarrow \alpha$ , etc., where the Latin and Greek letters stand for input and output vectors, respectively. It is

clear that now for one input item there can be different output associations, depending on the *temporal context* in which the training items are presented. In other words, *the model output is determined not only by the input, but also by the history of presented items so far*.

Obviously, the feed-forward ANN model described in the previous section cannot be used in such cases and the model must be further extended so that the temporal context is properly represented.

The architecturally simplest solution is provided by the so-called *time delay neural network* (TDNN) (Fig. 27.6). The input window *into the past* has a finite length  $D$ . If the output is an estimate of the next item of the input time series, such a network realizes a non-linear autoregressive model of order  $D$ .

If we are lucky, even such a simple solution can be sufficient to capture the temporal structure hidden in the data. An advantage of the TDNN architecture is that some training methods developed for feed-forward networks can be readily used. A disadvantage of TDNN networks is that fixing a finite order  $D$  may not be adequate for modeling the temporal structure of the data generating source. TDNN enables the feed-forward ANN to see, besides the current input at time  $t$ , the other inputs from the past up to time  $t - D$ . Of course, during the training, it is now imperative to preserve the order of training items in the training set. TDNN has been successfully applied in many fields where spatial-temporal structures are naturally present, such as robotics, speech recognition, etc. [27.8, 9].

In order to extend the ANN architecture so that the *variable* (even unbounded) length of input window can be flexibly considered, we need a different way of capturing the temporal context. This is achieved through the so-called *state space formulation*. In this case, we will need to change our outlook on training. The new architectures of this type are known as *recurrent neural networks* (RNN).

As in feed-forward ANNs, there are connections between the successive layers. In addition, and in contrast to feed-forward ANNs, connections between neurons of the same layer are allowed, but subject to a *time de-*

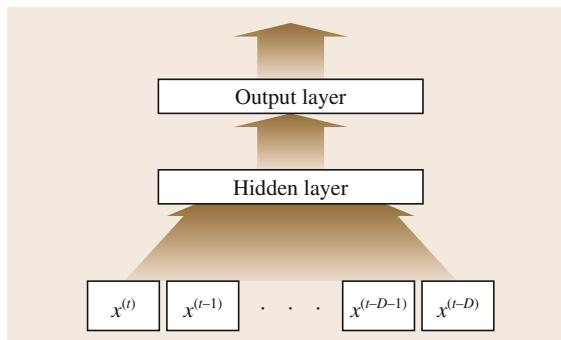

Fig. 27.6 TDNN of order  $D$

*lay*. It also may be possible to have connections from a higher-level layer to a lower layer, again subject to a time delay. In many cases it is, however, more convenient to introduce an additional fictional *context layer* that contains delayed activations of neurons from the selected layer(s) and represent the resulting RNN architecture as a feed-forward architecture with some fixed one-to-one delayed connections. As an example, consider the so-called *simple recurrent network* (SRN) of Elman [27.10] shown in Fig. 27.7. The output of SRN at time  $t$  is given by

$$\begin{aligned} o_k^{(t)} &= f \left( \sum_{j=1}^J m_{kj} y_j^{(t)} \right), \\ y_j^{(t)} &= f \left( \sum_{i=1}^J w_{ji} y_i^{(t-1)} + \sum_{i=1}^I v_{ji} x_i^{(t)} \right). \end{aligned} \quad (27.25)$$

The hidden layer constitutes the state of the input-driven dynamical system whose role it is to represent the relevant (with respect to the output) information

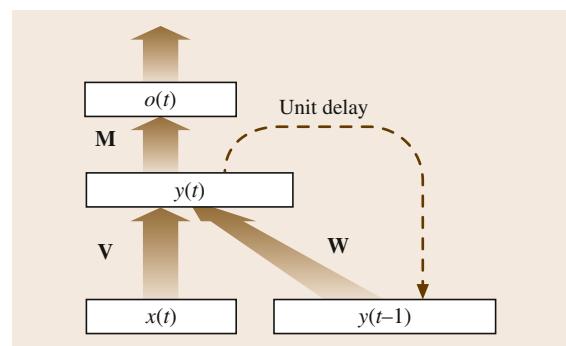

Fig. 27.7 Schematic depiction of the SRN architecture

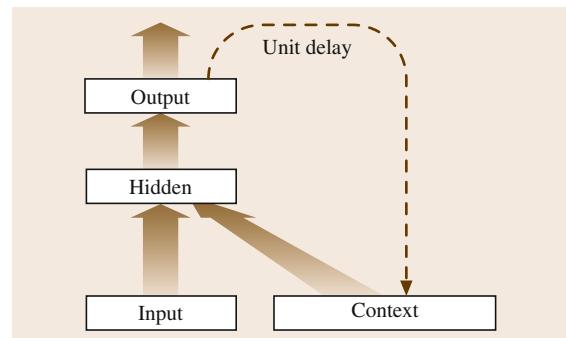

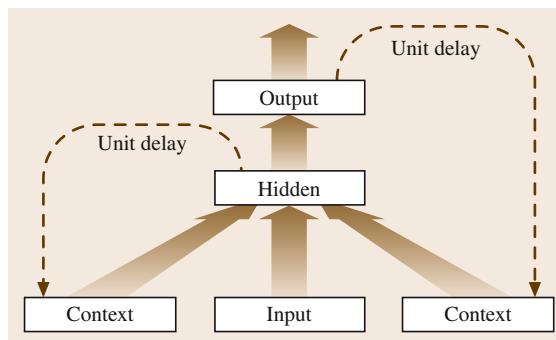

Fig. 27.8 Schematic depiction of the Jordan's RNN architecture

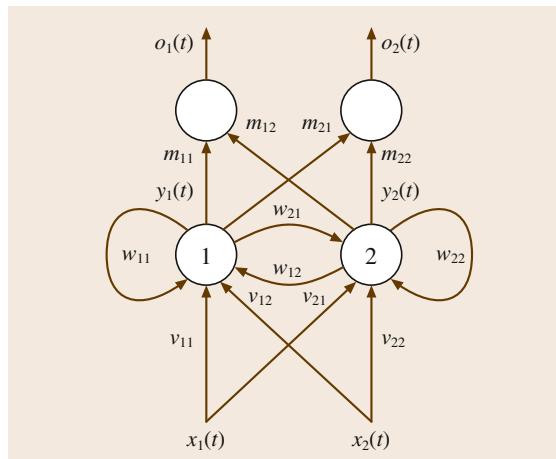

about the input history seen so far. The state (as in generic state space model) is updated recursively.

Many variations on such architectures with time-delayed feedback loops exist. For example, *Jordan* [27.11] suggested to feed back the outputs as the relevant temporal context, or *Bengio* et al. [27.12] mixed the temporal context representations of **SRN** and the Jordan network into a single architecture. Schematic representations of these architectures are shown in Figs. 27.8 and 27.9.

Training in such architectures is more complex than training of feed-forward **ANNs**. The principal problem is that changes in weights propagate in time and this needs to be explicitly represented in the update rules. We will briefly mention two approaches to training **RNNs**, namely *back-propagation through time* (**BPTT**) [27.13] and *real-time recurrent learning* (**RTRL**) [27.14]. We will demonstrate **BPTT** on a clas-

**Fig. 27.9** Schematic depiction of the Bengio's **RNN** architecture

**Fig. 27.10** A two-neuron SRN

sification task, where the label of the input sequence is known only after  $T$  time steps (i.e., after  $T$  input items have been processed). The **RNN** is unfolded in time to form a feed-forward network with  $T$  hidden layers. Figure 27.10 shows a simple two-neuron **RNN** and Fig. 27.11 represents its unfolded form for  $T = 2$  time steps.

The first input comes at time  $t = 1$  and the last at  $t = T$ . Activities of context units are initialized at the beginning of each sequence to some fixed numbers. The unfolded network is then trained as a feed-forward network with  $T$  hidden layers. At the end of the sequence, the model output is determined as

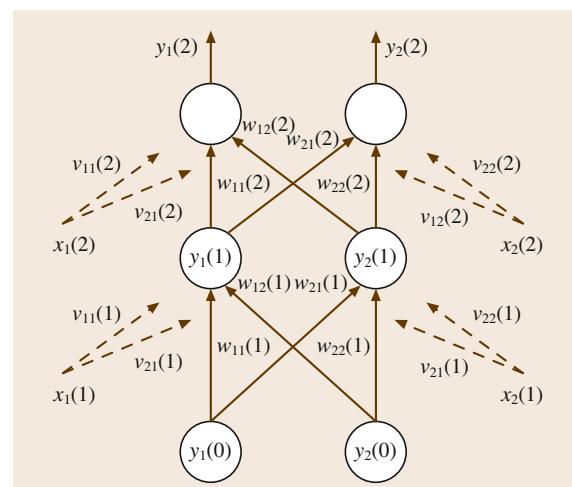

$$\begin{aligned} o_k^{(T)} &= f \left( \sum_{j=1}^J m_{kj}^{(T)} y_j^{(T)} \right), \\ y_j^{(t)} &= f \left( \sum_{i=1}^I w_{ji}^{(t)} y_i^{(t-1)} + \sum_{i=1}^I v_{ji}^{(t)} x_i^{(t)} \right). \end{aligned} \quad (27.26)$$

Having the model output enables us to compute the error

$$E(T) = \frac{1}{2} \sum_{k=1}^K (d_k^{(T)} - o_k^{(T)})^2. \quad (27.27)$$

The hidden-to-output weights are modified according to

$$\Delta m_{kj}^{(T)} = -\alpha \frac{\partial E(T)}{\partial m_{kj}} = \alpha \delta_k^{(T)} y_j^{(T)}, \quad (27.28)$$

**Fig. 27.11** Two-neuron **SRN** unfolded in time for  $T = 2$

where

$$\delta_k^{(T)} = \left( d_k^{(T)} - o_k^{(T)} \right) f' \left( \text{net}_k^{(T)} \right). \quad (27.29)$$

The other weight updates are calculated as follows

$$\Delta w_{hj}^{(T)} = -\alpha \frac{\partial E(T)}{\partial w_{hj}} = \alpha \delta_h^{(T)} y_j^{(T-1)}; \quad (27.30)$$

$$\delta_h^{(T)} = \left( \sum_{k=1}^K \delta_k^{(T)} m_{kh}^{(T)} \right) f' \left( \text{net}_h^{(T)} \right) \quad (27.30)$$

$$\Delta v_{ji}^{(T)} = -\alpha \frac{\partial E(T)}{\partial v_{ji}} = \alpha \delta_j^{(T)} x_i^{(T)}; \quad (27.31)$$

$$\delta_j^{(T)} = \left( \sum_{k=1}^K \delta_k^{(T)} m_{kj}^{(T)} \right) f' \left( \text{net}_j^{(T)} \right) \quad (27.31)$$

$$\Delta w_{hj}^{(T-1)} = \alpha \delta_h^{(T-1)} y_j^{(T-2)};$$

$$\delta_h^{(T-1)} = \left( \sum_{j=1}^J \delta_j^{(T-1)} w_{jh}^{(T-1)} \right) f' \left( \text{net}_h^{(T-1)} \right) \quad (27.32)$$

$$\Delta v_{ji}^{(T-1)} = \alpha \delta_j^{(T-1)} x_i^{(T-1)};$$

$$\delta_j^{(T-1)} = \left( \sum_{h=1}^H \delta_h^{(T-1)} w_{hj}^{(T-1)} \right) f' \left( \text{net}_j^{(T-1)} \right), \quad (27.33)$$

etc. The final weight updates are the averages of the  $T$  partial weight update suggestions calculated on the unfolded network

$$\Delta w_{hj} = \frac{\sum_{t=1}^T \Delta w_{hj}^{(t)}}{T} \quad \text{and} \quad \Delta v_{ji} = \frac{\sum_{t=1}^T \Delta v_{ji}^{(t)}}{T}. \quad (27.34)$$

For every new training sequence (of possibly different length  $T$ ) the network is unfolded to the desired length and the weight update process is repeated. In some cases (e.g., continual prediction on time series), it is necessary to set the maximum unfolding length  $L$  that will be used in every update step. Of course, in such cases we can lose vital information from the past. This problem is eliminated in the **RTRL** methodology.

Consider again the **SRN** architecture in Fig. 27.6. In **RTRL** the weights are updated *on-line*, i.e., at every

time step  $t$

$$\begin{aligned} \Delta w_{kj}^{(t)} &= -\alpha \frac{\partial E^{(t)}}{\partial w_{kj}^{(t)}}, \\ \Delta v_{ji}^{(t)} &= -\alpha \frac{\partial E^{(t)}}{\partial v_{ji}^{(t)}}, \\ \Delta m_{jl}^{(t)} &= -\alpha \frac{\partial E^{(t)}}{\partial m_{jl}^{(t)}}. \end{aligned} \quad (27.35)$$

The updates of hidden-to-output weights are straightforward

$$\Delta m_{kj}^{(t)} = \alpha \delta_k^{(t)} y_j^{(t)} = \alpha \left( d_k^{(t)} - o_k^{(t)} \right) f'_k \left( \text{net}_k^{(t)} \right) y_j^{(t)}. \quad (27.36)$$

For the other weights we have

$$\Delta v_{ji}^{(t)} = \alpha \sum_{k=1}^K \left( \delta_k^{(t)} \sum_{h=1}^J w_{kh} \frac{\partial y_h^{(t)}}{\partial v_{ji}} \right),$$

$$\Delta w_{ji}^{(t)} = \alpha \sum_{k=1}^K \left( \delta_k^{(t)} \sum_{h=1}^J w_{kh} \frac{\partial y_h^{(t)}}{\partial w_{ji}} \right), \quad (27.37)$$

where

$$\frac{\partial y_h^{(t)}}{\partial v_{ji}} = f' \left( \text{net}_h^{(t)} \right) \left( x_i^{(t)} \delta_{jh}^{\text{Kron.}} + \sum_{l=1}^J w_{hl} \frac{\partial y_l^{(t-1)}}{\partial v_{ji}} \right) \quad (27.38)$$

$$\frac{\partial y_h^{(t)}}{\partial w_{ji}} = f' \left( \text{net}_h^{(t)} \right) \left( x_i^{(t)} \delta_{jh}^{\text{Kron.}} + \sum_{l=1}^J w_{hl} \frac{\partial y_l^{(t-1)}}{\partial w_{ji}} \right), \quad (27.39)$$

and  $\delta_{jh}^{\text{Kron.}}$  is the Kronecker delta ( $\delta_{jh}^{\text{Kron.}} = 1$ , if  $j = h$ ;  $\delta_{jh}^{\text{Kron.}} = 0$  otherwise). The partial derivatives required for the weight updates can be recursively updated using (27.37)–(27.39). To initialize training, the partial derivatives at  $t = 0$  are usually set to 0.

There is a well-known problem associated with gradient-based parameter fitting in recurrent networks (and, in fact, in any parameterized state space models of similar form) [27.15]. In order to *latch* an important piece of past information for future use, the state-transition dynamics (27.25) should have an attractive set.

However, in the neighborhood of such an attractive set, the derivatives of the dynamic state-transition map

vanish. Vanishingly small derivatives cannot be reliably propagated back through time in order to form a useful latching set. This is known as the *information latching problem*. Several suggestions for dealing with information latching problem have been made, e.g., [27.16]. The most prominent include *long short term memory (LSTM) RNN* [27.17] and *reservoir computation* models [27.18].

**LSTM** models operate with a specially designed formal neuron model that contains so-called *gate* units. The gates determine when the input is *significant* (in terms of the task given) to be remembered, whether the neuron should continue to remember the value, and when the value should be output. The **LSTM** architecture is especially suitable for situations where there are long time intervals of unknown size between *important* events. **LSTM** models have been shown to provide superior results over traditional **RNNs** in a variety of applications (e.g., [27.19, 20]).

Reservoir computation models try to avoid the information latching problem by fixing the state-transition part of the **RNN**. Only linear readout from the state activations (hidden recurrent layer) producing the output is fit to the data. The state space with the as-

sociated dynamic state transition structure is called the *reservoir*. The main idea is that the reservoir should be sufficiently complex so as to capture a large number of potentially useful features of the input stream that can be then exploited by the simple readout.

The reservoir computing models differ in how the fixed reservoir is constructed and what form the readout takes. For example, *echo state networks (ESN)* [27.21] have fixed **RNN** dynamics (27.25), but with a linear hidden-to-output layer map. *Liquid state machines (LSM)* [27.22] also have (mostly) linear readout, but the reservoirs are realized through the dynamics of a set of coupled spiking neuron models. *Fractal prediction machines (FPM)* [27.23] are reservoir **RNN** models for processing discrete sequences. The reservoir dynamics is driven by an affine iterative function system and the readout is constructed as a collection of multinomial distributions. Reservoir models have been successfully applied in many practical applications with competitive results, e.g., [27.21, 24, 25].

Several books that are solely dedicated to **RNNs** have appeared, e.g., [27.26–28] and they contain a much deeper elaboration on theory and practice of **RNNs** than we were able to provide here.

## 27.5 Radial Basis Function ANN Models

In this section we will introduce another implementation of the idea of feed-forward **ANN**. The activations of hidden neurons are again determined by the *closeness* of inputs  $\bar{x} = (x_1, x_2, \dots, x_n)$  to weights  $\bar{c} = (c_1, c_2, \dots, c_n)$ . Whereas in the feed-forward **ANN** in Sect. 27.3, the closeness is determined by the dot-product of  $\bar{x}$  and  $\bar{c}$ , followed by the sigmoid activation function, in *radial basis function (RBF) networks* the closeness is determined by the squared Euclidean distance of  $\bar{x}$  and  $\bar{c}$ , transferred through the inverse exponential. The output of the  $j$ -th hidden unit with input weight vector  $\bar{c}_j$  is given by

$$\varphi_j(\bar{x}) = \exp\left(-\frac{\|\bar{x} - \bar{c}_j\|^2}{\sigma_j^2}\right), \quad (27.40)$$

where  $\sigma_j$  is the *activation strength* parameter of the  $j$ -th hidden unit and determines the width of the spherical (un-normalized) Gaussian. The output neurons are usually linear (for regression tasks)

$$o_k(\bar{x}) = \sum_{j=1}^J w_{kj} \varphi_j(\bar{x}). \quad (27.41)$$

The **RBF** network in this form can be simply viewed as a form of kernel regression. The  $J$  functions  $\varphi_j$  form a set of  $J$  linearly independent basis functions (e.g., if all the centers  $\bar{c}_j$  are different) whose span (the set of all their linear combinations) forms a linear subspace of functions that are realizable by the given **RBF** architecture (with given centers  $\bar{c}_j$  and kernel widths  $\sigma_j$ ).

For the training of **RBF** networks, it is important that the basis functions  $\varphi_j(\bar{x})$  cover the structure of the inputs space *faithfully*. Given a set of training inputs  $\bar{x}^p$  from  $A_{\text{train}} = \{(\bar{x}^1, \bar{d}^1), (\bar{x}^2, \bar{d}^2), \dots, (\bar{x}^p, \bar{d}^p)\}$ , many **RBF-ANN** training algorithms determine the centers  $\bar{c}_j$  and widths  $\sigma_j$  based on the inputs  $\{\bar{x}^1, \bar{x}^2, \dots, \bar{x}^p\}$  only. One can employ different clustering algorithms, e.g., *k-means* [27.29], which attempts to position the centers among the training inputs so that the overall sum of (Euclidean) distances between the centers and the inputs they represent (i.e., the inputs falling in their respective Voronoi compartments – the set of inputs for which the current center is the closest among all the centers) is minimized:

- *Step 1:* Set  $J$ , the number of hidden units. The optimum value of  $J$  can be obtained through a model selection method, e.g., cross-validation.
- *Step 2:* Randomly select  $J$  training inputs that will form the initial positions of the  $J$  centers  $\bar{c}_j$ .
- *Step 3:* At time step  $t$ :
  - a) Pick a training input  $\bar{x}(t)$  and find the center  $\bar{c}(t)$  closest to it.
  - b) Shift the center  $\bar{c}(t)$  towards  $\bar{x}(t)$
$$\bar{c}(t) \leftarrow \bar{c}(t) + \rho(t)(\bar{x}(t) - \bar{c}(t)),$$

where  $0 \leq \rho(t) \leq 1$ . (27.42)

The learning rate  $\rho(t)$  usually decreases in time towards zero. The training is stopped once the centers settle in their positions and move only slightly (some norm of weight updates is below a certain threshold). Since  $k$ -means is guaranteed to find only locally optimal solutions, it is worth re-initializing the centers and re-running the algorithm several times, keeping the solution with the lowest quantization error.

Once the centers are in their positions, it is easy to determine the **RBF** widths, and once this is done, the

output weights can be solved using methods of linear regression.

Of course, it is more optimal to position the centers with respect to *both* the inputs and target outputs in the training set. This can be formulated, e.g., as a gradient descent optimization. Furthermore, covering of the input space with spherical Gaussian kernels may not be optimal, and algorithms have been developed for learning of general covariance structures. A comprehensive review of **RBF** networks can be found, e.g., in [27.30].

Recently, it was shown that if enough hidden units are used, their centers can be set randomly at very little cost, and determination of the only remaining free parameters – output weights – can be done cheaply and in a closed form through linear regression. Such architectures, known as *extreme learning machines* [27.31] have shown surprisingly high performance levels. The idea of extreme learning machines can be considered as being analogous to the idea of reservoir computation, but in the *static* setting. Of course, extreme learning machines can be built using other implementations of feed-forward **ANNs**, such as the sigmoid networks of Sect. 27.3.

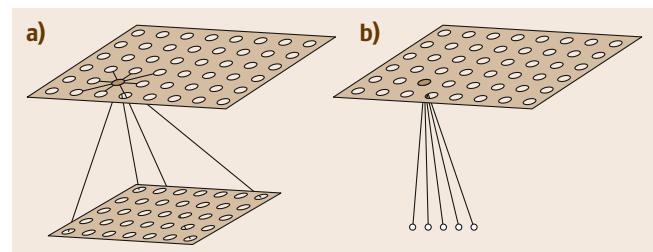

## 27.6 Self-Organizing Maps

In this section we will introduce **ANN** models that learn without any signal from a teacher, i.e., learning is based solely on training inputs – there are no output targets. The **ANN** architecture designed to operate in this setting was introduced by *Kohonen* under the name *self-organizing map* (**SOM**) [27.32]. This model is motivated by organization of neuron sensitivities in the brain cortex.

In Fig. 27.12a we show schematic illustration of one of the principal organizations of biological neural networks. In the bottom layer (grid) there are receptors representing the inputs. Every element of the inputs (each receptor) has forward connections to all neurons in the upper layer representing the cortex. The neurons are organized spatially on a grid. Outputs of the neurons represent activation of the **SOM** network. The neurons, besides receiving connections from the input receptors, have a lateral interconnection structure among themselves, with connections that can be excitatory, or inhibitory. In Fig. 27.12b we show a formal **SOM** architecture – neurons spatially organized on a grid receive inputs (elements of input vectors) through connections with synaptic weights.

A particular feature of the **SOM** is that it can map the training set on the neuron grid in a manner that preserves the training set's topology – two input patterns *close* in the input space will activate neurons most that are close on the **SOM** grid. Such *topological mapping* of inputs (feature mapping) has been observed in biological neural networks [27.32] (e.g., visual maps, orientation maps of visual contrasts, or auditory maps, frequency maps of acoustic stimuli).

Teuvo Kohonen presented one possible realization of the Hebb rule that is used to train **SOM**. Input

**Fig. 27.12a,b** Schematic representation of the **SOM ANN** architecture

weights of the neurons are initialized as small random numbers. Consider a training set of inputs,  $A_{\text{train}} = \{\bar{x}_p\}_{p=1}^P$  and linear neurons

$$o_i = \sum_{j=1}^m w_{ij}x_j = \bar{w}_i \bar{x}, \quad (27.43)$$

where  $m$  is the input dimension and  $i = 1, \dots, n$ . Training inputs are presented in random order. At each training step, we find the (winner) neuron with the weight vector *most similar* to the current input  $\bar{x}$ . The measure of similarity can be based on the dot product, i.e., the index of the winner neuron is  $i^* = \arg \max(\bar{w}_i^T \bar{x})$ , or the (Euclidean) distance  $i^* = \arg \min_i \|\bar{x} - \bar{w}_i\|$ . After identifying the winner the learning continues by adapting the winner's weights *along with the weights all its neighbors on the neuron grid*. This will ensure that nearby neurons on the grid will eventually represent similar inputs in the input space. This is moderated by a *neighborhood function*  $h(i^*, i)$  that, given a winner neuron index  $i^*$ , quantifies how many other neurons on the grid should be adapted

$$\bar{w}_i(t+1) = \bar{w}_i(t) + \alpha(t) \cdot h(i^*, i) \cdot (\bar{x}(t) - \bar{w}_i(t)). \quad (27.44)$$

The learning rate  $\alpha(t) \in (0, 1)$  decays in time as  $1/t$ , or  $\exp(-kt)$ , where  $k$  is a positive time scale constant. This ensures convergence of the training process. The simplest form of the neighborhood function operates with rectangular neighborhoods,

$$h(i^*, i) = \begin{cases} 1, & \text{if } d_M(i^*, i) \leq \lambda(t) \\ 0, & \text{otherwise,} \end{cases} \quad (27.45)$$

where  $d_M(i^*, i)$  represents the  $2\lambda(t)$  (*Manhattan*) distance between neurons  $i^*$  and  $i$  on the map grid. The neighborhood size  $2\lambda(t)$  should decrease in time, e.g., through an exponential decay as  $\exp(-qt)$ , with time scale  $q > 0$ . Another often used neighborhood function is the Gaussian kernel

$$h(i^*, i) = \exp\left(-\frac{d_E(i^*, i)^2}{\lambda^2(t)}\right), \quad (27.46)$$

where  $d_E(i^*, i)$  is the Euclidean distance between  $i^*$  and  $i$  on the grid, i.e.,  $d_E(i^*, i) = \|\bar{r}_{i^*} - \bar{r}_i\|$ , where  $\bar{r}_i$  is the co-ordinate vector of the  $i$ -th neuron on the grid **SOM**.

Training of **SOM** networks can be summarized as follows:

- *Step 1:* Set  $\alpha_0$ ,  $\lambda_0$  and  $t_{\max}$  (maximum number of iterations). Randomly (e.g., with uniform distribution) generate the synaptic weights (e.g., from  $(-0.5, 0.5)$ ). Initialize the counters:  $t = 0$ ,  $p = 1$ ;  $t$  indexes time steps (iterations) and  $p$  is the input pattern index.
- *Step 2:* Take input  $\bar{x}^p$  and find the corresponding winner neuron.
- *Step 3:* Update the weights of the winner and its topological neighbors on the grid (as determined by the neighborhood function). Increment  $t$ .
- *Step 4:* Update  $\alpha$  and  $\lambda$ .
- *Step 5:* If  $p < P$ , set  $p \leftarrow p + 1$ , go to step 2 (we can also use randomized selection), otherwise go to step 6.
- *Step 6:* If  $t = t_{\max}$ , finish the training process. Otherwise set  $p = 1$  and go to step 2. A new training epoch begins.

The **SOM** network can be used as a tool for non-linear data visualization (grid dimensions 1, 2, or 3). In general, **SOM** implements constrained vector quantization, where the codebook vectors (vector quantization centers) cannot move freely in the data space during adaptation, but are constrained to lie on a lower dimensional manifold  $\Psi$  in the data space. The dimensionality of  $\Psi$  is equal to the dimensionality of the neural grid. The neural grid can be viewed as a discretized version of the local co-ordinate system  $\Upsilon$  (e.g., computer screen) and the weight vectors in the data space (connected by the neighborhood structure on the neuron grid) as its image in the data space. In this interpretation, the neuron positions on the grid represent co-ordinate functions (in the sense of differential geometry) mapping elements of the manifold  $\Psi$  to the coordinate system  $\Upsilon$ . Hence, the **SOM** algorithm can also be viewed as one particular implementation of manifold learning.

There have been numerous successful applications of **SOM** in a wide variety of applications, e.g., in image processing, computer vision, robotics, bioinformatics, process analysis, and telecommunications. A good survey of **SOM** applications can be found, e.g., in [27.33]. **SOMs** have also been extended to temporal domains, mostly by the introduction of additional feedback connections, e.g., [27.34–37]. Such models can be used for topographic mapping or constrained clustering of time series data.

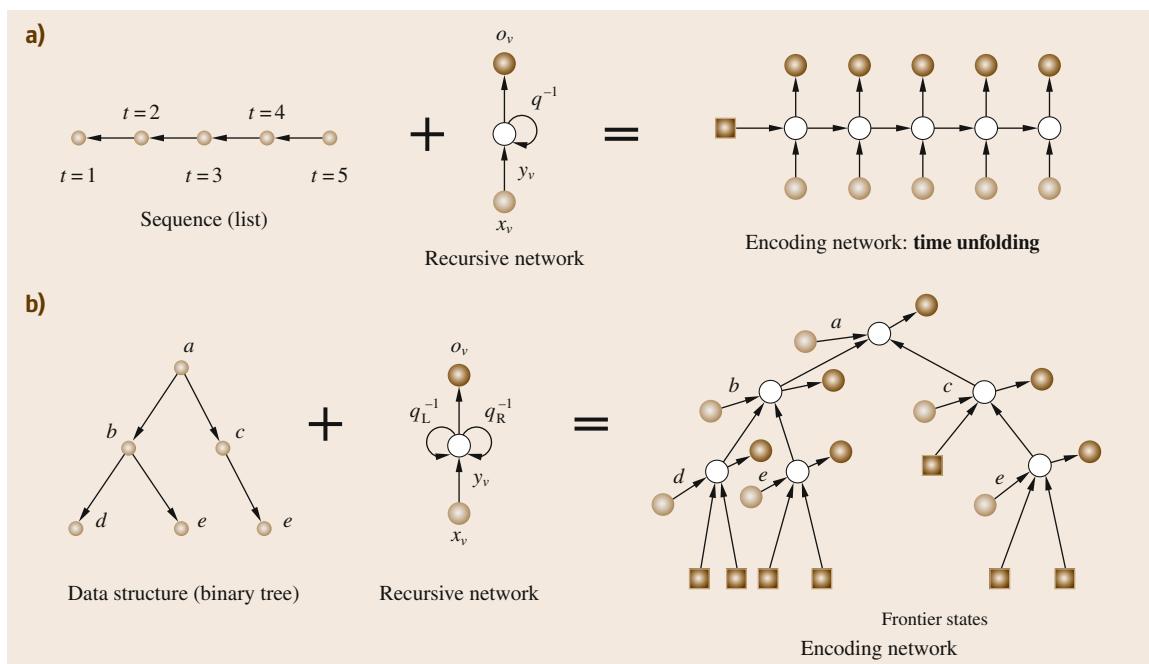

## 27.7 Recursive Neural Networks

In many application domains, data are naturally organized in structured form, where each data item is composed of several components related to each other in a non-trivial way, and the specific nature of the task to be performed is strictly related not only to the information stored at each component, but also to the structure connecting the components. Examples of structured data are parse trees obtained by parsing sentences in natural language, and the molecular graph describing a chemical compound.

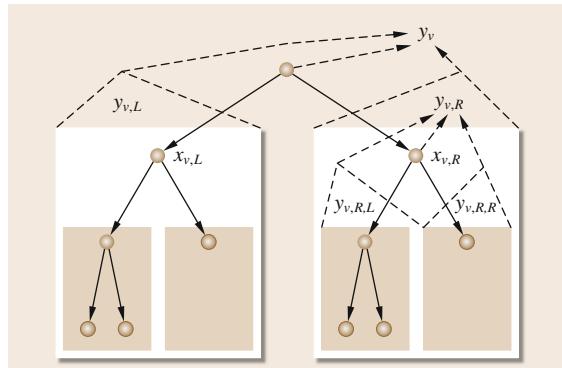

**Recursive neural networks (RecNN)** [27.38, 39] are neural network models that are able to directly process structured data, such as trees and graphs. For the sake of presentation, here we focus on positional trees. Positional trees are trees for which each child has an associated index, its position, with respect to the siblings. Let us understand how RecNN is able to process a tree by analogy with what happens when unfolding a RNN when processing a sequence, which can be understood as a special case of tree where each node  $v$  possesses a single child.

In Fig. 27.13 (top) we show the unfolding in time of a sequence when considering a graphical model (*re-*

*cursive network*) representing, for a generic node  $v$ , the functional dependencies among the input information  $x_v$ , the state variable (hidden node)  $y_v$ , and the output variable  $o_v$ . The operator  $q^{-1}$  represents the shift operator in time (unit time delay), i.e.,  $q^{-1}y_t = y_{t-1}$ , which applied to node  $v$  in our framework returns the child of node  $v$ . At the bottom of Fig. 27.13 we have reported the unfolding of a binary tree, where the recursive network uses a generalization of the shift operator, which given an index  $i$  and a variable associated to a vertex  $v$  returns the variable associated to the  $i$ -th child of  $v$ , i.e.,  $q_i^{-1}y_v = y_{\text{ch}_i[v]}$ . So, while in RNN the network is *unfolded in time*, in RecNN the network is *unfolded on the structure*. The result of unfolding, in both cases, is the *encoding network*. The encoding network for the sequence specifies how the components implementing the different parts of the recurrent network (e.g., each node of the recurrent network could be instantiated by a layer of neurons or by a full feed-forward neural network with hidden units) need to be interconnected. In the case of the tree, the encoding network has the same semantics: this time, however, a set of parameters (weights) for each child should be considered, leading to a net-

**Fig. 27.13a,b** Generation of the encoding network (a) for a sequence and (b) a tree. Initial states are represented by squared nodes

**Fig. 27.14** The causality style of computation induced by the use of recursive networks is made explicit by using nested boxes to represent the recursive dependencies of the hidden variable associated to the root of the tree ▶

work that, given a node  $v$ , can be described by the equations

$$o_k^{(v)} = f \left( \sum_{j=1}^J m_{kj} y_j^{(v)} \right),$$

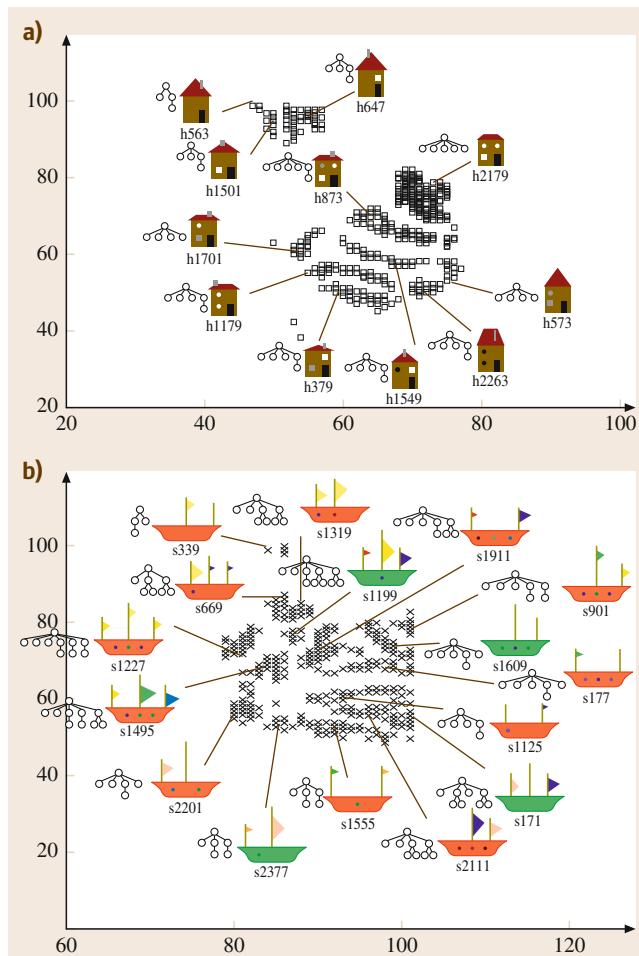

$$y_j^{(v)} = f \left( \sum_{s=1}^d \sum_{i=1}^J w_{ji}^s y_i^{(\text{ch}_s[v])} + \sum_{i=1}^I v_{ji} x_i^{(v)} \right),$$

where  $d$  is the maximum number of children an input node can have, and weights  $w_{ji}^s$  are indexed on the  $s$ -th child. Note that it is not difficult to generalize *all the learning algorithms* devised for **RNN** to these extended equations.

It should be remarked that recursive networks clearly introduce a causal style of computation, i.e., the computation of the hidden and output variables for a vertex  $v$  only depends on the information attached to  $v$  and the hidden variables of the children of  $v$ . This dependence is satisfied recursively by all  $v$ 's descendants and is clearly shown in Fig. 27.14. In the figure, nested boxes are used to make explicit the recursive dependencies among hidden variables that contribute to the determination of the hidden variable  $y_v$  associated to the root of the tree.

Although an encoding network can be generated for a directed acyclic graph (**DAG**), this style of computation limits the discriminative ability of **RecNN** to the class of trees. In fact, the hidden state is not able to encode information about the *parents* of nodes. The introduction of *contextual processing*, however, allows us to discriminate, with some specific exceptions, among **DAGs** [27.40]. Recently, *Micheli* [27.41] also showed how contextual processing can be used to extend **RecNN** to the treatment of *cyclic* graphs.

The same idea described above for supervised neural networks can be adapted to unsupervised models, where the output value of a neuron typically represents the similarity of the weight vector associated to the neuron with the input vector. Specifically, in [27.37] **SOMs** were extended to the processing of structured data (**SOM-SD**). Moreover, a general framework for self-organized processing of structured data

**Fig. 27.15a,b** Schematic illustration of a principal organization of biological self-organizing neural network (a) and its formal counterpart **SOM ANN** architecture (b)

was proposed in [27.42]. The key concepts introduced are:

- i) The explicit definition of a representation space  $R$  equipped with a similarity measure  $d_R(\cdot, \cdot)$  to evaluate the similarity between two hidden states.
- ii) The introduction of a general representation function, denoted  $rep(\cdot)$ , which transforms the activation of the map for a given input into an hidden state representation.

In these models, each node  $v$  of the input structure is represented by a tuple  $[\bar{x}_v, \bar{r}_{v_1}, \dots, \bar{r}_{v_d}]$ , where  $\bar{x}_v$  is a real-valued vectorial encoding of the information attached to vertex  $v$ , and  $\bar{r}_{v_i}$  are real-valued

vectorial representations of hidden states returned by the  $rep(\cdot)$  function when processing the activation of the map for the  $i$ -th neighbor of  $v$ . Each neuron  $n_j$  in the map is associated to a weight vector  $[\bar{w}_j, \bar{c}_j^1, \dots, \bar{c}_j^d]$ . The computation of the winner neuron is based on the joint contribution of the similarity measures  $d_x(\cdot, \cdot)$  for the input information, and  $d_R(\cdot, \cdot)$  for the hidden states, i.e., the internal representations. Some parts of a SOM-SD map trained on DAGs representing visual patterns are shown in Fig. 27.15. Even in this case the style of computation is causal, ruling out the treatment of undirected and/or cyclic graphs. In order to cope with general graphs, recently a new model, named GraphSOM [27.43], was proposed.

## 27.8 Conclusion

The field of artificial neural networks ([ANN](#)) has grown enormously in the past 60 years. There are many journals and international conferences specifically devoted to neural computation and neural network related models and learning machines. The field has gone a long way from its beginning in the form of simple threshold units existing in isolation (e.g., the perceptron, Sect. 27.2) or connected in circuits. Since then we have learnt how to generalize such networks as parameterized differentiable models of various sorts that can be fit to data (*trained*), usually by transforming the learning task into an optimization one.

[ANN](#) models have found numerous successful practical applications in many diverse areas of science and engineering, such as astronomy, biology, finance, geology, etc. In fact, even though basic feed-forward [ANN](#) architectures were introduced long time ago, they continue to surprise us with successful applications, most recently in the form of *deep networks* [27.44]. For example, a form of deep [ANN](#) recently achieved the best performance on a well-known benchmark problem – the recognition of handwritten digits [27.45]. This is quite remarkable, since such a simple [ANN](#) architecture trained in a purely data driven fashion was able to outperform the current state-of-art techniques, formulated in more sophisti-

cated frameworks and possibly incorporating domain knowledge.

[ANN](#) models have been formulated to operate in supervised (e.g., feed-forward [ANN](#), Sect. 27.3; [RBF](#) networks, Sect. 27.5), unsupervised (e.g., [SOM](#) models, Sect. 27.6), semi-supervised, and reinforcement learning scenarios and have been generalized to process inputs that are much more general than simple vector data of fixed dimensionality (e.g., the recurrent and recursive networks discussed in Sects. 27.4 and 27.7). Of course, we were not able to cover all important developments in the field of [ANNs](#). We can only hope that we have sufficiently motivated the interested reader with the variety of modeling possibilities based on the idea of interconnected networks of formal neurons, so that he/she will further consult some of the many (much more comprehensive) monographs on the topic, e.g., [27.3, 6, 7].

We believe that [ANN](#) models will continue to play an important role in modern computational intelligence. Especially the inclusion of [ANN](#)-like models in the field of probabilistic modeling can provide techniques that incorporate both explanatory model-based and data-driven approaches, while preserving a much fuller modeling capability through operating with full distributions, instead of simple point estimates.

# 28. Deep and Modular Neural Networks

Ke Chen

In this chapter, we focus on two important areas in neural computation, i.e., deep and modular neural networks, given the fact that both deep and modular neural networks are among the most powerful machine learning and pattern recognition techniques for complex AI problem solving. We begin by providing a general overview of deep and modular neural networks to describe the general motivation behind such neural architectures and fundamental requirements imposed by complex AI problems. Next, we describe background and motivation, methodologies, major building blocks, and the state-of-the-art hybrid learning strategy in context of deep neural architectures. Then, we describe background and motivation, taxonomy, and learning algorithms pertaining to various typical modular neural networks in a wide context. Furthermore, we also examine relevant

issues and discuss open problems in deep and modular neural network research areas.

Part D | 28.1

## 28.1 Overview

The human brain is a generic effective and efficient system that solves complex and difficult problems and generates the trait of intelligence and creation. Neural computation has been inspired by brain-related research in different disciplines, e.g., biology and neuroscience, on various levels ranging from a simple single-neuron to complex neuronal structure and organization [28.1]. Among many discoveries in brain-related sciences, two of the most important properties are modularity and hierarchy of neuronal organization in the human brain.

Neuroscientific research has revealed that the central nervous system (CNS) in the human brain is a distributed, massively parallel, and self-organizing modular system [28.1–3]. The CNS is composed of several regions such as the spinal cord, medulla oblongata, pons, midbrain, diencephalon, cerebellum, and the two cerebral hemispheres. Each such region forms a functional module and all regions are interconnected with

other parts of the brain [28.1]. In particular, the cerebral cortex consists of several regions attributed to main perceptual and cognitive tasks, where modularity emerges in two different aspects: i.e., structural and functional modularity. Structural modularity is observable from the fact that there are sparse connections between different neuronal groups but neurons are often densely connected within a neuronal group, while functional modularity is evident from different response patterns produced by neural modules for different perceptual and cognitive tasks. Modularity evidence in the human brain strongly suggests that domain-specific modules are required by specific tasks and different modules can cooperate for high level, complex tasks, which primarily motivates the modular neural network (MNN) development in neural computation (NC) [28.4, 5].

Apart from modularity, the human brain also exhibits a functional and structural hierarchy given the fact

that information processing in the human brain is done in a hierarchical way. Previous studies [28.6, 7] suggested that there are different cortical visual areas that lead to hierarchical information representations to carry out highly complicated visual tasks, e.g., object recognition. In general, hierarchical information processing enables the human brain to accomplish complex perceptual and cognitive tasks in an effective and extremely efficient way, which mainly inspires the study of deep neural networks (**DNNs**) of multiple layers in **NC**.

In general, both **DNNs** and **MNNs** can be categorized into biologically plausible [28.8] and artificial

models [28.9] in **NC**. The main difference between biologically plausible and artificial models lies their methodologies that a biologically plausible model often takes both structural and functional resemblance to its biological counterpart into account, while an artificial model simply works towards modeling the functionality of a biological system without considering those bio-mimetic factors. Due to the limited space, in this chapter we merely focus on artificial **DNNs** and **MNNs**. Readers interested in biologically plausible models are referred to the literature, e.g., [28.4], for useful information.

## 28.2 Deep Neural Networks

In this section, we overview main deep neural network (**DNN**) techniques with an emphasis on the latest progress. We first review background and motivation for **DNN** development. Then we describe major building blocks and relevant learning algorithms for constructing different **DNNs**. Next, we present a hybrid learning strategy in the context of **NC**. Finally, we examine relevant issues related to **DNNs**.

### 28.2.1 Background and Motivation

The study of **NC** dates back to the 1940s when McCulloch and Pitts modeled a neuron mathematically. After that **NC** was an active area in **AI** studies until Minsky and Papert published their influential book, Perceptron [28.10], in 1969. In the book, they formally proved the limited capacities of the single-layer perceptron and further concluded that there is a slim chance to expand its capacities with its multi-layer version, which significantly slowed down **NC** research until the back-propagation (**BP**) algorithm was invented (or reinvented) to solve the learning problem in a multi-layer perceptron (**MLP**) [28.11].

In theory, the **BP** algorithm enables one to train an **MLP** of many hidden layers to form a powerful **DNN**. Such an attractive technique has aroused tremendous enthusiasm in applying **DNNs** in different fields [28.9]. Apart from a few exceptions, e.g., [28.12], researchers soon found that an **MLP** of more than two hidden layers often failed [28.13] due to the well-known fact that **MLP** learning involves an extremely difficult non-convex optimization problem, and the gradient-based local search used in the **BP** algorithm easily gets stuck in an unwanted local minimum. As a result, most re-

searchers gradually gave up deep architectures and devoted their attention to shallow learning architectures of theoretical justification, e.g., the formal but non-constructive proof that an **MLP** of single hidden layer may be a universal function approximator [28.14] and a support vector machine (**SVM**) [28.15], instead. It has been shown that shallow architectures often work well with support of effective feature extraction techniques (but these are often handcrafted). However, recent theoretic justification suggests that learning models of insufficient depth have a fundamental weakness as they cannot efficiently represent the very complicated functions often required in complex **AI** tasks [28.16, 17].

To solve complex the non-convex optimization problem encountered in **DNN** learning, Hinton and his colleagues made a breakthrough by coming up with a hybrid learning strategy in 2006 [28.18]. The novel learning strategy combines unsupervised and supervised learning paradigms where a layer-wise greedy unsupervised learning is first used to construct an initial **DNN** with chosen building blocks (such an initial **DNN** alone can also be used for different purposes, e.g., unsupervised feature learning [28.19]), and supervised learning is then fulfilled based on the pre-trained **DNN**. Their seminal work led to an emerging machine learning (**ML**) area, *deep learning*. As a result, different building blocks and learning algorithms have been developed to construct various **DNNs**. Both theoretical justification and empirical evidence suggest that the hybrid learning strategy [28.18] greatly facilitates learning of **DNNs** [28.17].

Since 2006, **DNNs** trained with the hybrid learning strategy have been successfully applied in different and complex **AI** tasks, such as pattern recogni-

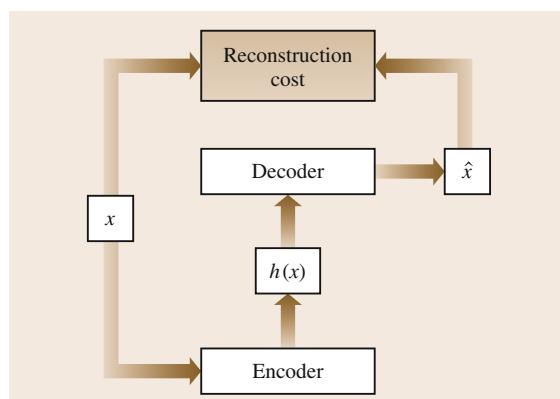

tion [28.20–23], various computer vision tasks [28.24–26], audio classification and speech information processing [28.27–31], information retrieval [28.32–34], natural language processing [28.35–37], and robotics [28.38]. Thus, DNNs have become one of the most promising ML and NC techniques to tackle challenging AI problems [28.39].

### 28.2.2 Building Blocks and Learning Algorithms

In general, a building block is composed of two parametric models, *encoder* and *decoder*, as illustrated in Fig. 28.1. An encoder transforms a raw input or a low-level representation  $\mathbf{x}$  into a high-level and abstract representation  $\mathbf{h}(\mathbf{x})$ , while a decoder generates an output  $\hat{\mathbf{x}}$ , a reconstructed version of  $\mathbf{x}$ , from  $\mathbf{h}(\mathbf{x})$ . The learning building block is a self-supervised learning task that minimizes an elaborate *reconstruction cost function* to find appropriate parameters in encoder and decoder. Thus, the distinction between two building blocks of different types lies in their encoder and decoder mechanisms and reconstruction cost functions (as well as optimization algorithms used for parameter estimation). Below we describe different building blocks and their learning algorithms in terms of the generic architecture shown in Fig. 28.1.

#### Auto-Encoders

The auto-encoder [28.40] and its variants are simple building blocks used to build an MLP of many layers. It is carried out by an MLP of one hidden layer. As depicted in Fig. 28.2, the input and the hidden layers constitute an encoder to generate a  $M$ -

**Fig. 28.1** Schematic diagram of a generic building block architecture

dimensional representation  $\mathbf{h}(\mathbf{x}) = (h_1(\mathbf{x}), \dots, h_M(\mathbf{x}))^\top$  (hereinafter, we use the notation  $\mathbf{h}(\mathbf{x}) = (h_m(\mathbf{x}))_{m=1}^M$  to indicate a vector-element relationship for simplifying the presentation) for a given input  $\mathbf{x} = (x_n)_{n=1}^N$  in  $N$ -dimensional space

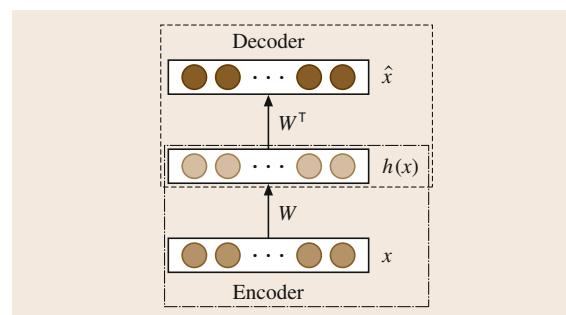

$$\mathbf{h}(\mathbf{x}) = f(W\mathbf{x} + \mathbf{b}_h),$$

where  $W$  is a connection weight matrix between the input and the hidden layers,  $\mathbf{b}_h$  is the bias vector for all hidden neurons, and  $f(\cdot)$  is a transfer function, e.g., the sigmoid function [28.9]. Let  $f(\mathbf{u}) = (f(u_k))_{k=1}^K$  be a collective notation for output of all  $K$  neurons in a layer. Accordingly, the hidden and the output layers form a decoder that yields a reconstructed version  $\hat{\mathbf{x}} = (\hat{x}_n)_{n=1}^N$

$$\hat{\mathbf{x}} = f(W^\top \mathbf{h}(\mathbf{x}) + \mathbf{b}_o),$$

where  $W^\top$  is the transpose of the weight matrix  $W$  and  $\mathbf{b}_o$  is the bias vector for all output neurons. Note that the auto-encoder can be viewed as a special case of auto-associator when the same weights are tied to be used in connections between different layers, which will be clearly seen in the learning algorithm later on. Doing so avoids an unwanted solution when an over-complete representation, i.e.,  $M > N$ , is required [28.22].

Further studies [28.41] suggest that the auto-encoder is unlikely to lead to the discovery of a more useful representation than the input despite the fact that a representation should encode much of the information conveyed in the input whenever the auto-encoder produces a good reconstruction of its input. As a result, a variant named the denoising auto-encoder (DAE) was proposed to capture stable structures underlying the distribution of its observed input. The basic idea is as follows: instead of learning the auto-encoder from the intact input, the DAE will be trained to recover the

**Fig. 28.2** Auto-encoder architecture

original input from its distorted version of partial destruction [28.41]. As is illustrated in Fig. 28.3, the DAE leads to a more useful representation  $\mathbf{h}(\tilde{\mathbf{x}})$  by restoring the corrupted input  $\tilde{\mathbf{x}}$  to a reconstructed version  $\hat{\mathbf{x}}$  as close to the clean input  $\mathbf{x}$  as possible. Thus, the encoder yields a representation as

$$\mathbf{h}(\tilde{\mathbf{x}}) = f(W\tilde{\mathbf{x}} + \mathbf{b}_h),$$

and the decoder produces a restored version  $\hat{\mathbf{x}}$  via the representation  $\mathbf{h}(\tilde{\mathbf{x}})$

$$\hat{\mathbf{x}} = f(W^T \mathbf{h}(\tilde{\mathbf{x}}) + \mathbf{b}_o).$$

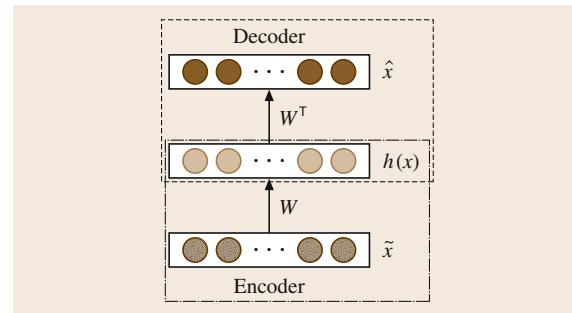

To produce a corrupted input, we need to distort a clean input by corrupting it with appropriate noise. Depending on the attribute nature of input, there are three kinds of noise used in the corruption process: i.e., the isotropic *Gaussian noise*,  $N(0, \sigma^2 I)$ , *masking noise* (by setting some randomly chosen elements of  $\mathbf{x}$  to zero) and *salt-and-pepper noise* (by flipping some randomly chosen elements' values of  $\mathbf{x}$  to the maximum or the minimum of a given range). Normally, Gaussian noise is used for input of real or continuous values, while masking and salt-and-pepper noise is applied to input of discrete values, e.g., pixel intensities of gray images. It is worth stating that the variance  $\sigma^2$  in Gaussian noise and the number of randomly chosen elements in masking and salt-and-pepper noise are hyper-parameters that affect DAE learning. By corrupting a clean input with the chosen noise, we achieve an example,  $(\tilde{\mathbf{x}}, \mathbf{x})$ , for self-supervised learning.

Given a training set of  $T$  examples  $\{(\mathbf{x}_t, \mathbf{x}_t)\}_{t=1}^T$  (auto-encoder) or  $\{(\tilde{\mathbf{x}}_t, \mathbf{x}_t)\}_{t=1}^T$  (DAE) two reconstruction cost functions are commonly used for learning auto-encoders as follows

$$L(W, \mathbf{b}_h, \mathbf{b}_o) = \frac{1}{2T} \sum_{t=1}^T \sum_{n=1}^N (x_m - \hat{x}_m)^2, \quad (28.1a)$$

$$\begin{aligned} L(W, \mathbf{b}_h, \mathbf{b}_o) \\ = -\frac{1}{T} \sum_{t=1}^T \sum_{n=1}^N (x_m \log \hat{x}_m + (1 - x_m) \log (1 - \hat{x}_m)). \end{aligned} \quad (28.1b)$$

The cost function in (28.1a) is used for input of real or discrete values, while the cost function in (28.1b) is employed especially for input of binary values.

**Fig. 28.3** Denoising auto-encoder architecture

To minimize reconstruction functions in (28.1), application of the stochastic gradient descent algorithm [28.12] leads to a generic learning algorithm for training the auto-encoder and its variant, summarized as follows:

**Auto-Encoder Learning Algorithm.** Given a training set of  $T$  examples,  $\{(\mathbf{z}_t, \mathbf{x}_t)\}_{t=1}^T$  where  $\mathbf{z}_t = \mathbf{x}_t$  for the auto-encoder or  $\mathbf{z}_t = \tilde{\mathbf{x}}_t$  for the DAE, and a transfer function,  $f(\cdot)$ , randomly initialize all parameters,  $W$ ,  $\mathbf{b}_h$  and  $\mathbf{b}_o$ , in auto-encoders and pre-set a learning rate  $\epsilon$ . Furthermore, the training set is randomly divided into several batches of  $T_B$  examples,  $\{(\mathbf{z}_t, \mathbf{x}_t)\}_{t=1}^{T_B}$ , and then parameters are updated based on each batch:

- Forward computation

For the input  $\mathbf{z}_t$  ( $t = 1, \dots, T_B$ ), output of the hidden layer is

$$\mathbf{h}(\mathbf{z}_t) = f(\mathbf{u}_h(\mathbf{z}_t)), \quad \mathbf{u}_h(\mathbf{z}_t) = W\mathbf{z}_t + \mathbf{b}_h.$$

And output of the output layer is

$$\hat{\mathbf{x}}_t = f(\mathbf{u}_o(\mathbf{z}_t)), \quad \mathbf{u}_o(\mathbf{z}_t) = W^T \mathbf{h}(\mathbf{z}_t) + \mathbf{b}_o.$$

- Backward gradient computation

For the cost function in (28.1a),

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(\mathbf{z}_t)} = ((\hat{x}_m - x_m)f'(u_{o,n}(\mathbf{z}_t)))_{n=1}^N,$$

where  $f'(\cdot)$  is the first-order derivative function of  $f(\cdot)$ . For the cost function in (28.1b),

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(\mathbf{z}_t)} = \hat{\mathbf{x}}_t - \mathbf{x}_t.$$

Then, the gradient with respect to  $\mathbf{h}(\mathbf{z}_t)$  is

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{h}(\mathbf{z}_t)} = W \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(\mathbf{z}_t)}.$$

Applying the chain rule achieves the gradient with respect to  $\mathbf{u}_h(z_t)$  as

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_h(z_t)} = \left( f'(u_{h,m}(z_t)) \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial h_m(z_t)} \right)_{m=1}^M.$$

Gradients with respect to biases are

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{b}_o} = \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(z_t)},$$

and

$$\frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{b}_h} = \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_h(z_t)}.$$

- Parameter update

Applying the gradient descent method and tied weights leads to update rules

$$\begin{aligned} W &\leftarrow W - \frac{\epsilon}{T_B} \sum_{t=1}^{T_B} \left[ \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_h(z_t)} [z_t]^\top \right. \\ &\quad \left. + \mathbf{h}(z_t) \left( \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(z_t)} \right)^\top \right], \\ \mathbf{b}_o &\leftarrow \mathbf{b}_o - \frac{\epsilon}{T_B} \sum_{t=1}^{T_B} \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_o(z_t)}, \end{aligned}$$

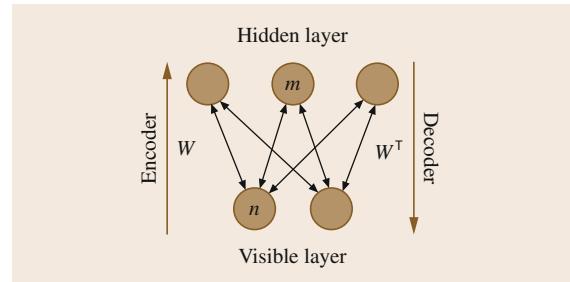

and

$$\mathbf{b}_h \leftarrow \mathbf{b}_h - \frac{\epsilon}{T_B} \sum_{t=1}^{T_B} \frac{\partial L(W, \mathbf{b}_h, \mathbf{b}_o)}{\partial \mathbf{u}_h(z_t)}.$$

The above three steps repeat for all batches, which leads to a training epoch. The learning algorithm runs iteratively until a termination condition is met (typically based on a cross-validation procedure [28.12]).

### The Restricted Boltzmann Machine

Strictly speaking, the restricted Boltzmann machine (**RBM**) [28.42] is an energy-based generative model, a simplified version of the generic Boltzmann machine. As illustrated in Fig. 28.4, an **RBM** can be viewed as a probabilistic **NN** of two layers, i.e., *visible* and *hidden* layers, with bi-directional connections. Unlike the Boltzmann machine, there are no lateral connections among neurons in the same layer in an **RBM**. With the bottom-up connections from the visible to the

**Fig. 28.4** Restricted Boltzmann machine (**RBM**) architecture

hidden layer, **RBM** forms an encoder that yields a probabilistic representation  $\mathbf{h} = (h_m)_{m=1}^M$  for input data  $\mathbf{v} = (v_n)_{n=1}^N$

$$\begin{aligned} P(\mathbf{h}|\mathbf{v}) &= \prod_{m=1}^M P(h_m|\mathbf{v}), \\ P(h_m|\mathbf{v}) &= \phi \left( \sum_{n=1}^N W_{mn} v_n + b_{h,m} \right), \end{aligned} \quad (28.2)$$

where  $W_{mn}$  is the connection weight between the visible neuron  $n$  and the hidden neuron  $m$ , and  $b_{h,m}$  is the bias of the hidden neuron  $m$ .  $\phi(u) = \frac{1}{1+e^{-u}}$  is the sigmoid transfer function. As  $h_m$  is assumed to take a binary value, i.e.,  $h_m \in \{0, 1\}$ ,  $P(h_m|\mathbf{v})$  is interpreted as the probability of  $h_m = 1$ . Accordingly, **RBM** performs a probabilistic decoder via the top-down connections from the hidden to the visible layer to reconstruct an input with the probability

$$\begin{aligned} P(\mathbf{v}|\mathbf{h}) &= \prod_{m=1}^M P(v_n|\mathbf{h}), \\ P(v_n|\mathbf{h}) &= \phi \left( \sum_{m=1}^N W_{nm} h_m + b_{v,n} \right), \end{aligned} \quad (28.3)$$

where  $W_{nm}$  is the connection weight between the hidden neuron  $m$  and the visible neuron  $n$ , and  $b_{v,n}$  is the bias of visible neuron  $n$ . Like connection weights in auto-encoders, bi-directional connection weights are tied, i.e.,  $W_{mn} = W_{nm}$ , as shown in Fig. 28.4. By learning a parametric model of the data distribution  $P(\mathbf{v})$  derived from the joint probability  $P(\mathbf{v}, \mathbf{h})$  for a given data set, **RBM** yields a probabilistic representation that tends to reconstruct any data subject to  $P(\mathbf{v})$ .

The joint probability  $P(\mathbf{v}, \mathbf{h})$  is defined based on the following energy function for  $v_n \in \{0, 1\}$

$$\begin{aligned} E(\mathbf{v}, \mathbf{h}) = & - \sum_{m=1}^M \sum_{n=1}^N W_{mn} h_m v_n \\ & - \sum_{m=1}^M h_m b_{h,m} - \sum_{n=1}^N v_n b_{v,n}. \end{aligned} \quad (28.4)$$

As a result, the joint probability is subject to the Boltzmann distribution

$$P(\mathbf{v}, \mathbf{h}) = \frac{e^{-E(\mathbf{v}, \mathbf{h})}}{\sum_{\mathbf{v}} \sum_{\mathbf{h}} e^{-E(\mathbf{v}, \mathbf{h})}}. \quad (28.5)$$

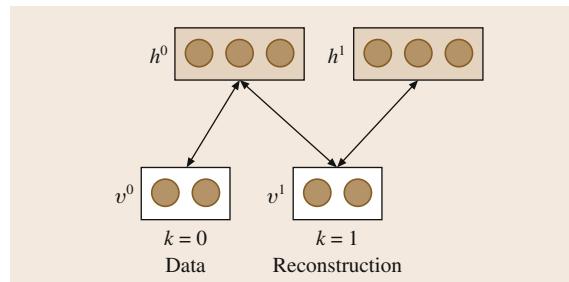

Thus, we achieve the data probability by marginalizing the joint probability as follows

$$P(\mathbf{v}) = \sum_{\mathbf{h}} P(\mathbf{v}, \mathbf{h}) = \sum_{\mathbf{h}} P(\mathbf{v}|\mathbf{h})P(\mathbf{h}).$$

In order to achieve the most likely reconstruction, we need to maximize the log-likelihood of  $P(\mathbf{v})$ . Therefore, the reconstruction cost function of an **RBM** is its negative log-likelihood function

$$L(W, \mathbf{b}_h, \mathbf{b}_v) = -\log P(\mathbf{v}) = -\log \sum_{\mathbf{h}} P(\mathbf{v}|\mathbf{h})P(\mathbf{h}). \quad (28.6)$$

From (28.5) and (28.6), it is observed that the direct use of a gradient descent method for optimal parameters often leads to intractable computation due to the fact that the exponential number of possible hidden-layer configurations needs to be summed over in (28.5) and then used in (28.6). Fortunately, an approximation algorithm named *contrastive divergence* (**CD**) has been proposed to solve this problem [28.42]. The key ideas behind the **CD** algorithm are (i) using Gibbs sampling based on the conditional distributions in (28.2) and (28.3), and (ii) running only a few iterations of Gibbs sampling by treating the data  $\mathbf{x}$  input to an **RBM** as the initial state, i.e.,  $\mathbf{v}^0 = \mathbf{x}$ , of the Markov chain at the visible layer. Many studies have suggested that only the use of one iteration of the Markov chain in the **CD** algorithm works well for building up a deep belief network (**DBN**) in practice [28.17, 18, 22], and hence the algorithm is dubbed **CD-1** in this situation, a special case of the **CD-k** algorithm that executes  $k$  iterations of the Markov chain in the Gibbs sampling process.

**Fig. 28.5** Gibbs sampling process in the **CD-1** algorithm

Figure 28.5 illustrates a Gibbs sampling process used in the **CD-1** algorithm as follows

- Estimating probabilities  $P(h_m^0|\mathbf{v}^0)$ , for  $m = 1, \dots, M$ , with the encoder defined in (28.2) and then forming a realization of  $\mathbf{h}^0$  by sampling with these probabilities.
- Applying the decoder defined in (28.3) to estimate probabilities  $P(v_n^1|\mathbf{h}^0)$ , for  $n = 1, \dots, N$ , and then producing a reconstruction of  $\mathbf{v}^1$  via sampling.
- With the reconstruction, estimating probabilities  $P(h_m^1|\mathbf{v}^1)$ , for  $m = 1, \dots, M$ , with the encoder.

With the above Gibbing sampling procedure, the **CD-1** algorithm is summarized as follows:

#### Algorithm 28.1 RBM CD-1 Learning Algorithm

Given a training set of  $T$  instances,  $\{\mathbf{x}_t\}_{t=1}^T$ , randomly initialize all parameters,  $W, \mathbf{b}_h$  and  $\mathbf{b}_v$ , in an **RBM** and pre-set a learning rate  $\epsilon$ :

- Positive phase
  - Present an instance to the visible layer, i.e.,  $\mathbf{v}^0 = \mathbf{x}_t$ .
  - Estimate probabilities with the encoder:  $\hat{P}(\mathbf{h}^0|\mathbf{v}^0) = (P(h_m^0|\mathbf{v}^0))_{m=1}^M$  by using (28.2).
- Negative phase
  - Form a realization of  $\mathbf{h}^0$  by sampling with probabilities  $\hat{P}(\mathbf{h}^0|\mathbf{v}^0)$ .
  - With the realization of  $\mathbf{h}^0$ , apply the decoder to estimate probabilities:  $\hat{P}(\mathbf{v}^1|\mathbf{h}^0) = (P(v_n^1|\mathbf{h}^0))_{n=1}^N$  by using (28.3), and then produce a reconstruction  $\mathbf{v}^1$  via sampling based on  $\hat{P}(\mathbf{v}^1|\mathbf{h}^0)$ .
  - With the encoder and the reconstruction, estimate probabilities:  $\hat{P}(\mathbf{h}^1|\mathbf{v}^1) = (P(h_m^1|\mathbf{v}^1))_{m=1}^M$  by using (28.2).
- Parameter update
  - Based on Gibbs sampling results in the positive and

the negative phases, parameters are updated as follows:

$$\begin{aligned} W &\leftarrow W + \epsilon \left( \hat{\mathbf{P}}(\mathbf{h}^0|\mathbf{v}^0)(\mathbf{v}^0)^\top - \hat{\mathbf{P}}(\mathbf{h}^1|\mathbf{v}^1)(\mathbf{v}^1)^\top \right), \\ \mathbf{b}_h &\leftarrow \mathbf{b}_h + \epsilon \left( \hat{\mathbf{P}}(\mathbf{h}^0|\mathbf{v}^0) - \hat{\mathbf{P}}(\mathbf{h}^1|\mathbf{v}^1) \right), \end{aligned}$$

and

$$\mathbf{b}_v \leftarrow \mathbf{b}_v + \epsilon (\mathbf{v}^0 - \mathbf{v}^1).$$

The above three steps repeat for all instances in the given training set, which leads to a training epoch. The learning algorithm runs iteratively until it converges.

### Predictive Sparse Decomposition

Predictive sparse decomposition (**PSD**) [28.43] is a building block obtained by combining sparse coding [28.44] and auto-encoder ideas. In a **PSD** building block, the encoder is specified by

$$\mathbf{h}(\mathbf{x}_t) = G \tanh(W_E \mathbf{x}_t + \mathbf{b}_h), \quad (28.7)$$

where  $W_E$  is the  $M \times N$  connection matrix between input and hidden neurons in the encoder and  $G = \text{diag}(g_{mm})$  is an  $M \times M$  learnable diagonal gain matrix for an  $M$ -dimensional representation of an  $N$ -dimensional input,  $\mathbf{x}_t, \mathbf{b}_h$  are biases of hidden neurons, and  $\tanh(\cdot)$  is the hyperbolic tangent transfer function [28.9]. Accordingly, the decoder is implemented by a linear mapping used in the sparse coding [28.44]

$$\hat{\mathbf{x}}_t = W_D \mathbf{h}(\mathbf{x}_t), \quad (28.8)$$

where  $W_D$  is an  $N \times M$  connection matrix between hidden and output neurons in the decoder, and each column of  $W_D$  always needs to be normalized to a unit vector to avoid trivial solutions [28.44].

Given a training set of  $T$  instances,  $\{\mathbf{x}_t\}_{t=1}^T$ , the **PSD** cost function is defined as

$$\begin{aligned} L_{\text{PSD}}(G, W_E, W_D, \mathbf{b}_h; \mathbf{h}^*(\mathbf{x}_t)) \\ = \sum_{t=1}^T \|W_D \mathbf{h}^*(\mathbf{x}_t) - \mathbf{x}_t\|_2^2 + \alpha \|\mathbf{h}^*(\mathbf{x}_t)\|_1 \\ + \beta \|\mathbf{h}^*(\mathbf{x}_t) - \mathbf{h}(\mathbf{x}_t)\|_2^2, \end{aligned} \quad (28.9)$$

where  $\mathbf{h}^*(\mathbf{x}_t)$  is the optimal sparse hidden representation of  $\mathbf{x}_t$ , while  $\mathbf{h}(\mathbf{x}_t)$  is the output of the encoder in (28.7) based on the current parameter values. In (28.9),  $\alpha$  and  $\beta$  are two hyper-parameters to control regularization strengths, and  $\|\cdot\|_1$  and  $\|\cdot\|_2$  are  $\mathcal{L}_1$  and  $\mathcal{L}_2$  norm, respectively. Intuitively, in the multi-objective

cost function defined in (28.9), the first term specifies reconstruction errors, the second term refers to the magnitude of non-sparse representations, and the last term drives the encoder towards yielding the optimal representation.

For learning a **PSD** building block, the cost function in (28.9) needs to be optimized simultaneously with respect to the hidden representation and all the parameters. As a result, a learning algorithm of two alternate steps has been proposed to solve this problem [28.43] as follows:

#### Algorithm 28.2 PSD Learning algorithm

Given a training set of  $T$  instances  $\{\mathbf{x}_t\}_{t=1}^T$  randomly initialize all the parameters,  $W_E, W_D, G, \mathbf{b}_h$ , and the optimal sparse representation  $\{\mathbf{h}^*(\mathbf{x}_t)\}_{t=1}^T$  in a **PSD** building block and pre-set hyper-parameters  $\alpha$  and  $\beta$  as well as learning rates  $\epsilon_i$  ( $i = 1, \dots, 4$ ):

- Optimal representation update

In this step, the gradient descent method is applied to find the optimal sparse representation based on the current parameter values of the encoder and the decoder, which leads to the following update rule

$$\begin{aligned} \mathbf{h}^*(\mathbf{x}_t) \leftarrow \mathbf{h}^*(\mathbf{x}_t) - \epsilon_1 [\alpha \text{sign}(\mathbf{h}^*(\mathbf{x}_t)) \\ + \beta (\mathbf{h}^*(\mathbf{x}_t) - \mathbf{h}(\mathbf{x}_t))] \\ + (W_D)^\top (W_D \mathbf{h}^*(\mathbf{x}_t) - \mathbf{x}_t)], \end{aligned}$$

where  $\text{sign}(\cdot)$  is the sign function;  $\text{sign}(u) = \pm 1$  if  $u \geq 0$  and  $\text{sign}(u) = 0$  if  $u = 0$ .

- Parameter update

In this step,  $\mathbf{h}^*(\mathbf{x}_t)$  achieved in the above step is fixed. Then the gradient descent method is applied to the cost function (28.9) with respect to all encoder and decoder parameters, which results in the following update rules

$$\begin{aligned} W_E &\leftarrow W_E - \epsilon_2 \mathbf{g}(\mathbf{x}_t)(\mathbf{x}_t)^\top, \\ \mathbf{b}_h &\leftarrow \mathbf{b}_h - \epsilon_3 \mathbf{g}(\mathbf{x}_t). \end{aligned}$$

Here  $\mathbf{g}(\mathbf{x}_t)$  is obtained by

$$\begin{aligned} \mathbf{g}(\mathbf{x}_t) = \left[ g_{mm}^{-1} (g_{mm}^2 - h_m^2(\mathbf{x}_t)) \right. \\ \left. (h_m^*(\mathbf{x}_t) - h_m(\mathbf{x}_t)) \right]_{m=1}^M. \end{aligned}$$

$$\begin{aligned} G &\leftarrow G - \epsilon_2 \text{diag} \left[ \left( h_m^*(\mathbf{x}_t) - h_m(\mathbf{x}_t) \right) \right. \\ &\quad \left. \times \tanh \left( \sum_{n=1}^N [W_E]_{mn} x_n + b_{v,m} \right) \right], \end{aligned}$$

and

$$W_D \leftarrow W_D - \epsilon_4 [W_D \mathbf{h}^*(\mathbf{x}_t) - \mathbf{x}_t] [\mathbf{h}^*(\mathbf{x}_t)]^\top.$$

Normalize each column of  $W_D$  such that

$$\|W_D\|_2^2 = 1 \text{ for } n = 1, \dots, N.$$

The above two steps repeat for all the instances in the given training set, which leads to a training epoch. The learning algorithm runs iteratively until it converges.

### Other Building Blocks

While the auto-encoders and the **RBM** are building blocks widely used to construct **DNNs**, there are other building blocks that are either derived from existing building blocks for performance improvement or are developed with an alternative principle. Such building blocks include regularized auto-encoders and **RBM** variants. Due to the limited space, we briefly overview them below.

Recently, a number of auto-encoder variants have been developed by adding a regularization term to the standard reconstruction cost function in (28.1) and hence are dubbed regularized auto-encoders. The contrastive auto-encoder (**CAE**) is a typical regularized version of the auto-encoder with the introduction of the norm of the Jacobian matrix of the encoder evaluated at each training example  $\mathbf{x}_t$  into the standard reconstruction cost function [28.45]

$$L_{\text{CAE}}(W, \mathbf{b}_h, \mathbf{b}_o) = L(W, \mathbf{b}_h, \mathbf{b}_o) + \alpha \sum_{t=1}^T \|J(\mathbf{x}_t)\|_F^2, \quad (28.10)$$

where  $\alpha$  is a trade-off parameter to control the regularization strength and  $\|J(\mathbf{x}_t)\|_F^2$  is the Frobenius norm of the Jacobian matrix of the encoder and is calculated as follows

$$\|J(\mathbf{x}_t)\|_F^2 = \sum_{m=1}^M \sum_{n=1}^N [f'(u_{h,m}(\mathbf{x}_t))]^2 W_{mn}^2.$$

Here,  $f'(\cdot)$  is the first-order derivative of a transfer function  $f(\cdot)$ , and  $f'[u_{h,m}(\mathbf{x}_t)] = h_m(\mathbf{x}_t)[1 - h_m(\mathbf{x}_t)]$  when  $f(\cdot)$  is the sigmoid function [28.9]. It is straightforward to apply the stochastic gradient method [28.12]

to the **CAE** cost function in (28.10) to derive a learning algorithm used for training a **CAE**. Furthermore, an improved version of **CAE** was also proposed by penalizing additional higher order derivatives [28.46]. The sparse auto-encoder (**SAE**) is another class of regularized auto-encoders. The basic idea underlying **SAEs** is the introduction of a sparse regularization term working on either hidden neuron biases, e.g., [28.47], or their outputs, e.g., [28.48], into the standard reconstruction cost function. Different forms of sparsity penalties, e.g.,  $L_1$  norm and student- $t$ , are employed for regularization, and the learning algorithm is derived by applying the coordinate descent optimization procedure to a new reconstruction cost function [28.47, 48].

The **RBM** described above works only for an input of binary values. When an input has real values, a variant named Gaussian **RBM (GRBM)** [28.49], has been proposed with the following energy function

$$E(\mathbf{v}, \mathbf{h}) = - \sum_{m=1}^M \sum_{n=1}^N W_{mn} h_m \frac{v_n}{\sigma_n} - \sum_{m=1}^M h_m b_{h,m} - \sum_{n=1}^N \frac{(v_n - b_{v,n})^2}{2\sigma_n^2}, \quad (28.11)$$

where  $\sigma_n$  is the standard deviation of the Gaussian noise for the visible neuron  $n$ . In the **CD** learning algorithm, the update rule for the hidden neurons remains the same except that each  $v_n$  is substituted by  $\frac{v_n}{\sigma_n}$ , and the update rule for all visible neurons needs to use reconstructions  $\mathbf{v}$ , produced by sampling from a Gaussian distribution with mean  $\sigma_n \sum_{m=1}^M W_{nm} h_m + b_{v,n}$  and variance  $\sigma_n^2$  for  $n = 1, \dots, N$ . In addition, an improved **GRBM** was also proposed by introducing an alternative parameterization of the energy function in (28.11) and incorporating it into the **CD** algorithm [28.50]. Other **RBM** variants will be discussed later on, as they often play a different role from being used to construct a **DNN**.

### 28.2.3 Hybrid Learning Strategy

Based on the building blocks described in Sect. 28.2.2, we describe a systematic approach to establishing a feed-forward **DNN** for supervised and semi-supervised learning. This approach employs a hybrid learning strategy that combines unsupervised and supervised learning paradigms to overcome the optimization difficulty in training **DNNs**. The hybrid learning

strategy [28.18, 40] first applies layer-wise greedy unsupervised learning to set up a **DNN** and initialize parameters with input data only and then uses a global supervised learning algorithm with teachers' information to train all the parameters in the initialized **DNN** for a given task.

### Layer-Wise Unsupervised Learning

In the hybrid learning strategy, unsupervised learning is a layer-wise greedy learning process that constructs a **DNN** with a chosen building block and initializes parameters in a layer-by-layer way.

Suppose we want to establish a **DNN** of  $K$  ( $K > 1$ ) hidden layers and denote output of hidden layer  $k$  as  $h_k(x)$  ( $k = 1, \dots, K$ ) for a given input  $x$  and output of the output layer as  $o(x)$ , respectively. To facilitate the presentation, we stipulate  $h_0(x) = x$ . Then, the generic layer-wise greedy learning procedure can be summarized as follows:

#### Algorithm 28.3 Layer-wise greedy learning procedure

Given a training set of  $T$  instances  $\{x_t\}_{t=1}^T$ , randomly initialize its parameters in a chosen building block and pre-set all hyper-parameters required for learning such a building block:

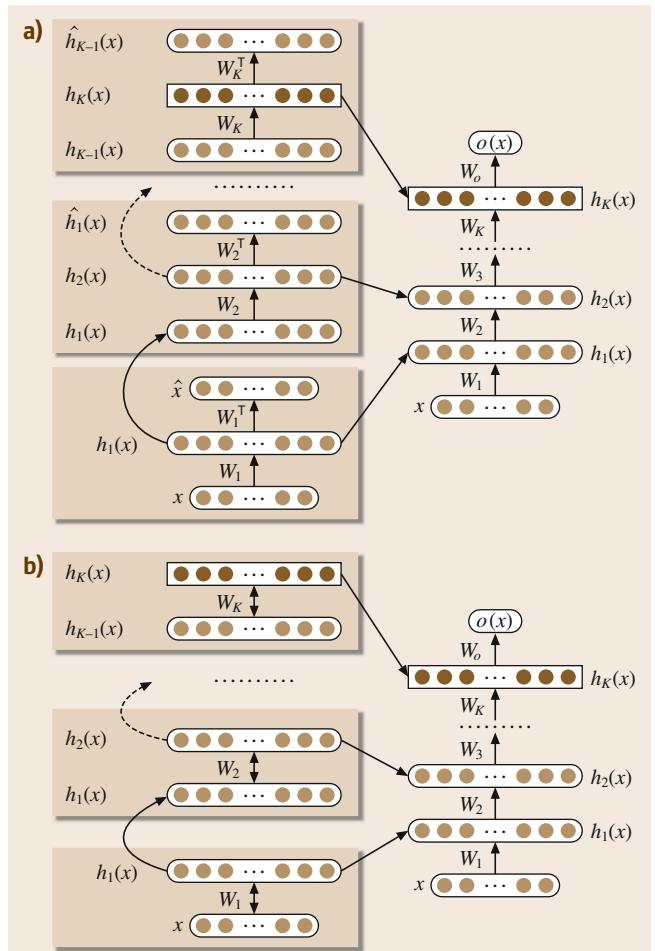

- Train a building block for hidden layer  $k$ 
  - Set the number of neurons required by hidden layer  $k$  to be the dimension of the hidden representation in the chosen building block.
  - Use the training data set  $\{h_{k-1}(x_t)\}_{t=1}^T$  train the building block to achieve its optimal parameters.

- Construct a **DNN** up to hidden layer  $k$

With the trained building block in the above step, discard its decoder part, including all associated parameters, and stack its hidden layer on the existing **DNN** with connection weights of the encoder and biases of hidden neurons achieved in the above step (the input layer  $h_0(x) = x$  is viewed as the starting architecture of a **DNN**).

The above steps are repeated for  $k = 1, \dots, K$ . Then, the output layer  $o(x)$  is stacked onto hidden layer  $K$  with randomly initialized connection weights so as to finalize the initial **DNN** construction and its parameter initialization.

Figure 28.6 illustrated two typical instances for constructing an initial **DNN** via the layer-wise greedy learning procedure described above. Figure 28.6a

**Fig. 28.6a,b** Construction of a **DNN** with a building block via layer-wise greedy learning. (a) Auto-encoder or its variants. (b) RBM or its variants

shows a schematic diagram of the layer-wise greedy learning process with the auto-encoder or its variants; to construct the hidden layer  $k$ , the output layer and its associated parameters  $W_k^T$  and  $b_{o,k}$  are removed and the remaining part is stacked onto hidden layer  $k-1$ , and  $W_o$  is a randomly initialized weight matrix for the connection between the hidden layer  $K$  and the output layer. When a **DNN** is constructed with the **RBM** or its variants, all backward connection weights in the decoder are abandoned after training and only the hidden layer with those forward connection weights and biases of hidden neurons are used to construct the **DNN**, as depicted in Fig. 28.6b.

### Global Supervised Learning

Once a **DNN** is constructed and initialized based on the layer-wise greedy learning procedure, it is ready to be further trained in a supervision fashion for a classification or regression task. There are a variety of optimization methods for supervised learning, e.g., stochastic gradient descent and the second-order Levenberg–Marquadt methods [28.9, 12]. Also there are cost functions of different forms used for various supervised learning tasks and regularization towards improving the generalization of a **DNN**. Due to the limited space, we only review the stochastic gradient descent algorithm with a generic cost function for global supervised learning.

For a generic cost function  $L(\Theta, \mathcal{D})$ , where  $\Theta$  is a collective notation of all parameters in a **DNN** (Fig. 28.6) and  $\mathcal{D}$  is a training data set for a given supervised learning task, applying the stochastic gradient descent method [28.9, 12] to  $L(\Theta, \mathcal{D})$  leads to the following learning algorithm for fine-tuning parameters.

#### Algorithm 28.4 Global supervised learning algorithm

Given a training set of  $T$  examples  $\mathcal{D} = \{\langle \mathbf{x}_t, \mathbf{y}_t \rangle\}_{t=1}^T$  pre-set a learning rate  $\epsilon$  (and other hyper-parameters if required). Furthermore, the training set is randomly divided into many mini-batches of  $T_B$  examples  $\{\langle \mathbf{x}_t, \mathbf{y}_t \rangle\}_{t=1}^{T_B}$  and then parameters are updated based on each mini-batch.  $\Theta = (\{W_k\}_{k=1}^{K+1}, \{b_k\}_{k=1}^{K+1})$  are all parameters in a **DNN**, where  $W_k$  is the weight matrix for the connection between the hidden layers  $k$  and  $k-1$ , and  $b_k$  is biases of neurons in layer  $k$  (Fig. 28.6). Here, input and output layers are stipulated as layers 0 and  $K+1$ , respectively, i.e.,  $\mathbf{h}_0(\mathbf{x}_t) = \mathbf{x}_t$ ,  $W_o = W_{K+1}$ ,  $b_o = b_{K+1}$  and  $\mathbf{o}(\mathbf{x}_t) = \mathbf{h}_{K+1}(\mathbf{x}_t)$ :

- Forward computation

Given the input  $\mathbf{x}_t$ , for  $k = 1, \dots, K+1$ , the output of layer  $k$  is

$$\mathbf{h}_k(\mathbf{x}_t) = f(u_k(\mathbf{x}_t)), \quad u_k(\mathbf{x}_t) = W_k \mathbf{h}_{k-1}(\mathbf{x}_t) + b_k.$$

- Backward gradient computation

Given a cost function on each mini-batch,  $L_B(\Theta, \mathcal{D})$  calculate gradients at the output layer, i.e.,

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{h}_{K+1}(\mathbf{x}_t)} = \frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{o}(\mathbf{x}_t)},$$

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{u}_{K+1}(\mathbf{x}_t)} = \left( \frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{h}_{(K+1)j}(\mathbf{x}_t)} f'(u_{(K+1)j}(\mathbf{x}_t)) \right)_{j=1}^{|\mathbf{o}|},$$

where  $f'(\cdot)$  is the first-order derivative of the transfer function  $f(\cdot)$ .

For all hidden layers, i.e.,  $k = K, \dots, 1$ , applying the chain rule leads to

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{u}_k(\mathbf{x}_t)} = \left( \frac{\partial L_B(\Theta, \mathcal{D})}{\partial h_{kj}(\mathbf{x}_t)} f'(u_{kj}(\mathbf{x}_t)) \right)_{j=1}^{|h_k|},$$

and

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{h}_k(\mathbf{x}_t)} = \left( W_{k+1}^{(i)} \right)^T \frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{u}_{k+1}(\mathbf{x}_t)}.$$

For  $k = K+1, \dots, 1$ , gradients with respect to biases of layer  $k$  are

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{b}_k} = \frac{\partial L_B(\Theta, \mathcal{D})}{\partial u_k(\mathbf{x}_t)}.$$

- Parameter update

Applying the gradient descent method results in the following update rules:

For  $k = K+1, \dots, 1$

$$W_k \leftarrow W_k - \frac{\epsilon}{T_B} \sum_{t=1}^{T_B} \frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{u}_k(\mathbf{x}_t)} (\mathbf{h}_{k-1}(\mathbf{x}_t))^T,$$

$$\mathbf{b}_k \leftarrow \mathbf{b}_k - \frac{\epsilon}{T_B} \sum_{t=1}^{T_B} \frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{u}_k(\mathbf{x}_t)}.$$

The above three steps repeat for all mini-batches, which leads to a training epoch. The learning algorithm runs iteratively until a termination condition is met (typically based on a cross-validation procedure [28.12]).

For the above learning algorithm, the **BP** algorithm [28.11] is a special case when the transfer function is the sigmoid function, i.e.,  $f(u) = \phi(u)$ , and the cost function is the mean square error (**MSE**) function, i.e., for each mini-batch

$$L_B(\Theta, \mathcal{D}) = \frac{1}{2T_B} \sum_{t=1}^{T_B} \|\mathbf{o}(\mathbf{x}_t) - \mathbf{y}_t\|_2^2.$$

Thus, we have

$$\phi'(u) = \phi(u)(1 - \phi(u)),$$

$$\frac{\partial L_B(\Theta, \mathcal{D})}{\partial \mathbf{o}(\mathbf{x}_t)} = \frac{1}{T_B} \sum_{t=1}^{T_B} (\mathbf{o}(\mathbf{x}_t) - \mathbf{y}_t),$$

and

$$\begin{aligned} & \frac{\partial L_B(\Theta, \mathcal{D})}{\partial u_{K+1}(x_t)} \\ &= \left[ \frac{1}{T_B} \sum_{t=1}^{T_B} (o_j(x_t) - y_{tj}) o_j(x_t) (1 - o_j(x_t)) \right]_{j=1}^{|\Theta|}. \end{aligned}$$

### 28.2.4 Relevant Issues

In the literature, the hybrid learning strategy described in Sect. 28.2.3 is often called the semi-supervised learning strategy [28.17, 39]. Nevertheless, semi-supervised learning implies the situation that there are few labeled examples but many unlabeled instances in a training set. Indeed, such a strategy works well in a situation where both unlabeled and labeled data in a training set are used for layer-wise greedy learning, and only labeled data are used for fine-tuning in global supervised learning. However, other studies, e.g., [28.28, 29, 51], also show that this strategy can considerably improve the generalization of a **DNN** even though there are abundant labeled examples in a training data set. Hence we would rather name it hybrid learning. On the other hand, our review focuses on only primary supervised learning tasks in the context of **NC**. In a wider context, the unsupervised learning process itself develops a novel approach to automatic feature discovery/extraction via learning, which is an emerging **ML** area named representation learning [28.39]. In such a context, some **DNNs** can perform a generative model. For instance, the **DBN** [28.18] is a **RBM**-based **DNN** by retaining both forward and backward connections during layer-wise greedy learning. To be a generative model, the **DBN** needs an alternative learning algorithm, e.g., the wake-sleep algorithm [28.18], for global unsupervised learning. In general, the global unsupervised learning for a generative **DNN** is still a challenging problem.

While the hybrid learning strategy has been successfully applied to many complex **AI** tasks, in general, it is still not entirely clear why such a strategy works well empirically. A recent study attempted to provide some justification of the role played by layer-wise greedy learning for supervised learning [28.51]. The findings can be summarized as follows: such an unsupervised learning process brings about a regularization effect that initializes **DNN** parameters towards the basin of attraction corresponding to a *good* local minimum, which facilitates global supervised learning in terms of generalization [28.51]. In general, a deeper understanding of such a learning strategy will be required in the future.

On the other hand, a successful story was recently reported [28.52] where no unsupervised pre-training was used in the **DNN** learning for a non-trivial task; which poses another open problem as to when and where such a learning strategy must be employed for training a **DNN** to yield a satisfactory generalization performance.

Recent studies also suggest that the use of artificially distorted or deformed training data and unsupervised *front-ends* can considerably improve the performance of **DNNs** regardless of the hybrid learning strategy. As **DNN** learning is of the data-driven nature, augmenting training data with known input deformation amounts to the use of more representative examples conveying intrinsic variations underlying a class of data in learning. For example, speech corrupted by some known channel noise and deformed images by using affine transformation and adding noise have significantly improved the **DNN** performance in various speech and visual information processing tasks [28.22, 28, 29, 51, 52]. On the other hand, the generic building blocks reviewed in Sect. 28.2.2 can be extended to be specialist *front-ends* by exploiting intrinsic data structures. For instance, the **RBM** has several variants, e.g., [28.53–55], to capture covariance and other statistical information underlying an image. After unsupervised learning, such *front-ends* generate powerful representations that greatly facilitate further **DNN** learning in visual information processing.

While our review focuses on only fully connected feed-forward **DNNs**, there are alternative and more effective **DNN** architectures for specific tasks. Convolutional **DNNs** [28.12] make use of topological locality constraints underlying images to form more effective locally connected **DNN** architecture. Furthermore, various pooling techniques [28.56] used in convolutional **DNNs** facilitate learning invariant and robust features. With appropriate building blocks, e.g., the **PSD** reviewed in Sect. 28.2.2, convolutional **DNNs** work very well with the hybrid learning strategy [28.43, 57]. In addition, novel **DNN** architectures need to be developed by exploring the nature of a specific problem, e.g., a regularized Siamese **DNN** was recently developed for generic speaker-specific information extraction [28.28, 29]. As a result, novel **DNN** architecture development and model selection are among important **DNN** research topics.

Finally, theoretical justification of deep learning and the hybrid learning strategy, along with other developed recently techniques, e.g., parallel graphics processing unit (**GPU**) computing, enable researchers to develop

large-scale **DNNs** to tackle very complex real world problems. While some theoretic justification has been provided in the literature, e.g., [28, 16, 17, 39], to show strengths in their potential capacity and efficient representational schemes of **DNNs**, more and more successful applications of **DNNs**, particularly working with the hybrid learning strategy, lend evidence to support the argument that **DNNs** are one of the most promis-

ing learning systems for dealing with complex and large-scale real world problems. For example, such evidence can be found from one of the latest developments in a **DNN** application to computer vision where it is demonstrated that applying a **DNN** of nine layers constructed with the **SAE** building block via layer-wise greedy learning results in the favorable performance in object recognition of over 22 000 categories [28, 58].

## 28.3 Modular Neural Networks

In this section, we review main modular neural networks (**MNN**) and their learning algorithms with our own taxonomy. We first review background and motivation for **MNN** research and present our **MNN** taxonomy. Then we describe major **MNN** architectures and relevant learning algorithms. Finally, we examine relevant issues related to **MNNs** in a broader context.

### 28.3.1 Background and Motivation

Soon after neural network (**NN**) research resurged in the middle of the 1980s, **MNN** studies emerged; they have become an important area in **NC** since then. There are a variety of motivations that inspire **MNN** researches, e.g., biological, psychological, computational, and implementation motivations [28, 4, 5, 9]. Here, we only describe the background and motivation of **MNN** researches from learning and computational perspectives.

From the learning perspective, **MNNs** have several advantages over monolithic **NNs**. First of all, **MNNs** adopt an alternative methodology for learning, so that complex problem can be solved based on ensemble of simple **NNs**, which might avoid/alleviate the complex optimization problems encountered in monolithic **NN** learning without decreasing the learning capacity. Next, modularity enables **MNNs** to use a priori knowledge flexibly and facilitates knowledge integration and update in learning. To a great extent, **MNNs** are immune to temporal and spatial *cross-talk*, a problem faced by monolithic **NNs** during learning [28, 9]. Finally, theoretic justification and abundant empirical evidence show that an **MNN** often yields a better generalization than its component networks [28, 5, 59]. From the computational perspective, modularization in **MNNs** leads to more efficient and robust computation, given the fact that **MNNs** often do not suffer from a high coupling burden in a monolithic **NN** and hence tend to have

a lower overall structural complexity in tackling the same problem [28, 5]. This main computational merit makes **MNNs** scalable and extensible to large-scale **MNN** implementation.

There are two highly influential principles that are often used in artificial **MNN** development; i.e., *divide-and-conquer* and *diversity-promotion*. The divide-and-conquer principle refers to a generic methodology that tackles a complex and difficult problem by dividing it into several relatively simple and easy subproblems, whose solutions can be combined seamlessly to yield a final solution. On the other hand, theoretical justification [28, 60, 61] and abundant empirical studies [28, 62] suggest that apart from the condition that component networks need to reach some certain accuracy, the success of **MNNs** are largely attributed to diversity among them. Hence, the promotion of diversity in **MNNs** becomes critical in their design and development. To understand motivations and ideas underlying different **MNNs**, we believe that it is crucial to examine how two principles are applied in their development.

There are different taxonomies of **MNNs** [28, 4, 5, 9]. In this chapter, we present an alternative taxonomy that highlights the interaction among component networks in an **MNN** during learning. As a result, there is a dichotomy between *tightly* and *loosely coupled models* in **MNNs**. In a tightly coupled **MNN**, all component networks are jointly trained in a dependent way by taking their interaction into account during a single learning stage, and hence all parameters of different networks (and combination mechanisms if there are any) need to be updated simultaneously by minimizing a cost function defined at the global level. In contrast, training of a loosely coupled **MNN** often undergoes multiple stages in a hierarchical or sequential way where learning undertaken in different stages may be either correlated or uncorrelated via different strategies. We believe that such a taxonomy facilitates not only un-

derstanding different MNNs especially from a learning perspective but also relating MNNs to generic ensemble learning in a broader context.

### 28.3.2 Tightly Coupled Models

There are two typical tightly coupled MNNs: the mixture of experts (MoE) [28.63, 64] and MNNs trained via negative correlation learning (NCL) [28.65].

#### Mixture of Experts

The MoE [28.63, 64] refers to a class of MNNs that dynamically partition input space to facilitate learning in a complex and non-stationary environment. By applying the divide-and-conquer principle, a soft-competition idea was proposed to develop the MoE architecture. That is, at every input data point, multiple expert networks compete to take on a given supervised learning task. Instead of winner-take-all, all expert networks may work together but the winner expert plays a more important role than the losers.

The MoE architecture is composed of  $N$  expert networks and a gating network, as illustrated in Fig. 28.7. The  $n$ -th expert network produces an output vector,  $\mathbf{o}_n(\mathbf{x})$ , for an input,  $\mathbf{x}$ . The gating network receives the vector  $\mathbf{x}$  as input and produces  $N$  scalar outputs that form a partition of the input space at each point  $\mathbf{x}$ . For the input  $\mathbf{x}$ , the gating network outputs  $N$  linear combination coefficients used to verdict the importance of all expert networks for a given supervised learning task. The final output of MoE is a convex weighted sum of all the output yielded by  $N$  expert networks. Although NNs of different types can be used as expert networks, a class of generalized linear NNs are often employed where such an NN is linear with a single output non-

linearity [28.64]. As a result, output of the  $n$ -th expert network is a generalized linear function of the input  $\mathbf{x}$

$$\mathbf{o}_n(\mathbf{x}) = f(W_n \mathbf{x}),$$

where  $W_n$  is a parameter matrix, a collective notation for both connection weights and biases, and  $f(\cdot)$  is a nonlinear transfer function. The gating network is also a generalized linear model, and its  $n$ -th output  $g(\mathbf{x}, \mathbf{v}_n)$  is the softmax function of  $\mathbf{v}_n^\top \mathbf{x}$

$$g(\mathbf{x}, \mathbf{v}_n) = \frac{e^{\mathbf{v}_n^\top \mathbf{x}}}{\sum_{k=1}^N e^{\mathbf{v}_k^\top \mathbf{x}}},$$

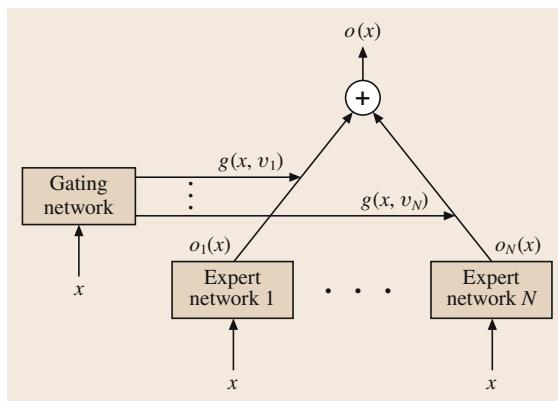

where  $\mathbf{v}_n$  is the  $n$ -th column of the parameter matrix  $V$  in the gating network and is responsible for the linear combination coefficient regarding the expert network  $n$ . The overall output of the MoE is the weighted sum resulted from the soft-competition at the point  $\mathbf{x}$

$$\mathbf{o}(\mathbf{x}) = \sum_{n=1}^N g(\mathbf{x}, \mathbf{v}_n) \mathbf{o}_n(\mathbf{x}).$$

There is a natural probabilistic interpretation of the MoE [28.64]. For a training example  $(\mathbf{x}, \mathbf{y})$ , the values of  $\mathbf{g}(\mathbf{x}, V) = (g(\mathbf{x}, \mathbf{v}_n))_{n=1}^N$  are interpreted as the multinomial probabilities associated with the decision that terminates in a regressive process that maps  $\mathbf{x}$  to  $\mathbf{y}$ . Once a decision has been made that leads to a choice of regressive process  $n$ , the output  $\mathbf{y}$  is chosen from a probability distribution  $P(\mathbf{y}|\mathbf{x}, W_n)$ . Hence, the overall probability of generating  $\mathbf{y}$  from  $\mathbf{x}$  is the mixture of the probabilities of generating  $\mathbf{y}$  from each component distribution and the mixing proportions are subject to a multinomial distribution

$$P(\mathbf{y}|\mathbf{x}, \Theta) = \sum_{n=1}^N g(\mathbf{x}, \mathbf{v}_n) P(\mathbf{y}|\mathbf{x}, W_n), \quad (28.12)$$

where  $\Theta$  is a collective notation of all the parameters in the MoE, including both expert and gating network parameters. For different learning tasks, specific component distribution models are required. For example, the probabilistic component model should be a Gaussian distribution for a regression task, while a Bernoulli distribution and multinomial distributions are required for binary and multi-class classification tasks, respectively. In general, MoE is viewed as a conditional mixture model for supervised learning, a non-trivial extension of finite mixture model for unsupervised learning.

**Fig. 28.7** Architecture of the mixture of experts

By means of the above probabilistic interpretation, learning in the MoE is treated as a maximum likelihood problem defined based on the model in (28.12). An expectation-maximization (EM) algorithm was proposed to update parameters in the MoE [28.64]. It is summarized as follows:

#### **Algorithm 28.5 EM algorithm for MoE learning**

Given a training set of  $T$  examples  $\mathcal{D} = \{\mathbf{x}_t, \mathbf{y}_t\}_{t=1}^T$  pre-set the number of expert networks,  $N$ , and randomly initialize all the parameters  $\Theta = \{V, (W_n)_{n=1}^N\}$  in the MoE:

- E-step

For each example,  $(\mathbf{x}_t, \mathbf{y}_t)$  in  $\mathcal{D}$ , estimate posterior probabilities,  $\mathbf{h}_t = (h_{nt})_{n=1}^N$ , with the current parameter values,  $\hat{V}$  and  $\{\hat{W}_n\}_{n=1}^N$

$$h_{nt} = \frac{g(\mathbf{x}_t, \hat{v}_n)P(\mathbf{y}_t|\mathbf{x}_t, \hat{W}_n)}{\sum_{k=1}^N g(\mathbf{x}_t, \hat{v}_k)P(\mathbf{y}_t|\mathbf{x}_t, \hat{W}_k)}.$$

- M-step

- For expert network  $n$  ( $n = 1, \dots, N$ ), solve the maximization problems

$$\hat{W}_n = \arg \max_{W_n} \sum_{t=1}^T h_{nt} \log P(\mathbf{y}_t|\mathbf{x}_t, W_n),$$

with all examples in  $\mathcal{D}$  and posterior probabilities  $\{\mathbf{h}_t\}_{t=1}^T$  achieved in the E-step.

- For the gating network, solve the maximization problem

$$\hat{V} = \arg \max_V \sum_{t=1}^T \sum_{n=1}^N h_{nt} \log g(\mathbf{x}_t, v_n),$$

with training examples,  $\{(\mathbf{x}_t, \mathbf{h}_t)\}_{t=1}^T$ , derived from posterior probabilities  $\{\mathbf{h}_t\}_{t=1}^T$ .

Repeat the E-step and the M-step alternately until the EM algorithm converges.

To solve optimization problems in the M-step, the iteratively re-weighted least squares (IRLS) algorithm was proposed [28.64]. Although the IRLS algorithm has the strength to solve maximum likelihood problems arising from MoE learning, it might result in some instable performance due to its incorrect assumption on multi-class classification [28.66]. As learning in the gating network is a multi-class classification

task in essence, the problem always exists if the IRLS algorithm is used in the EM algorithm. Fortunately, improved algorithms were proposed to remedy this problem in the EM learning [28.66]. In summary, numerous MoE variants and extensions have been developed in the past 20 years [28.59], and the MoE architecture turns out to be one of the most successful MNNs.

#### **Negative Correlation Learning**

The NCL [28.65] is a learning algorithm to establish an MNN consisting of diverse neural networks (NNs) by promoting the diversity among component networks during learning. The NCL development was clearly inspired by the bias-variance analysis of generalization errors [28.60, 61]. As a result, the NCL encourages cooperation among component networks via interaction during learning to manage the bias-variance trade-off.

In the NCL, an unsupervised penalty term is introduced to the MSE cost function for each component NN so that the error diversity among component networks is explicitly managed via training towards negative correlation. Suppose that an NN ensemble  $F(\mathbf{x}, \Theta)$  is established by simply taking the average of  $N$  neural networks  $f(\mathbf{x}, W_n)$  ( $n = 1, \dots, N$ ), where  $W_n$  denotes all the parameters in the  $n$ -th component network and  $\Theta = \{W_n\}_{n=1}^N$ . Given a training set  $\mathcal{D} = \{(\mathbf{x}_t, \mathbf{y}_t)\}_{t=1}^T$  the NCL cost function for the  $n$ -th component network [28.65] is defined as follows

$$L(\mathcal{D}, W_n) = \frac{1}{2T} \sum_{t=1}^T \|f(\mathbf{x}_t, W_n) - \mathbf{y}_t\|_2^2 - \frac{\lambda}{2T} \sum_{t=1}^T \|f(\mathbf{x}_t, W_n) - F(\mathbf{x}_t, \Theta)\|_2^2, \quad (28.13)$$

where  $F(\mathbf{x}_t, \Theta) = \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_t, W_n)$  and  $\lambda$  is a trade-off hyper-parameter. In (28.13), the first term is the MSE cost for network  $n$  and the second term refers to the negative correlation cost. By taking all component networks into account, minimizing the second term leads to maximum negative correlation among them. Therefore,  $\lambda$  needs to be set properly to control the penalty strength [28.65].

For the NCL, all  $N$  cost functions specified in (28.13) need to be optimized together for parameter estimation. Based on the stochastic descent method, the generic NCL algorithm is summarized as follows:

---

**Algorithm 28.6 Negative correlation learning algorithm**

Given a training set of  $T$  examples  $\mathcal{D} = \{(\mathbf{x}_t, \mathbf{y}_t)\}_{t=1}^T$  pre-set the number of component networks,  $N$ , and learning rate,  $\epsilon$ , as well as randomly initialize all the parameters  $\Theta = \{W_n\}_{n=1}^N$  in component networks:

- Output computation

For each example,  $(\mathbf{x}_t, \mathbf{y}_t)$  in  $\mathcal{D}$ , calculate output of each component network  $f(\mathbf{x}_t, W_n)$  and that of the **NN** ensemble by

$$F(\mathbf{x}_t, \Theta) = \frac{1}{N} \sum_{n=1}^N f(\mathbf{x}_t, W_n).$$

- Gradient computation

For component network  $n$  ( $n = 1, \dots, N$ ), calculate the gradient of the **NCL** cost function in (28.13) with respect to the parameters based on all training examples in  $\mathcal{D}$

$$\begin{aligned} \frac{\partial L(\mathcal{D}, W_n)}{\partial W_n} &= \frac{1}{T} \sum_{t=1}^T \left\{ \|f(\mathbf{x}_t, W_n) - \mathbf{y}_t\|_2 \right. \\ &\quad \left. - \frac{\lambda(N-1)}{N} \|f(\mathbf{x}_t, W_n) - F(\mathbf{x}_t, \Theta)\|_2 \right\} \frac{\partial f(\mathbf{x}_t, W_n)}{\partial W_n}. \end{aligned}$$

- Parameter update

For component network  $n$  ( $n = 1, \dots, N$ ), update the parameters

$$W_n \leftarrow W_n - \epsilon \frac{\partial L(\mathcal{D}, W_n)}{\partial W_n}.$$

Repeat the above three steps until a pre-specified termination condition is met.

---

While the **NCL** was originally proposed based on the **MSE** cost function, the **NCL** idea can be extended to other cost functions without difficulty. Hence, applying appropriate optimization techniques on alternative cost functions leads to **NCL** algorithms of different forms accordingly.

### 28.3.3 Loosely Coupled Models

In a loosely coupled model, component networks are trained independently or there is no direct interaction among them during learning. There are a variety of **MNNs** that can be classified as loosely coupled mod-

els. Below we review several typical loosely coupled **MNNs**.

#### Neural Network Ensemble

An neural network ensemble here refers to a committee machine where a number of **NNs** trained independently but their outputs are somehow combined to reach a consensus as a final solution. The development of **NN** ensembles is explicitly motivated by the diversity-promotion principle [28.67, 68].

Intuitively, errors made by component **NNs** can be corrected by taking their diversity or mutual complement into account. For example, three **NNs**,  $NN_i$  ( $i = 1, 2, 3$ ), trained on the same data set have different yet imperfect performance on test data. Given three test points,  $\mathbf{x}_t$ , ( $t = 1, 2, 3$ ),  $NN_1$  yields the correct output for  $\mathbf{x}_2$  and  $\mathbf{x}_3$  but does not for  $\mathbf{x}_1$ ,  $NN_2$  yields the correct output for  $\mathbf{x}_1$  and  $\mathbf{x}_3$  but does not for  $\mathbf{x}_2$  and  $NN_3$  yields the correct output for  $\mathbf{x}_1$  and  $\mathbf{x}_2$  but does not for  $\mathbf{x}_3$ , respectively. In such circumstances, an error made by one **NN** can be corrected by other two **NNs** with a majority vote so that the ensemble can outperform any component **NNs**. Formally, there is a variety of theoretical justification [28.60, 61] for **NN** ensembles. For example, it has been proven for regression that the **NN** ensemble performance is never inferior to the average performance of all component **NNs** [28.60]. Furthermore, a theoretical bias-variance analysis [28.61] suggests that the promotion of diversity can improve the performance of **NN** ensembles provided that there is an adequate trade-off between bias and variance. In general, there are two non-trivial issues in constructing **NN** ensembles; i. e., creating diverse component **NNs** and ensembling strategies.

Depending on the nature of a given problem [28.5, 62], there are several methodologies for creating diverse component **NNs**. First of all, a **NN** learning process itself can be exploited. For instance, learning in a monolithic **NN** often needs to solve a complex non-convex optimization problem [28.9]. Hence, a local-search-based learning algorithm, e.g., **BP** [28.11], may end up with various solutions corresponding to local minima due to random initialization. In addition, model selection is required to find out an appropriate **NN** structure for a given problem. Such properties can be exploited to create component networks in a homogeneous **NN** ensemble [28.67]. Next, **NNs** of different types trained on the same data may also yield different performance and hence are candidates in a heterogeneous **NN** ensemble [28.5]. Finally, exploration/exploitation of input space and different representations is an alternative

methodology for creating different component NNs. Instead of training an NN on the input space, NNs can be trained on different input subspaces achieved by a partitioning method, e.g., random partitioning [28.69], which results in a subspace NN ensemble. Whenever raw data can be characterized by different representations, NNs trained on different feature sets would constitute a multi-view NN ensemble [28.70].

Ensembling strategies are required for different tasks. For regression, some optimal fusion rules have been developed for NN ensembles, e.g., [28.68], which are supported by theoretical justification, e.g., [28.60, 61]. For classification, ensembling strategies are more complicated but have been well-studied in a wider context, named combination of multiple classifiers. As is shown in Fig. 28.8, ensembling strategies are generally divided into two categories: learnable and non-learnable. Learnable strategies use a parametric model to learn an optimal fusion rule, while non-learnable strategies fulfil the combination by directly using the statistics of all competent network outputs along with simple measures. As depicted in Fig. 28.8, there are six main non-learnable fusion rules: sum, product, min, max, median, and majority vote; details of such non-learnable rules can be found in [28.71]. Below, we focus on the main learnable ensembling strategies in terms of classification.

In general, learnable ensembling strategies are viewed as an application of the stacked generalization principle [28.72]. In light of stacked generalization, all component NNs serve as level 0 generalizers, and a learnable ensembling strategy carried out by a combination mechanism would perform a level 1 generalizer working on the output space of all component NNs to

improve the overall generalization. In this sense, such a combination mechanism is trained on a validation data set that is different from the training data set used in component NN learning. As is shown in Fig. 28.8, combination mechanisms have been developed from different perspectives, i.e., input-dependent and input-independent.

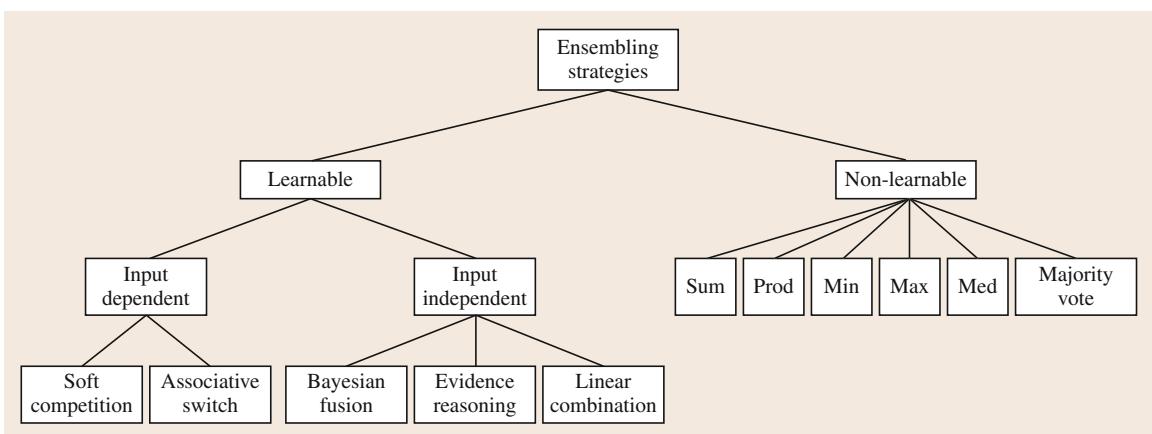

An input-dependent mechanism combines component NNs based on test data; i.e., given two inputs,  $x_1$  and  $x_2$ ; there is the property:  $c(x_1|\Theta) \neq c(x_2|\Theta)$  if  $x_1 \neq x_2$ , where  $c(x|\Theta) = (c_n(x|\Theta))_{n=1}^N$  is an input-dependent mechanism used to combine an ensemble of  $N$  component NNs and  $\Theta$  collectively denotes all learnable parameters in this parametric model. As a result, output of an NN ensemble with the input-dependent ensembling strategy is of the following form

$$o(x) = \Omega(o_1(x), \dots, o_N(x) | c(x|\Theta)),$$

where  $o_n(x)$  is output of the  $n$ -th component NN for  $n = 1, \dots, N$  and  $\Omega$  indicates a method on how to apply  $c(x|\Theta)$  to component NNs. For example,  $\Omega$  may be a linear combination scheme such that

$$o(x) = \sum_{n=1}^N c_n(x|\Theta) o_n(x). \quad (28.14)$$

As listed in Fig. 28.8, soft-competition and associative switch are two commonly used input-dependent combination mechanisms. The soft-competition mechanism can be regarded as a special case of the MoE described earlier when all expert networks were trained on a data set independently in advance. In this case, the gating network plays the role of the combination mechanism

**Fig. 28.8** A taxonomy of ensembling strategies

by deciding the importance of component NNs via soft-competition. Although various learning models may be used as such a gating network, a RBF-like (radial basis function) parametric model [28.73] trained on the EM algorithm has been widely used for this purpose. Unlike a soft-competition mechanism that produces the continuous-value weight vector  $c(x)$  used in (28.14), the associative switch [28.74] adopts a winner-take-all strategy, i.e.,  $\sum_{n=1}^N c_n(x|\Theta) = 1$  and  $c_n(x|\Theta) \in \{0, 1\}$ . Thus, an associative switch yields a specific code for a given input so that the output of the best performed component NN can be selected as the final output of the NN ensemble according to (28.14). The associative switch learning is a multi-class classification problem, and an MLP is often used to carry it out [28.74]. Although an input-dependent ensembling strategy is applicable to most NN ensembles, it is difficult to apply it to multi-view NN ensembles, since different representations need to be considered simultaneously in training a combination mechanism. Fortunately, such issues have been explored in a wider context on how to use different representations simultaneously for ML [28.70, 75–79] so that both soft-competition and associative switch mechanisms can be extended to multi-view NN ensembles.

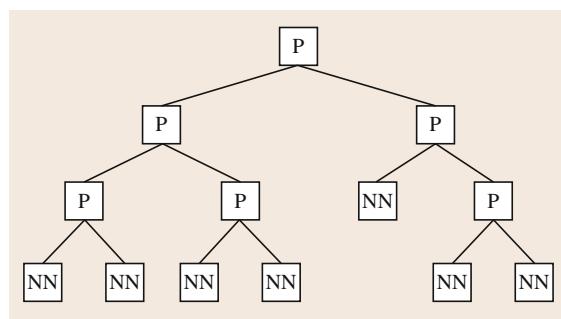

In contrast, an input-independent mechanism combines component NNs based on the dependence of their outputs without considering input data directly. Given two inputs  $x_1$  and  $x_2$ , and  $x_1 \neq x_2$ , the same  $c(\Theta)$  may be applied to outputs of component NNs, where  $c(\Theta) = (c_n(\Theta))_{n=1}^N$  is an input-independent combination mechanism used to combine an ensemble of  $N$  component NNs. Several input-independent mechanisms have been developed [28.62], which often fall into one of three categories, i.e., Bayesian fusion, evidence reasoning, and a linear combination scheme, as shown in Fig. 28.8. Bayesian fusion [28.80] refers to a class of combination schemes that use the information collected from errors made by component NNs on a validation set in order to find out the optimal output of the maximum a posteriori probability,  $C^* = \arg \max_{1 \leq l \leq L} P(C_l|o_1(x), \dots, o_N(x), \Theta)$ , via Bayesian reasoning, where  $C_l$  is the label for the  $l$ -th class in a classification task of  $L$  classes, and  $\Theta$  here encodes the information gathered, e.g., a confusion matrix achieved during learning [28.80]. Similarly, evidence reasoning mechanisms make use of alternative reasoning theories [28.80], e.g., the Dempster–Shafer theory, to yield the best output for NN ensembles via an evidence reasoning process that works on all outputs of component NNs in an ensemble. Finally, linear com-

bination schemes of different forms are also popular as input-independent combination mechanisms [28.62]. For instance, the work presented in [28.68] exemplifies how to achieve optimal linear combination weights in a linear combination scheme.

### Constructive Modularization Learning

Efforts have also been made towards constructive modularization learning for a given supervised learning task. In such work, the divide-and-conquer principle is explicitly applied in order to develop a constructive learning strategy for modularization. The basic idea behind such methods is to divide a difficult and complex problem into a number of subproblems that are easily solvable by NNs of proper capacities, matching the requirements of the subproblems, and then the solutions to subproblems are combined seamlessly to form a solution to the original problem. On the other hand, constructive modularization learning may alleviate the model selection problem encountered by a monolithic NN. As NNs of simple and even different architectures may be used to solve subproblems, empirical studies suggest that an MNN generated via constructive modularization learning is often insensitive to component NN architectures and hence is less likely to suffer from overall overfitting or underfitting [28.81]. Below we describe two constructive modularization learning strategies [28.81–83] for exemplification.

The partitioning-based strategy [28.81, 82] performs the constructive modularization learning by applying the divide-and-conquer principle explicitly. For a given supervised learning task, the strategy consists of two learning stages: *dividing* and *conquering*. In the dividing stage, it first recursively partitions the input space into overlapping subspaces, which facilitates dealing with various uncertainties, by taking into supervision information into account until the nature of each subproblem defined in generated subspaces

**Fig. 28.9** A self-generated tree-structured MNN

matches the capacity of one pre-selected **NN**. In the conquering stage, an **NN** works on a given input subspace to complete the corresponding learning subtask. As a result, a tree-structured **MNN** is *self-generated*, where a learnable partitioning mechanism  $P$ , is situated at intermediate levels and **NNs** works at leaves of the tree, as illustrated in Fig. 28.9. To enable the partition-based constructive modularization learning, two generic algorithms have been proposed, i. e., growing and credit-assignment algorithms [28.81, 82] as summarized below.

#### **Algorithm 28.7 Growing algorithm**

Given a training set  $\mathcal{D}$ , set  $\mathcal{X} \leftarrow \mathcal{D}$ . Randomly initialize parameters in all component **NNs** in a given repository and pre-set hyper-parameters in a learnable partitioning mechanism and compatibility criteria, respectively:

- Compatibility test

For a training (sub)set  $\mathcal{X}$ , apply the compatibility criteria to  $\mathcal{X}$  to examine whether the learning task defined on  $\mathcal{X}$  matches the capacity of a component **NN** in the repository.

- Partitioning space

If none in the repository can solve the problem defined on  $\mathcal{X}$ , then train the partitioning mechanism on the current  $\mathcal{X}$  to partition it into two overlapped  $\mathcal{X}_l$  and  $\mathcal{X}_r$ . Set  $\mathcal{X} \leftarrow \mathcal{X}_l$ , then go to the *compatibility test* step. Set  $\mathcal{X} \leftarrow \mathcal{X}_r$ , then go to the *compatibility test* step.

Otherwise, go to the *subproblem solving* step.

- Subproblem solving

Train this **NN** on  $\mathcal{X}$  with an appropriate learning algorithm. The trained **NN** resides at the current leaf node.

The growing algorithm expands a tree-structured **MNNs** until learning problems defined on all partitioned subspaces are solvable with **NNs** in the repository.

For a given test data point, output of such a tree-structured **MNN** may depend on several component **NNs** at the leaves of the tree since the input space is partitioned into overlapping subspaces. A credit-assignment algorithm [28.81, 82] has been developed to weight the importance of component **NNs** contributed to the overall output, which is summarized as follows:

#### **Algorithm 28.8 Credit-assignment algorithm**

$P(\tilde{x})$  is a trained partitioning mechanisms that resides at a nonterminal node and partitions the current input

(sub)space into two subspaces with an overlapping defined by  $-\tau \leq P(\tilde{x}) \leq \tau$  ( $\tau > 0$ ).  $C_L(\cdot)$ , and  $C_R(\cdot)$  are two credit assignment functions for two subspaces, respectively. For a test data point  $\tilde{x}$ :

- Initialization

Set  $\alpha(\tilde{x}) \leftarrow 1$  and  $\text{Pointer} \leftarrow \text{Root}$ .

- Credit assignment

As a recursive credit propagation process to assign credits to all the component **NNs** at leaf nodes that  $\tilde{x}$  can reach,  $CR[\alpha(\tilde{x}), \text{Pointer}]$  consists of three steps:

- If  $\text{Pointer}$  points to a leaf node, then output  $\alpha(\tilde{x})$  and stop.
- If  $P(\tilde{x}) \leq \tau$ ,  $\alpha(\tilde{x}) \leftarrow \alpha(\tilde{x}) \times C_L(P(\tilde{x}))$  and invoke  $CR[\alpha(\tilde{x}), \text{Pointer.Leftchild}]$ .
- If  $P(\tilde{x}) \geq -\tau$ ,  $\alpha(\tilde{x}) \leftarrow \alpha(\tilde{x}) \times C_R(P(\tilde{x}))$  and invoke  $CR[\alpha(\tilde{x}), \text{Pointer.Rightchild}]$ .

Thus, the output of a *self-generated* **MNN** is

$$o(\tilde{x}) = \sum_{n \in \mathcal{N}} \alpha_n(\tilde{x}) \times o_n(\tilde{x}),$$

where  $\mathcal{N}$  denotes all the component **NNs** that  $\tilde{x}$  can reach, and  $\alpha_n(\tilde{x})$  and  $o_n(\tilde{x})$  are the credit assigned and the output of the  $n$ -th component **NN** in  $\mathcal{N}$  for  $\tilde{x}$ , respectively.

To implement such a strategy, hyper-planes placed with heuristics [28.81] or linear classifiers trained with the Fisher discriminative analysis [28.82] were first used as the partition mechanism and **NNs** such as **MLP** or **RBF** can be employed to solve subproblems. Accordingly, two piece-wise linear credit assignment functions [28.81, 82] were designed for the hyperplane partitioning mechanism, so that  $C_L(x) + C_R(x) = 1$ . Heuristic compatibility criteria were developed by considering learning errors and efficiency [28.81, 82]. By using the same constructive learning algorithms described above, an alternative implementation was also proposed by using the self-organization map as a partitioning mechanism and **SVMs** were used for subproblem solving [28.84]. Empirical studies suggest that the partitioning-based strategy leads to favorable results in various supervised learning tasks despite different implementations [28.81, 82, 84].

By applying the divide-and-conquer principle, *task decomposition* [28.83] is yet another constructive modularization learning strategy for classification. Unlike the partitioning-based strategy, the task decomposition strategy converts a multi-class classification task into

a number of binary classification subtasks in a brute-force way and each binary classification subtask is expected to be fulfilled by a simple **NN**. If a subtask is too *difficult* to carry out by a given **NN**, the subtask is allowed to be further decomposed into simpler binary classification subtasks. For a multi-class classification task of  $M$  categories, the task decomposition strategy first exhaustively decomposes it into  $\frac{1}{2}M(M - 1)$  different primary binary subtasks where each subtask merely concerns classification between two different classes without taking remaining  $M - 2$  classes into account, which differs from the commonly used one-against-rest decomposition method. In general, the original multi-class classification task may be decomposed into more binary subtasks if some primary subtasks are too *difficult*. Once the decomposition is completed, all the subtasks are undertaken by pre-selected simple **NNs**, e.g., **MLP** of one hidden layer, in parallel. For a final solution to the original problem, three non-learnable operations, *min*, *max*, and *inv*, were proposed to combine individual binary classification results achieved by all the component **NNs**. By applying three operations properly, all the component **NNs** are integrated together to form a min-max **MNN** [28.83].

### 28.3.4 Relevant Issues

In general, studies of **MNNs** closely relate to several areas in different disciplines, e.g., **ML** and statistics. We here examine several important issues related to **MNNs** in a wider context.

As described above, a tightly coupled **MNN** leads to an optimal solution to a given supervised learning problem. The **MoE** is rooted in the finite mixture model (**FMM**) studied in probability and statistics and becomes a non-trivial extension to conditional models where each expert is a parametric conditional probabilistic model and the mixture coefficients also depend on input [28.64]. While the **MoE** has been well studied for 20 years [28.59] in different disciplines, there still exist some open problems in general, e.g., model selection, global optimal solution, and convergence of its learning algorithms for arbitrary component models. Different from the **FMM**, the product of experts (**PoE**) [28.42] was also proposed to combine a number of experts (parametric probabilistic models) by taking their product and normalizing the result into account. The **PoE** has been argued to have some advantages over the **MoE** [28.42] but has so far merely been developed in the context of unsupervised learning. As a result, extending the **PoE** to

conditional models for supervised learning would be a non-trivial topic in tightly coupled **MNN** studies. On the other hand, the **NCL** [28.65] directly applies the bias-variance analysis [28.60, 61] to construction of an **MNN**. This implies that **MNNs** could be also built up via alternative loss functions that properly promote diversities among component **MNNs** during learning.

Almost all existing **NN** ensemble methods are now included in ensemble learning [28.85], which is an important area in **ML**, or the multiple classifier system [28.62] in the context of pattern recognition. In statistical ensemble learning, generic frameworks, e.g., boosting [28.86] and bootstrapping [28.87], were developed to construct ensemble learners where any learning models including **NNs** may be used as component learners. Hence, most of common issues raised for ensemble learning are applicable to **NN** ensembles. Nevertheless, ensemble learning researches suggest that behaviors of component learners may considerably affect the stability and overall performance of ensemble learning. As exemplified in [28.88], properties of different **NN** ensembles are worth investigating from both theoretical and application perspectives.

While constructive modularization learning provides an alternative way of model selection, it is generally a less developed area in **MNNs**, and existing methods are subject to limitation due to a lack of theoretical justification and underpinning techniques. For example, a critical issue in the partitioning-based strategy [28.81, 82] is how to measure the nature of a subproblem to decide if any further partitioning is required and the appropriateness of a pre-selected **NN** to a subproblem in terms of its capacity. In previous studies [28.81, 82], a number of heuristic and simple criteria were proposed based on learning errors and efficiency. Although such heuristic criteria work practically, there is no theoretical justification. As a result, more sophisticated compatibility criteria need to be developed for such a constructive learning strategy based on the latest **ML** development, e.g., manifold and adaptive kernel learning. Fortunately, the partitioning-based strategy has inspired the latest developments in **ML** [28.89]. In general, constructive modularization learning is still a non-trivial topic in **MNN** research.

Finally, it is worth stating that our **MNN** review here only focuses on supervised learning due to the limited space. Most **MNNs** described above may be extended to other learning paradigms, e.g., semi-supervised and unsupervised learning. More details on such topics are available in the literature, e.g., [28.90, 91].

## 28.4 Concluding Remarks

In this chapter, we have reviewed two important areas, **DNNs** and **MNNs**, in **NC**. While we have presented several sophisticated techniques that are ready for applications, we have discussed several challenging problems in both deep and modular neural network research as well. Apart from other non-trivial issues discussed in the chapter, it is worth emphasizing that it is still an open problem to develop large-scale **DNNs** and **MNNs** and integrate them for

modeling highly intelligent behaviors, although some progress has been made recently [28.58]. In a wider context, **DNNs** and **MNNs** are closely related to two active areas, deep learning and ensemble learning, in **ML**. We anticipate that motivation and methodologies from different perspectives will mutually benefit each other and lead to effective solutions to common challenging problems in the **NC** and **ML** communities.

# Machine Learning

James T. Kwok, Zhi-Hua Zhou, Lei Xu

This tutorial provides a brief overview of a number of important tools that form the crux of the modern machine learning toolbox. These tools can be used for supervised learning, unsupervised learning, reinforcement learning and their numerous variants developed over the years. Because of the lack of space, this survey is not intended to be comprehensive. Interested readers are referred to conference proceedings such as Neural Information Processing Systems ([NIPS](#)) and the International Conference on Machine Learning ([ICML](#)) for the most recent advances.

## 29.1 Overview

Machine learning represents one of the most prolific developments in modern artificial intelligence. It provides a new generation of computational techniques and tools that support understanding and extraction of useful knowledge from complicated data sets. So what is machine learning? *Simon* [29.1] defined machine learning as:

*changes in the system that are adaptive in the sense that they enable the system to do the same task or tasks drawn from the same population more effectively the next time.*

Hence, fundamentally, the emphasis of machine learning is on the system's ability to adapt or change. Typically, this is in response to some form of experience provided to the system. After learning or adaptation, the system is expected to have better future performance on the same or a related task.

Over the past decades, machine learning has grown from a few toy applications to being almost everywhere. It is now being applied to numerous real-world applications. For example, the control of autonomous robots that can navigate on their own, the filtering of spam from mailboxes, the recognition of characters

from handwriting, the recognition of speech on mobile devices, the detection of faces in digital cameras, and so on. Indeed, one can find applications of machine learning from everyday consumer products to advanced information systems in corporations. Studies of machine learning may be overviewed from either the perspective of learning intelligent systems or that of a machine learning toolbox. For the former, learning is considered as a process of an intelligent system for coordinately solving three levels of inverse problems, namely problem solving for making pattern recognition and various other tasks, parameter learning for estimating unknown parameters in the system, and model selection for shaping system configuration with an appropriate scale or complexity to describe regularities underlying a finite size of samples. Different learning approaches are featured by differences in one or more of three ingredients, namely as a learner that has an appropriate system configuration, a theory that guides learning, and an algorithm or dynamic procedure that implements learning. Examples of studies from this prospect are recently overviewed in [29.2, 3], and will not be further addressed in this chapter. Instead, this chapter aims at a tutorial on studies of machine learning from the second prospect, that is, on those important collections pooled in the machine learning toolbox for decades. Actually, the current prosperity of machine learning comes from not only further developments of the classical statistical modeling and neural network learning, but also emerging achievements of machine learning and data mining in recent decades. Due to limited space, the focus of this tutorial will be particularly placed on those advancements made in the last two decades or so.

Classically, there are three basic learning paradigms, namely, supervised learning (Sect. 29.2), unsupervised learning (Sect. 29.3), and reinforcement learning (Sect. 29.4). In supervised learning, the learner is provided with a set of inputs together with the corresponding desired outputs. This is similar to the familiar human learning process for pattern recognition, in which a teacher provides examples to teach children to recognize different objects (say, for example, animals). Such a pattern recognition task is featured by data with each input sample associated with a label, namely labeled data. In the current literature on machine learning, the term labeled data is even generally used to refer data with each input associated with an output beyond simply a label, which is also adopted in this chapter. Section 29.2 provides not only a tutorial on basic issues of supervised learning but

also an overview on a number of interesting topics developed in recent years. The coverage of this section is not complete, e.g., it does not cover the supervised learning studies in the literature on neural networks. Interested readers are referred to a number of survey papers, e.g., especially those on multi-layer perceptron and radial basis functions [29.4, 5].

Unlike supervised learning, the tasks of unsupervised learning are featured by data that consist of only inputs, namely, the data is unlabeled and there is no longer the presence of a teacher. Unsupervised learning aims at finding certain dependence structure underlying data via optimizing a learning principle. Considering different types of structures, studies include not only classic topics of data clustering, subspace, and topological maps, but also emerging topics of learning latent factor models, hidden state-space models, and hierarchical structures. Section 29.3 also consists of two parts. The first part provides a tutorial on three classic topics, while the second part makes an overview on emerging topics. Extensive studies have been made on unsupervised learning for many decades. Instead of seeking a complete coverage, this section focuses on a tutorial on fundamentals and an overview on interesting developments of recent years, mainly based on a more systematic overview [29.6]. Further, readers are referred to several recent survey papers, e.g., [29.7] for an overview on 50 years of studies beyond k-means for data clustering, [29.8, 9] for subspace and manifold learning, and [29.10] for topological maps.

The third paradigm is reinforcement learning. Upon observing the current environment and obtaining some input (if any), the learner makes an action and changes to a new environment, receiving an evaluation (award or punish) value about the action. A learning process makes a series of actions with the received total award maximized. Different to unsupervised learning, the learner gets a guidance from an external evaluation. Also unlike supervised learning in which the teacher clearly specifies the output that corresponds to an input, in reinforcement learning the learner is only provided with an evaluative value about the action made. Section 29.4 starts at giving a tutorial on basic issues of reinforcement learning, especially temporal difference TD learning and Q-learning, plus improvements on the Q-learning with the help of some unsupervised learning methods.

Besides these three basic learning paradigms, many more variants have been developed in recent years because of the advances in machine learning. Some of these will also be described in this tutorial. They are of-

ten a hybrid of the previous learning paradigms. A very popular variant is semi-supervised learning (Sect. 29.5), which uses both labeled data (as in supervised learning) and unlabeled data (as in unsupervised learning) for training. This is advantageous as labeled data typically are expensive and involve tedious human effort, while a large amount of unlabeled data can often be obtained in an inexpensive manner (e.g., simply downloadable from the web). Another hybrid of supervised learning and unsupervised learning is discriminative clustering. Here, one adopts a cost function originally used for supervised learning as a clustering criterion. A well-known example in this category is called maximum margin clustering [29.11–13], which tries to maximize the margin (used as a criterion in constructing the highly

successful supervised learning model: support vector machine) between clusters.

Moreover, instead of just constructing one learner from training data, one can construct a set of learners and combine them to solve the problem. This approach, known as *ensemble learning* [29.14], has become very popular in recent years and will be discussed in more detail in Sect. 29.6. Finally, before learning can proceed, the data need to be appropriately represented by a set of features. In many real-world data sets, there are often a large number of features, many of which are abundant or irrelevant. Feature selection and extraction aim at automatically extracting the good features and removing the bad ones, and this will be covered in Sect. 29.7.

## 29.2 Supervised Learning

A supervised learner is provided with some labeled data (often called *training data*). This consists of a set of *training samples*, each of which is an input together with the corresponding desired outputs. Hence, the first step in machine learning is to collect these training samples. Moreover, as each training sample needs to be represented in a form amendable by the computer algorithm, one has to define a set of *features*. As an example, consider the task of recognizing handwritten characters on an envelope. To construct the training samples, obviously one first has to collect a number of envelopes with handwritten characters on. Then, the characters on each envelope have to be separated from each other. This can be performed either manually or automatically by some image segmentation algorithm. Afterwards, each character is a block of pixels (typically rectangular). A simple feature representation will be to use the intensities of these raw pixels. Each input is represented as a vector of feature values, and this vector is called the *feature vector*. Obviously, it is important to have a good set of features to work with. The presence of bad features may confuse the learning algorithm and makes learning more difficult. For example, in the context of character recognition, the color of the ink is not relevant to the identity of the character and so can be considered as a bad feature. Depending on the domain knowledge, more sophisticated features can be manually defined. It is desirable that good features can be automatically extracted and bad features automatically removed. More details on these feature selection/extraction algorithms will be covered

in Sect. 29.7. Finally, each character on the envelope has to be manually labeled.

In practice, as the real-world data are often dirty, a significant amount of time may have to be spent on data pre-processing in order to create the training data. There are many forms of *dirty* data. For example, it can be incomplete in that certain attribute values (e.g., occupation) may be lacking; it can contain outliers or errors (e.g., the salary is negative); parts of it may be inconsistent (e.g., the customer's age is 42 but his/her birthday is 03/07/2012); it may also be redundant in that there are duplicate records or unnecessary attributes. All these problems may be due to faulty or careless data collection, human/hardware/software problems, errors in data transmission; or that the data may have come from a number of different data sources. In all cases, data pre-processing can have a significant impact on the resultant machine learning system, as no quality data implies no quality learning results!

### 29.2.1 Classification and Regression

The two main goals in supervised learning are (i) classification, which aims at assigning the input pattern to different categories (also called classes or labels); and (ii) regression, which aims at predicting a real value or vector associated with the input. The basic idea and the training/testing procedures in regression are similar to those in classification. Hence, we will mainly focus on the classification problem in the sequel.

The simplest case for classification is binary classification, in which there are only two classes. Examples include classifying an email as spam or non-spam; and classifying an image as face or non-face. For each sample, the supervised learner examines the feature values in that sample and predicts the class that the sample belongs to. Essentially, the supervised learner partitions the whole feature space (the space of all possible feature value combinations) into two regions, one for each class. The boundary is called the *decision boundary*. A wide variety of models can be used to construct this decision boundary. A simple example is the linear classifier, which creates a linear boundary. Depending on the task, the linear classifier may be too simple to differentiate the two classes. Then, one can also use a more complicated decision boundary, such as a quadratic surface, leading to a quadratic classifier. In machine learning, a large number of various models that are capable of producing nonlinear decision boundaries have been proposed. The most popular ones include the decision tree classifier, nearest neighbor classifiers, neural network classifiers, Bayesian classifiers, and support vector machines. Each of these models has some parameters that have to be adapted to the particular data set. For example, the parameters of a linear classifier include the weight on each feature (which controls the slope of the linear boundary) and a bias (which controls the offset). To estimate or train these parameters, one has to provide a training set, where the  $i$ -th training pattern  $(x_i, y_i)$  consists of an input  $x_i$  and the corresponding target output label  $y_i$  (for regression problems, this  $y_i$  is a real value or vector). The greater the amount of training data, intuitively the more accurate the learned model. However, since the training data in supervised learning are labeled, obtaining these output labels typically involve expensive and tedious human effort. Hence, recent machine learning algorithms also try to utilize data that are unlabeled, leading to the development of semi-supervised learning algorithms in Sect. 29.5.

Given the model, different strategies can be used to learn the model parameters so that it fits the training set (i.e., train the model). Parameter estimation and feature selection (Sect. 29.7) can sometimes be performed together. However, note that there is the danger of *overfitting*, which occurs when the model performs better than other models on the training data, but worse on the entire data distribution as it has captured the trends of the noise underlying the data. Often this happens when the model is excessively complex, such as when it has a lot more parameters than can be re-

liably estimated from the limited number of training patterns. To combat overfitting, one can constrain the model's freedom during training by adding a regularizer or Bayesian to the parameters or model beforehand. Alternatively, one can stop the learning procedure before convergence (*early stopping*) or remove part of the model when training is complete (*pruning*). If there are noisy training samples that significantly deviate from the underlying input–output trend, one can also perform outlier detection to first remove these outlying samples.

There are two general approaches to train the model parameters. The first approach treats the model as a generative model that defines how the data are generated (typically by using a probabilistic model). One can then maximize the likelihood by varying the parameters, or to maximize the posterior probability of the parameters given the training data. Alternatively, one can take a discriminative approach that directly considers how the output is related to the input. The parameters can be obtained by *empirical risk minimization*, which seeks the parameters which best fit the training data. The risk is dependent on the loss function, which measures the difference between the prediction and the target output. Let  $y_i$  be the target output for sample  $i$ , and  $\hat{y}_i$  be the predicted output from the supervised learner. For classification problems, commonly used loss functions include the logistic loss  $\ln(1 + \exp(-y_i\hat{y}_i))$  and the hinge loss  $\max(0, 1 - y_i\hat{y}_i)$ ; and for regression problems, the most common loss function is the square loss  $(y_i - \hat{y}_i)^2$ . However, in order to combat overfitting, it is better to perform *regularized risk minimization* instead of empirical risk minimization. Regularized risk consists of two components. The first component is the loss as in empirical risk minimization. The second component is a regularizer, which helps to control the model complexity and prevents overfitting. Various regularizers have been proposed. Let  $w = [w_1, w_2, \dots, w_d]^T$  be the vector of parameters. A popular regularizer is the  $\ell_2$ -norm of  $w$ , i.e.,

$$\|w\|_2^2 = \sum_{i=1}^d w_i^2.$$

This leads to ridge regression when the linear model is used, and is commonly called *weight decay* in the neural networks literature. Instead of using the  $\ell_2$ -norm, one can use the  $\ell_0$ -norm  $\|w\|_0$ , which counts the number of nonzero  $w_i$  in the model. However, this is nonconvex and the associated optimization is more difficult. A common way to alleviate this problem is by using the

$\ell_1$ -norm

$$\|w\|_1 = \sum_{i=1}^d |w_i|,$$

which is still convex (as for the  $\ell_2$ -norm) but can still lead to a sparse parameter solution (as for the  $\ell_0$ -norm). When used with the square loss on the linear model, this leads to the well-known lasso model.

Once trained, the classifier can be used to predict the label of an unseen test sample. The underlying assumption is that this test sample comes from the same distribution as that of the training samples. In this case, we expect the trained classifier to be able to generalize well to this new sample. This can also be formally described by generalization error bounds in computational learning theory.

There are multiple ways to measure the performance of a trained classifier. An obvious performance evaluation criterion is classification accuracy, which is the fraction of test samples that are correctly classified (by comparing the prediction obtained from the classifier and the true class output of the test sample). As mentioned above, because of the issue of overfitting, it can be misleading to simply gauge classification accuracy on the training set. Instead, one can measure classification accuracy on a separate validation set (which is used as a proxy for the underlying data distribution), or use cross-validation. Moreover, sometimes, when the sample sizes of the two classes differ significantly, this accuracy may again be misleading, as one may attain an apparently high accuracy by simply predicting the test sample to belong to the majority class. In these cases, other measures such as precision, recall, and F-measure may be more useful. Moreover, while the classifier's accuracy is often an important criterion, other aspects may also be important, such as the training and testing of computational complexities (including both time and space), user-friendliness (e.g., is the trained model considered as a black-box or can it be easily conveyed and explained to the users), etc.

While binary classification assumes the presence of only two output classes, many real-world applications have more than two (say,  $K$ ), leading to a multi-class classification problem. There are two common approaches to reduce a multi-class classification problem to binary classification problems, namely, the one-vs-rest (also called one-vs-all) approach and the one-vs-one approach. In the one-vs-rest approach,  $K$  binary classifiers are constructed, each one separating the samples belonging to the  $i$ -th class from those that do not.

On prediction, the test sample is sent to all the  $K$  classifiers, and its label corresponds to the classifier with the highest output. In the one-vs-one approach, one binary classifier is built for each pair of outputs (e.g., outputs  $i$  and  $j$ ), and each classifier tries to discriminate samples belonging to the  $i$  class from those belonging to the  $j$  class. Thus, there are a total of  $\frac{1}{2}K(K - 1)$  classifiers. On prediction, the test sample is again sent to all the binary classifiers, and the class that receives the largest number of votes is output.

## 29.2.2 Other Variants of Supervised Learning

### Multi-Label Classification

While an instance can only belong to one and only one class in multi-class classification, an instance in multi-label classification can belong to multiple classes. Many real-world applications involve multi-label classification. For example, in text categorization, a document can belong to more than one category, such as government and health; in bioinformatics, a gene may be associated with more than one function, such as metabolism, transcription, and protein synthesis; and in image classification, an image may belong to multiple semantic categories, such as beach and urban. Note that the number of labels associated with an unseen instance is unknown and can also vary from instance to instance. Hence, this makes the multi-label classification problem more complicated than the multi-class classification problem. In the special case where the number of labels associated with each instance is always equal to one, obviously multi-label classification reduces to multi-class classification.

In general, multi-label classification algorithms can be divided into two categories: *problem transformation* and *algorithm adaptation* [29.15]. Problem transformation methods transform a multi-label classification problem into one or more single-label classification problems. The basic approach (called *binary relevance*) simply decomposes a multi-label problem with  $K$  labels into  $K$  binary classification problems, one for each label. In other words, the  $i$ -th classifier is a binary classifier that tries to decide whether the sample belongs to the  $i$ -th class. However, since this considers the labels independently, any possible correlations among labels will be ignored, leading to inferior performance in problems with highly correlated labels. More refined variants thus take the label correlation into account during training, a similar idea that is also exploited in multi-task learning (Sect. 29.2.2). On the

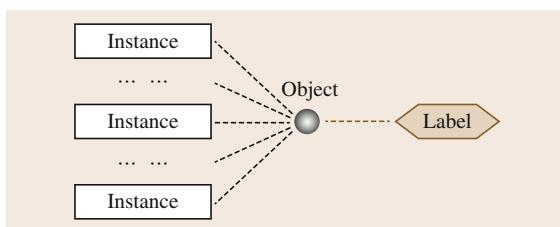

other hand, algorithm adaptation methods extend a specific learning algorithm for multi-label classification. The specific extension is thus tailor-made for each individual learning algorithm and less general. Example learning algorithms that have been extended in this way include boosting, decision trees, ensemble methods, neural networks, support vector machines, genetic algorithms, and the nearest-neighbor classifier. Recent surveys on the progress of multi-label classification and its use in different applications can be found in [29.15, 16].

In many applications, the labels are often organized in a hierarchy, either in the form of a tree (such as documents in Wikipedia) or as a directed acyclic graph (such as gene ontology). An instance is associated with a label only if it is also associated with the label's parent(s) in the hierarchy. Recently, progress has also been made in multi-label classification in these structured label hierarchies [29.17–19].

### Multi-Instance Learning

In multi-instance learning (**MIL**), the training set is composed of many *bags* each containing multiple instances, where a positive bag contains at least one positive instance, whereas a negative bag contains only negative instances; labels of the training bags are known, but labels of the instances are unknown. The task is to make predictions for labels of unseen bags. The multi-instance learning framework is illustrated in Fig. 29.1. Notice that the instances are described by the same feature set, rather than different feature sets.

The **MIL** learning framework originated from the study of drug activity [29.20], where a molecule with multiple low-energy shapes is known to be useful to make a drug, whereas it is unknown which shape is crucial. Later, many real tasks are found to be natural multi-instance learning problems. For example, in image retrieval if we regard each image patch as an instance, then the fact that an user is interested (or not interested) in an image implies that there are at least one patch (or no patch) that contains his/her interesting objects.

**Fig. 29.1** Illustration of multi-instance learning

Most **MIL** methods attempt to adapt single-instance supervised learning algorithms to the multi-instance representation by shifting their focus from discrimination on instances to discrimination on bags; there are also methods that try to adapt the multi-instance representation to single-instance algorithms by representation transformation [29.21]. Recently, it has been recognized that the instances in the bags should not be treated independently [29.22]; otherwise **MIL** is a special case of semi-supervised learning [29.23].

In addition to classification, multi-instance regression and clustering have been studied, and different versions of generalized multi-instance learning have been defined [29.24, 25]. To deal with complicated data objects that are associated with multiple labels simultaneously, a new framework, multi-instance, multi-label learning (**MIML**) [29.26], was developed recently.

Notice that the original **MIL** assumption implies that there exists a *key instance* in a positive bag; later, some other assumptions were introduced [29.27]. For example, some methods assumed that there is no key instance and every instance contributes to the bag label.

### Multi-View Learning

In many real tasks there is more than one feature set. For example, a video film can be described by audio features, image features, etc.; a web page can be described by features characterizing its own content, features characterizing its linked pages, etc. A classical routine is to take these features together and represent each instance using a concatenated feature vector. The different feature sets, however, usually convey information from different channels, and therefore, it may be better to consider the difference explicitly. This motivates multi-view learning, where each feature set is called a *view*.

Each instance in multi-view learning is represented by multiple feature vectors each in a different, usually non-overlapping feature set. Multi-view learning methods in supervised learning setting are closely related to studies of *information fusion*, *combining classifiers* [29.28–30], and *ensemble methods* [29.14]. A popular representative is to construct a model from each view, and then combine their predictions using *voting* or *averaging*. The models are often assigned with different weights, reflecting their different strength, reliability, and/or importance.

Multi-views make great sense when unlabeled data are considered. For example, it has been proved that when there are *sufficient and redundant views* (that is,

each view contains sufficient information for constructing a good model, and the two views are conditionally independent given the class label), *co-training* is able to boost the performance of any initial weak learner to an arbitrary performance using unlabeled data [29.31]. Later, it was found that such a process is beneficial even when the two views satisfy weaker assumptions, such as weak dependence, expansion, or large diversity [29.32–34], and when there are really sufficient and redundant views, even semi-supervised learning with a single labeled example is possible [29.35]. Moreover, in *active learning* where the learner actively selects some unlabeled instances to query their labels from an *oracle* (such as a human expert), it has been proved that multi-view learning enables exponential improvement of sample complexity in a setting close to real tasks [29.36], whereas previously it was believed that only polynomial improvement is possible.

### Multi-Task Learning

Many real-world problems involve the learning of a number of similar tasks. Consider the simple example of learning to recognize the numeric digits 0–9. One can build ten separate classifiers, one for each digit. However, apparently these ten classifiers share some common features, e.g., many of the digits consist of loops and strokes. Hence, the ability to detect these higher latent features is of common interest to all these classifiers, and learning all these tasks together will allow them to borrow strength from each other. Moreover, when the number of training examples is rare for each task, most single-task learning methods may fail. By learning them together, better generalization performance can be obtained by harnessing the intrinsic task relationships. Consequently, this leads to the development of *multi-task learning* (*MTL*) [29.37]. These different tasks have different output spaces and can also have different input features. But it is also quite often that these different tasks share the same set of input features. In this case, the problem is similar to multi-label classification (Sect. 29.2.2).

A popular *MTL* approach is regularized multi-task learning (*RMTL*) [29.38, 39]. It assumes that the tasks are highly related, and encourages the parameters of all the tasks to be close. More specifically, let there be  $T$  tasks and denote the parameter associated with the  $t$ -th task by  $w_t$ . *RMTL* assumes that all the  $w_t$ 's are close to some shared task  $\bar{w}$ , and that the  $w_t$ 's differ by each other only in a term  $\Delta w_t$ 's as  $w_t = \bar{w} + \Delta w_t$ . Hence,  $\bar{w}$  represents the component that is shared by all the tasks, and thus can benefit from learning all the tasks

together; while  $\Delta w_t$  is the component that is specific to each individual task, and can be used to capture the individual variations. Alternatively, other *MTL* methods, such as multi-task feature learning (*MTFL*) [29.40], assumes that all the tasks lie in a shared low-dimensional space.

Moreover, tasks are supposed to form several clusters rather than from the same group. If such a task clustering structure is known, then a simple remedy is to constrain task sharing to be just within the same cluster [29.39, 41]. More generally, all the tasks are related in different degrees, which can be represented by a network of task relationships [29.42]. In this case, *MTL* can also be performed. In practice, however, such an explicit knowledge of task clusters/network may not be readily available.

A number of efforts have made towards identifying task relationships simultaneously during parameter learning, e.g., learning a low-dimensional subspace shared by most of the tasks [29.43], finding the correlations between tasks [29.44], and inferring the clustering structure [29.45, 46], as well as integrating low-rank and group-sparse structures for robust multi-task learning [29.47].

### Transfer Learning

As discussed in Sect. 29.1, traditionally, *machine learning* is defined as:

*changes in the system that are adaptive in the sense that they enable the system to do the same task or tasks drawn from the same population more effectively the next time.*

However, recently, there has been increasing interest in adapting a classifier/regressor trained in one task for use in another. This so-called *transfer learning* is particularly crucial when the target application is in short supply of labeled data. For example, it is very expensive to calibrate a WiFi localization model in a large-scale environment. To reduce re-calibration effort, we might want to adapt the localization model trained in one time period (source domain) for a new time period (target domain), or to adapt the localization model trained on a mobile device (source domain) for a new mobile device (target domain). However, the WiFi signal strength is a function of time, device, and other dynamic factors. Thus, transfer learning is used to adapt the distributions of WiFi data collected over time or across devices.

In general, transfer learning addresses the problem of how to utilize plentiful labeled data in a source do-

main to solve related but different problems in a target domain, even when the training and testing problems have different distributions or features. The success to transfer learning from one context to another context depends on how similar the learning task is to the transferred task. There are two main approaches to transfer learning. The first approach tries to learn a common set of features from both domains, which can then be used for knowledge transfer [29.48–50]. Intuitively, a good feature representation should be able to reduce the difference in distributions between domains as much as possible, while at the same time preserving important (geometric or statistical) properties of the original data. With a good feature representation, we can apply standard machine learning methods to train classifiers or regression models in the source domain for use in the target domain. The second approach to transfer learning is based on instances [29.51–53]. It tries to learn different weights on the source examples for better adaptation in the target domain. For example, in the *kernel mean matching* algorithm [29.52], instances in a reproducing kernel Hilbert space are re-weighted based on the theory of *maximum mean discrepancy*.

### Cost-Sensitive Learning

In many real tasks, the costs of making different types of mistakes are usually unequal. In such situations, maximizing the *accuracy* (or equivalently, minimizing the number of mistakes) may not provide the optimal decision. For example, two instances that each cost 10 dollars are less important than one instance that costs 50 dollars. Cost-sensitive learning methods attempt to minimize the *total cost* by reducing serious mistakes through sacrificing minor mistakes.

There are two types of misclassification costs, i.e., *example-dependent* or *class-dependent* cost. The former assumes that every example has its own misclassification cost, whereas the latter assumes that every class has its own misclassification cost. To obtain example-dependent cost is usually much more difficult in real practice, and therefore, most studies focus on class-dependent cost.

## 29.3 Unsupervised Learning

Given a set  $X_N = \{x_t\}_{t=1}^N$  of unlabeled data samples, unsupervised learning aims at finding a certain dependence structure underlying data  $X_N$  with help of a learning principle. The simplest one is the structure

The essence of most cost-sensitive learning methods is *rescaling* (or *rebalance*), which tries to rebalance the classes such that the influence of each class in the learning process is in proportion to its costs. Suppose the cost of misclassifying the  $i$ -th class to the  $j$ -th class is  $\text{cost}_{ij}$ . For binary classification, it can be derived from the Bayes risk theory that the optimal rescaling ratio of the  $i$ -th class against the  $j$ -th class is  $\tau_{ij} = \frac{\text{cost}_{ij}}{\text{cost}_j}$  [29.54]. For multi-class problems, however, there is no direct solution to obtain the optimal rescaling ratios [29.55], and one may want to decompose a multi-class problem to a series of binary problems to solve.

*Rescaling* can be implemented in different ways, e.g., re-weighting or re-sampling the training examples of different classes, or even moving the decision threshold directly towards the cheaper class. It can be easily incorporated into existing supervised learning algorithms. For example, for support vector machines, the corresponding optimization problem can be written as

$$\begin{aligned} \min_{w,b,\xi} \quad & \frac{1}{2} \|w\|_{\mathcal{H}}^2 + C \sum_{i=1}^m \text{cost}(x_i) \xi_i \\ \text{s.t.} \quad & y_i(w^T \phi(x_i) + b) \geq 1 - \xi_i \\ & \xi_i \geq 0 \quad i = 1, \dots, m, \end{aligned} \quad (29.1)$$

where  $\phi$  is the feature induced from a kernel function and  $\text{cost}(x_i)$  is the cost for misclassifying  $x_i$ . It can be found that the only difference with the classical support vector machine is the insertion of  $\text{cost}(x_i)$ .

It is often difficult to know precise costs in real practice, and some recent studies have tried to address this issue [29.56]. Notice that a learning process may involve various costs such as the *test cost*, *teacher cost*, *intervention cost*, etc. [29.57], and these costs can also be considered in cost-sensitive learning. Last but not least, it should be noted that the variants introduced in this section already go beyond the classic paradigm of supervised learning. Many of them are integrated with unsupervised learning. Some further issues will be also addressed in the following sections.

of merely a point  $\mu$  in a vector space as illustrated in Fig. 29.2a(A(2)). It represents each sample  $x_t$  with an error measure  $\varepsilon_t = \|x_t - \mu\|^2$ . The best  $\mu$  may be obtained under a learning principle, e.g., minimizing the

following error

$$E_2 = \sum_{t=1}^N \varepsilon_t, \quad (29.2)$$

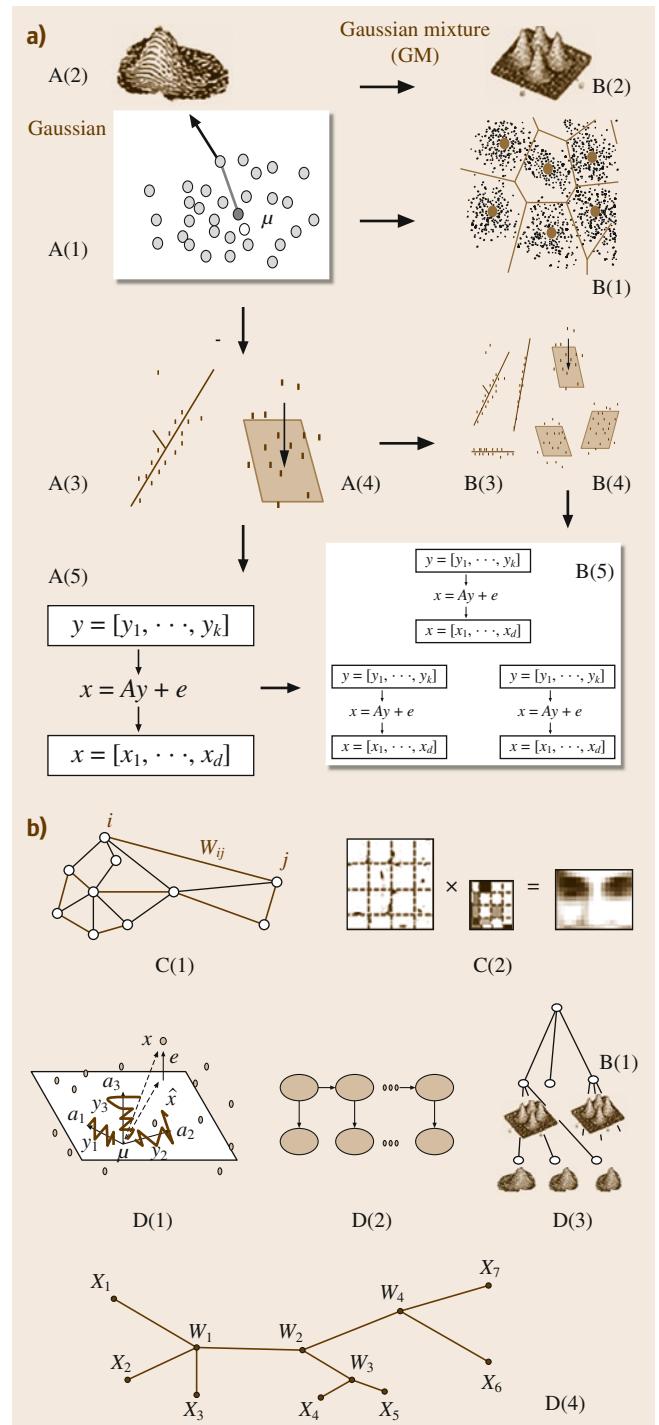

which results in that  $\mu$  is simply the mean of the samples.

Efforts made have been far from a simple point structure. As illustrated in Fig. 29.2, these efforts are roughly grouped into several closely related streams. One consists of those listed in Fig. 29.2a(A), featured by increasing the dimensionality of the modeling structure from a single point to a line, plane, and subspace. The second stream consists of those listed in Fig. 29.2a(B), with multiple structures replacing its counterparts listed in Fig. 29.2a(A). The third stream consists of those listed in Fig. 29.2b(C), based on matrix/graph representation of underlying dependence structures. Moreover, another stream is featured with underlying dependencies in tree structures, such as temporal modeling, hierarchical learning, and causal tree structuring, as illustrated in Fig. 29.2b(D). This section will provide a tutorial on the basic structures listed in Fig. 29.2. Also, an overview will be made of a number of emerging topics, mainly coming from a recent systematic overview [29.6].

Additionally, there is also a stream of studies that not only consist of unsupervised learning as a major ingredient but also include features of supervised learning and reinforcement learning, some of which are referred to under the term semi-supervised learning, while others are referred to under the names of semi-unsupervised learning, hybrid learning, mixture of experts, etc. Among them, semi-supervised learning has become a well-adopted name in the literature of machine learning and will be further introduced in Sect. 29.5. Moreover, readers are further referred to Sect. 4.3 of [29.58] and [29.59] for a general formulation called semi-blind learning.

### 29.3.1 Principal Subspaces and Independent Factor Analysis

When a point  $\mu$  is replaced with a line structure as illustrated in Fig. 29.2a(A(3)), e.g., represented by a vector  $w_\mu = w - \mu$  of a unit length, we consider the error  $\varepsilon_t$  as the shortest distance from  $x_t$  to the line. Then, minimizing  $E$  by (29.2) results in that  $w_\mu$  is the principal component direction of the sample set  $X_N$ , that is, we

**Fig. 29.2a,b** Four streams of unsupervised learning studies featured by types of underlying dependence structures

have

$$Sw_{\mu} = \lambda w_{\mu}, S = \frac{1}{N} \sum_{t=1}^N (x_t - \mu)(x_t - \mu)^T, \quad (29.3)$$

where  $\lambda$  is the largest eigenvalue of the sample covariance matrix  $S$ , and  $w_{\mu}$  is the corresponding eigenvector.

Moreover, we consider a plane or subspace illustrated in Fig. 29.2a(A(4)), resulting in a principal plane or subspace, i.e., a subspace spanned by  $m$  eigenvectors that correspond to the first  $m$  largest eigenvalue of  $S$ . Usually, the tasks in Fig. 29.2a(A(3)) and Fig. 29.2a(A(4)) are called *principal component analysis (PCA)* and *principal subspace analysis (PSA)*.

Considering a subspace spanned by the column vectors of  $A$ , each sample  $x_t$  is represented by  $\hat{x}_t = Ay_t$  from a vector  $y_t = [y_t^{(1)}, \dots, y_t^{(m)}]^T$  in the subspace with the mutually independent elements of  $y_t$  being the coordinates along these column vectors, subject to an error  $e_t = x_t - \hat{x}_t$  that is uncorrelated to or independent of  $y_t$ . Thus, as illustrated in Fig. 29.2a(A(5)),  $x_t$  comes from an underlying subspace as follows

$$\begin{aligned} x_t &= \hat{x}_t + e_t = Ay_t + e_t, \\ Ee_t y_t^T &= 0 \text{ or } p(e_t|y_t) = p(e_t), \end{aligned} \quad (29.4)$$

featured with the following independence

$$p(y_t) = p(y_t^{(1)}) \cdots p(y_t^{(m)}). \quad (29.5)$$

Particularly, it is called *factor analysis (FA)* if we consider

$$\begin{aligned} p(y_t) &= G(y_t|0, I), \\ p(e_t) &= G(e_t|0, D) \quad \text{for a diagonal } D, \end{aligned} \quad (29.6)$$

where  $G(x|\mu, \Sigma)$  denotes a Gaussian density with the mean vector  $\mu$  and the covariance matrix  $\Sigma$ .

In general, the matrix  $A$  and other unknowns in (29.4) are estimated by the maximum likelihood learning on

$$q(x|\theta) = G(x|0, \mathbf{A}\mathbf{A}^T + D), \quad (29.7)$$

with help of the expectation maximization (EM) algorithm. With the special case  $D = \sigma^2 I$ , the space spanned by the column vectors of  $A$  is the same subspace spanned by  $m$  eigenvectors that correspond to the first  $m$  largest eigenvalue of  $S$  in (29.3), which has been a well-known fact since Anderson's work in 1959. In the last two decades, there has been a renewed interest

in the machine learning literature under the new name of probabilistic PCA.

Classically, the principal subspace is obtained via computing the eigenvectors of the sample covariance  $\Sigma$ . However,  $\Sigma$  is usually poor in accuracy when the sample size  $N$  is small while the dimensionality of  $x_t$  is high. Alternatively, Oja's rule and variants thereof have been proposed to learn the eigenvectors adaptively per sample without directly computing  $\Sigma$ . Also, extensions have been made on adaptive robust PCA learning on data with outliers and on the adaptive principle curve as the line in Fig. 29.2a(A(3)) extended to a curve.

A hyperplane has two dual representations. One is spanned by several one-dimensional unit vectors, while the other is represented by a unit length normal vector  $w$  that is orthogonal to this subspace. In the latter case, minimizing  $E$  results in that  $w_{\mu}$  is still a solution of (29.3) but with  $\lambda$  becoming the smallest eigenvalue instead of the largest one. Accordingly, the problem is called *minor component analysis (MCA)*. In general, an  $m$ -dimensional subspace in  $R^d$  may also be represented by the spanning vectors of a  $d-m$  complementary subspace, for which minimizing  $E$  results in  $d-m$  eigenvectors that correspond to the first  $m$  smallest eigenvalues of  $S$ . The problem is called *minor subspace analysis (MSA)*. When  $m > d/2$ , the minor subspace needs fewer free parameters than the principal subspace does. In a dual subspace pattern classification, each class is represented by either a principal subspace or a minor subspace. Because they are different from PCA and PSA, MCA and MSA are more prone to noises. For further details about these topics the interested reader is referred to Sect. 3.2.1 of [29.58] and a recent overview [29.60]. In the following, we add brief summaries on three typical methods.

### PCA versus ICA

Independent component analysis (ICA) has been widely studied in the past two decades. The key point is to seek a linear mapping  $y_t = Wx_t$  such that the components  $y_t^{(1)}, \dots, y_t^{(m)}$  of  $y_t$  become mutually independent, as shown in (29.5), as an extension of PCA by which the components  $[y_t^{(1)}, \dots, y_t^{(m)}]$  of  $y_t = Wx_t$  become mutually de-correlated when the rows of  $W$  consist of the eigenvectors of the first  $m$  largest eigenvalue of  $S$  in (29.3). Strictly speaking, this is inexact since the counterpart of ICA should be called de-correlated component analysis (DCA), with independence among  $y_t^{(1)}, \dots, y_t^{(m)}$  in the second order of statistics. PCA is one extreme case of DCA that

chooses those de-correlated components with the first  $m$  largest variances/eigenvalues, while **MCA** is another extreme case that chooses those with the first  $m$  smallest variances/eigenvalues. Correspondingly, the extended counterpart of **PCA/MCA** should be the principal/minor **ICA** that chooses the independent components with the first  $m$  largest/smallest variances. Readers are referred to Sect. 2.4 of [29.61] for further details. Several adaptive learning algorithms have been developed for implementing **ICA**, but their implementation cannot be guaranteed (29.5). Theoretically, theorems have been proved that such a guarantee can be reached as long as one bit of information is provided to each component  $y_t^{(j)}$  [29.62].

### FA-a, FA-b, and Model Selection

In the literature of statistics and machine learning, the model (29.4) with (29.6) is conventionally referred to as **FA**. Actually, we have  $Ay = \tilde{A}\tilde{y}$  with  $\tilde{A} = A\phi^{-1}$ ,  $\tilde{y} = \phi y$  for any unknown nonsingular matrix. Among the different choices to handle this indeterminacy, the standard one, shortly denoted by **FA-a**, imposes (29.6) on  $y$ , which reduces an indeterminacy of a general nonsingular  $\phi$  to an orthonormal matrix. One other choice is given by (29.4) with

$$A^T A = I, \quad p(y_t) = G(y_t|0, \Lambda) \text{ for a diagonal } \Lambda, \quad (29.8)$$

shortly denoted by **FA-b**. We have  $\hat{x}_t = Ay = A\Lambda\Lambda^{-1}y = A\Lambda\phi^T\phi\Lambda^{-1}y = \tilde{A}\tilde{y}$ , with  $\tilde{A} = A\Lambda\phi^T$ ,  $\tilde{y} = \phi\Lambda^{-1}y$ , and  $\phi^T\phi = I$ , i.e., its  $\hat{x}_t$  is equivalent to the one by **FA-a** for a given  $m$  with an invertible  $\Lambda^{-1}$ . In other words, **FA-a** and **FA-b** are equivalent for a learning principle based on  $e_t = x_t - \hat{x}_t$ , e.g., minimizing  $E$  by (29.2) or maximizing the likelihood on  $x_t$ . Moreover, **FA-a** and **FA-b** are still equivalent when model selection is used for determining an appropriate value  $m$  by one of the classic model selection criteria to be introduced later in (29.14). However, **FA-a** and **FA-b** become considerably different to the Bayesian Yin-Yang (**BYY**) harmony learning in Sect. 3.2.1 of [29.58] and also to automatic model selection in general. Empirically, experiments show that not only **BYY** harmony learning but also the variational Bayes method perform considerably better on **FA-b** than on **FA-a** [29.63].

### Non-Gaussian FA

Both **FA-a** and **FA-b** still suffer an indeterminacy of an  $m \times m$  orthonormal matrix  $\phi$ , which can be fur-

ther removed when at most one of the components  $y_t^{(1)}, \dots, y_t^{(m)}$  is Gaussian. Accordingly, (29.4) with non-Gaussian components  $p(y_t^{(j)})$  in (29.5) is called *non-Gaussian FA (NFA)*. It is also referred to as *independent FA (IFA)*, although **NFA** sounds better, since the concept of **IFA** covers not only **NFA** but also **FA-a** and **FA-b**. One useful special case of **NFA** is called **binary FA** when  $y_t$  is a binary vector. Moreover, in the degenerated case  $e_t = 0$ , obtaining  $A$  of  $x_t = Ay_t$  subject to (29.5) is equivalent to getting  $W = A^{-1}$  such that  $Wx_t = y_t$  to satisfy (29.5). For this reason, **NFA** with  $e_t \neq 0$  is also sometimes referred to as noisy **ICA**. Strictly speaking, the map  $x_t \rightarrow y_t$  towards (29.5), being an inverse of **NFA**, should be nonlinear instead of a linear  $y_t = Wx_t$ . Maximum likelihood learning is implemented with help of the **EM** algorithm, which was developed in the middle to end of the 1990s for **BFA/NFA**, respectively. Also, learning algorithms have been proposed for implementing **BYY** harmony learning with automatic model selection on  $m$ . Recently, both **BFA** and **NFA** were used for transcription regulatory networks in gene analysis; for further details the reader is referred to the overview [29.60] and especially its *Roadmap*.

### 29.3.2 Multi-Model-Based Learning: Data Clustering, Object Detection, and Local Regression

The task of data clustering is partitioning a set of samples into several clusters such that samples within a sample cluster are similar while samples from different clusters should be as different as possible. An indicator matrix  $\mathbf{P} = [p_{\ell,t}]$  with  $\mathbf{P}\mathbf{P}^T = I$  is used to represent one possible partition of a sample set  $X_N = \{x_t\}_{t=1}^N$  into one of  $\ell = 1, \dots, k$  clusters, i.e.,  $p_{\ell,t} = 1$  if  $x_t$  belongs to the  $\ell$ -th cluster, otherwise  $p_{\ell,t} = 0$ . For multi-model-based clustering, each cluster is modeled by one structure, with  $p_{\ell,t}$  obtained by a competition of using the structure of each cluster to represent a sample  $x_t$ . The structure of each cluster could be one of the ones listed on the left-hand side of Fig. 29.2; multiple clusters are thus represented by multiple structures listed on the right-hand side of Fig. 29.2, which feature the basic topics of the second stream of studies.

We still start from the simplest point structure illustrated in Fig. 29.2a(A(1)), extending to the structure of multi-points illustrated in Fig. 29.2a(B(1)). With data already divided into  $k$  clusters, it is easy to obtain the mean  $\mu_j$  of each cluster. Given  $\{\mu_j\}_{j=1}^k$  fixed, it is also

easy to divide  $X_N$  into  $k$  clusters by

$$p_{\ell,t} = \begin{cases} 1, & \ell = \arg \min_j \varepsilon_{j,t}, \\ 0, & \text{otherwise,} \end{cases} \quad (29.9)$$

where  $\varepsilon_{j,t} = \|x_t - \mu_j\|^2$ , i.e.,  $x_t$  is assigned to the  $\ell$ -th cluster if  $p_{\ell,t} = 1$ . The key idea of the k-means algorithm is alternatively getting  $p_{\ell,t}$  and computing  $\mu_j$  from an initialization. Although it aims at minimizing  $E_2$  by 29.2 with  $\varepsilon_t = \sum_{\ell=1}^k p_{\ell,t} \varepsilon_{j,t}$ , k-means typically results in a local minimum of  $E_2$ , depending on the initialization.

Merely using the mean  $\mu_j$  is not good for describing a cluster beyond a ball shape. Instead, it is extended to considering the Gaussian illustrated in Fig. 29.2a(A(2)) and thus its counterpart in Fig. 29.2a(B(2)), i.e., the following Gaussian mixture

$$q(x|\theta) = \sum_{j=1}^k \alpha_j G(x|\mu_j, \Sigma_j). \quad (29.10)$$

K-means can be extended to getting  $p_{\ell,t}$  by (29.11) with

$$\varepsilon_{j,t} = -\ln[\alpha_j G(x_t|\mu_j, \Sigma_j)]. \quad (29.11)$$

and computing each Gaussian by

$$\begin{aligned} \alpha_\ell^* &= \frac{\sum_t p_{\ell,t}}{N}, \\ \mu_\ell^* &= \frac{1}{N\alpha_\ell^*} \sum_t p_{\ell,t} x_t, \\ \Sigma_\ell^* &= \frac{1}{N\alpha_\ell^*} \sum_t p_{\ell,t} (x_t - \mu_\ell^*)(x_t - \mu_\ell^*)^\top, \end{aligned} \quad (29.12)$$

which actually performs a type of elliptic clustering.

Instead of getting  $p_{\ell,t}$  by (29.9), we compute

$$p_{\ell,t} = q(\ell|x_t, \theta^*), \quad q(\ell|x_t, \theta) = e^{-\varepsilon_{j,t}} / \sum_{i=1}^k e^{-\varepsilon_{i,t}}. \quad (29.13)$$

Actually, alternatively iterating (29.13) and (29.12) is the well-known EM algorithm for carrying out maximum likelihood learning on the Gaussian mixture.

Another important topic is to determine an appropriate  $k$  (model selection), i.e. how many clusters are needed. Classic model selection seeks a best  $k^* =$

$\arg \min_k J(k)$  with a criterion  $J(k)$  in a format as follows

$$J(k) = -L(k, \theta^*) + \omega(k, N), \quad \theta^* = \arg \max_{\theta} L(k, \theta), \quad (29.14)$$

where  $L(k, \theta)$  is the likelihood function of  $q(x|\theta)$ , and  $\omega(k, N) > 0$  increases with  $k$  and decreases with  $N$ . One typical example is called the Bayesian information criterion (BIC) or minimum description length (MDL). To obtain  $k^*$  one needs to enumerate a set of  $k$  values and estimate  $\theta^*$  for each  $k$  value, which incurs an extensive computation and is thus difficult to scale up to a large number of clusters.

Alternatively, *automatic model selection* aims at obtaining  $k^*$  during learning  $\theta^*$  by a mechanism or principle that is different from the maximum likelihood. This learning drives away an extra cluster via a certain indicator  $\rho_j \rightarrow 0$ , e.g.,  $\rho_j = \alpha_j$  or  $\rho_j = \alpha_j \text{Tr}[\Sigma_j]$ . One early effort is rival penalized competitive learning (RPCL). RPCL learning does not implement (29.12) by either (29.9) or (29.13), with  $p_{\ell,t}$  given as follows

$$p_{\ell,t} = \begin{cases} 1, & \ell^* = \arg \min_j \varepsilon_{j,t}, \\ -\gamma, & \ell = \arg \min_{\ell \neq \ell^*} \varepsilon_{j,t}, \\ 0, & \text{otherwise,} \end{cases} \quad (29.15)$$

by which learning is made on a cluster when  $p_{\ell,t} = 1$ , and penalizing or de-learning is made on a cluster when  $p_{\ell,t} = -\gamma$ , with a heuristic penalizing strength of roughly  $\gamma \approx 0.005 \approx 0.05$ .

The BYY harmony learning gets rid of the difficulty of finding an appropriate penalizing strength, with both parameter learning and model selection made under the Ying Yang best harmony principle. The algorithm obtained still implements (29.12) and replaces  $p_{\ell,t}$  by (29.12) with

$$\begin{aligned} p_{\ell,t} &= q(\ell|x_t, \theta^*)(1 + \Delta\pi_{\ell,t}), \\ \Delta\pi_{\ell,t} &= \sum_j q(j|x_t, \theta^*) \varepsilon_{j,t} - \varepsilon_{\ell,t}. \end{aligned} \quad (29.16)$$

where  $\Delta\pi_{\ell,t} > 0$  means that the  $j$ -th component is better than the average of all the components for describing the sample  $x_t$ . We further update the  $j$ -th component in (29.12) to enhance the description. If  $0 > \Delta\pi_{\ell,t} > -1$ , i.e., the fitness by the  $j$ -th component to  $x_t$  is below the average but still not too far away, updating of the  $j$ -th component remains the same trend as in (29.12) but with reduced strength. Moreover, when  $-1 > \Delta\pi_{\ell,t}$ , the updating on the  $j$ -th component

reverses direction to become de-learning, similar to updating the rival in **RPCL** learning.

**RPCL** learning, which was proposed in 1992, and **BYY** harmony learning, which was developed in 1995, are similar in nature to the popular sparse learning method, which was developed in 1995 [29.64, 65], and prior-based automatic model selection approaches [29.66–68], that is, extra parts in a model are removed as some parameters are pushed towards zero. Without any priors on the parameters, these prior-based approaches degenerate to maximum likelihood learning, while **RPCL** learning and further improved by incorporating appropriate priors.

For further details about automatic model selection, prior-aided learning, and model selection criteria the reader is referred to Sect. 2.2 of [29.58, 69] and [29.70] for recent overviews. Also, readers are referred to Sect. 2.1 and Table 1 of [29.58] for a tutorial on several algorithms for learning Gaussian mixture, including the ones introduced above. In the following, only three typical ones are briefly summarized.

### Local Subspaces and Local Factor Analysis

As illustrated in Fig. 29.2a(B(3)–(5)), the structure of multi-points illustrated in Fig. 29.2a(B(1)) can be extended into multiple subspaces and **FA** models. Still, we can obtain  $p_{\ell,t}$  by (29.9), (29.15), and (29.13) with  $\varepsilon_{j,t}$  given by either (29.11) with  $\Sigma_j = A_j A_j^T + D_j$  or simply the shortest square distance from  $x_t$  to the  $j$ -th subspace. Given data divided into  $k$  clusters, we may estimate the subspace or **FA** of each cluster as introduced in Sect. 29.3.1, which leads to extensions of the k-means algorithm, the **EM** algorithm, and the **BYY** harmony learning algorithm for learning **FAs** or subspaces that locate at different  $\{\mu_j\}_{j=1}^k$ . Moreover, readers are referred to [29.71] and [29.2] for learning local **FAs** with both the number  $k$  and the dimensions  $\{m_j\}$  determined automatically during **BYY** harmony learning.

### Object Detection and Pattern-Based Clustering

The structures in Fig. 29.3a(B(3),(4)) are applicable to the tasks of detecting lines and subspaces among image data, which are topics that are widely studied in the literature of pattern recognition and handled by the well-known Hough transform (**HT**) and randomized **HT** (**RHT**) [29.70]. Extensions can be made to detect multiple objects such as circles, ellipses, lines and other shapes, as well as so-called pattern based clustering, still obtaining  $p_{\ell,t}$  by (29.9), (29.15), and (29.13) but with  $\varepsilon_{j,t}$  being the shortest square distance from  $x_t$

to each shape. However, it is no longer possible to use (29.12) for updating the parameters  $\theta_j$  of each shape. Instead, learning is done by

$$\theta_{\ell}^{\text{new}} = \theta_{\ell}^{\text{old}} + \eta p_{\ell,t} \nabla_{\theta_{\ell}} \varepsilon_{\ell,t}, \quad (29.17)$$

where  $\eta > 0$  is a learning step size; for further details the reader is referred to [29.69, 70] and [29.8].

### Mixture of Experts, RBF Networks, SBF Functions

Let each Gaussian to be associated with a function  $f(x|\phi_j)$  for a mapping  $x \rightarrow z$ , we consider the task of learning

$$q(z_t|x_t, \psi) = \sum_{j=1}^k q(\ell|x_t, \theta) G[z_t|f_j(x_t, \phi_j), I_j], \quad (29.18)$$

from a set  $D_N = \{x_i, z_i\}_{i=1}^N$  of labeled data. The above  $q(z_t|x_t, \psi)$  is actually the alternative mixture of experts [29.72], featured by a combination of unsupervised learning for the Gaussian mixture by (29.10) and supervised learning for every  $f(x|\phi_j)$ . For a regression task, typically we consider  $f(x|\phi_j) = w_j^T x + c_j$  with  $E[z|x] = \sum_{j=1}^k q(j|x, \theta) f_j(x, \phi_j)$  implementing a type of piecewise linear regression. In implementation, we still obtain  $p_{\ell,t}$  by (29.9), (29.15), and (29.13) but with the following  $\varepsilon_{j,t}$

$$\varepsilon_{j,t} = -\ln[\alpha_j G(x|\mu_j, \Sigma_j) G(z_t|f_j(x_t, \phi_j))], \quad (29.19)$$

and then compute each Gaussian by (29.12), as well as update  $G(z_t|f_j(x_t, \phi_j), I_j)$ . When  $\alpha_j = |\Sigma_j| / \sum_{i=1}^k |\Sigma_i|$ , it becomes equivalent to an extended normalized radial basis function (**RBF**) network and a normalized **RBF** network simply with  $w_j = 0$ . Moreover, letting each subspace be associated with  $f(x|\phi_j)$  will lead to subspace-based functions (**SBFs**). For further details readers are referred to [29.5] and Sect. 7 of [29.69].

### 29.3.3 Matrix-Based Learning: Similarity Graph, Nonnegative Matrix Factorization, and Manifold Learning

We proceed to the third stream, featured with graph/matrix structures. We start with the sample similarity graph, with each node for a sample and each edge

attached with a similarity measure between two samples, as illustrated in Fig. 29.2b(C(1)). Such a graph is also equivalently represented by a symmetric matrix  $\mathbf{W} = [w_{ij}]$ .

One similarity measure is simply the inner product  $w_{ij} = x_i^T x_j$  of two samples. Given a data matrix  $\mathbf{X} = [x_1, \dots, x_N]$ , we simply have  $\mathbf{W} = \mathbf{X}^T \mathbf{X}$ . We seek an indicator matrix  $\mathbf{P} = [p_{\ell,i}]$  that divides  $X_N = \{x_i\}_{i=1}^N$  into  $k$  clusters, with help of the following maximization

$$\max_{HHT=I, H \geq 0} \text{Tr}[\mathbf{H}^T \mathbf{W} \mathbf{H}], \\ \mathbf{H} = \text{diag}[n_1^{-0.5}, \dots, n_k^{-0.5}] P, \quad (29.20)$$

where  $\mathbf{H} \geq 0$  is a nonnegative matrix with each element  $h_{ij} \geq 0$ , and  $n_\ell$  is the number of samples in the  $\ell$ -th cluster. It can be shown that this problem is equivalent to minimizing  $E_2$  by (29.2) with  $\varepsilon_t = \sum_{\ell=1}^k p_{\ell,t} \|x_t - \mu_j\|^2$ , i.e., the same target that k-means aims at.

Computationally, (29.20) is a typical intractable binary quadratic programming problem, for which various approximate methods are proposed. The most simple one is dropping the constraint  $\mathbf{H} \geq 0$  to do a PCA analysis about the matrix  $\mathbf{W}$ . That is, the columns of  $\mathbf{H}$  consist of the  $k$  eigenvectors of  $\mathbf{W}$  that correspond to the first  $k$  largest eigenvalues. Then, each element of the matrix  $\text{diag}[n_1^{0.5}, \dots, n_k^{0.5}] \mathbf{H}$  is chopped into 1 or 0 by a rule of thumb.

Another similarity measure is  $w_{ij} = \exp(-\|x_i - x_j\|^2)$ , based on which we consider dividing the nodes of a graph into balanced two sets  $A, B$  such the total sum of  $w_{ij}$  associated with edges connecting the two sets becomes as small as possible. Using a vector  $f = [f_1, \dots, f_N]^T$  with  $f_t = 1$  if  $x_t \in A$  and  $f_t = -1$  if  $x_t \in B$ , the problem is formulated as follows

$$\min_f f^T L f, \text{ s.t. } [1, \dots, 1] f = 0, \\ L = D - W, D = \text{diag}[w_{11}, \dots, w_{NN}], \quad (29.21)$$

where  $L$  is the graph Laplacian. Again, it is an intractable combinatorial problem and needs to consider some approximation. A typical one is given as follows

$$\min_f \frac{f^T L f}{f^T f}, \text{ s.t. } [1, \dots, 1] f = 0. \quad (29.22)$$

Its solution  $f$  is the eigenvector of  $L$  that corresponds the second smallest eigenvalue. Moreover, this idea has been extended to cutting a graph into multiple clusters, which leads to approximately finding  $\mathbf{H}$  with its

columns being the eigenvectors of  $\tilde{\mathbf{W}} = D^{-0.5} W D^{-0.5}$ , corresponding to the first  $k$  largest eigenvalues.

Moreover, the above studies are closely related to nonnegative matrix factorization (NMF) problems [29.73]. For example, the above problem can be equivalently expressed as factorization  $\tilde{\mathbf{W}} \approx \mathbf{H}^T \mathbf{H}$  by

$$\min_{HHT=I, H \geq 0} \|\tilde{\mathbf{W}} - \mathbf{H}^T \mathbf{H}\|^2. \quad (29.23)$$

More generally, the NMF problem considers that

$$\mathbf{X} \approx \mathbf{F} \mathbf{H}, \mathbf{X} \geq 0, \mathbf{F} \geq 0, \mathbf{H} \geq 0, \quad (29.24)$$

as illustrated in Fig. 29.2b(C(1)). One typical method is to iterate the following multiplicative update rule

$$\mathbf{H}_{ij}^{\text{new}} = \mathbf{H}_{ij}^{\text{old}} \frac{(\mathbf{F}^T \mathbf{X})_{ij}}{(\mathbf{F}^T \mathbf{F} \mathbf{H})_{ij}}, \mathbf{F}_{ij}^{\text{new}} = \mathbf{F}_{ij}^{\text{old}} \frac{(\mathbf{X} \mathbf{H}^T)_{ij}}{(\mathbf{F} \mathbf{H} \mathbf{H}^T)_{ij}}, \quad (29.25)$$

which guarantees nonnegativity and is supposed to converge to a local solution of the following minimization

$$\min_{HHT=I, H \geq 0, F \geq 0} \|\mathbf{X} - \mathbf{F} \mathbf{H}\|^2. \quad (29.26)$$

Particularly, if we also impose the constraint  $\mathbf{F}^T \mathbf{F} = \mathbf{I}$ , the resulted  $\mathbf{H}$  divides the columns of  $\mathbf{X}$  into  $k$  clusters, while the resulted  $\mathbf{F}$  also divides the rows of  $\mathbf{X}$  into  $k$  clusters, and is thus called *bi-clustering* [29.74].

Several NMF learning algorithms have been developed in the literature. In [29.75], a binary matrix factorization (BMF) algorithm was developed under BYY harmony learning for clustering proteins that share similar interactions, featured with the nature of automatically determining the cluster number, while this number has to be pre-given for most existing BMF algorithms.

In the past decade, the similarity graph and especially the graph Laplacian  $L$  have also taken important roles in another popular topic called *manifold learning* [29.76, 77]. Considering a mapping  $Y \approx WX$ , a locality preserving projection is made to minimize the sum of each distance between two mapped points on the graph, subject to a unity  $L_2$  norm of this projection  $WX$ .

Alternatively, we may also regard that  $X$  is generated via  $X = AY + E$  such that the topological dependence among  $Y$  is preserved by considering

$$q(Y) \propto e^{-\frac{1}{2} \text{Tr}[YLY^T \mathbf{\Lambda}^{-1}]}, \quad (29.27)$$

where  $\Lambda$  is a positive diagonal matrix. Learning is implemented by **BYY** harmony learning, during which automatic model selection is made via updating  $q(Y)$  to drive some diagonal elements of  $\Lambda$  towards zeros. For further details readers are referred to the end part of Sect. 5 in [29.58].

### 29.3.4 Tree-Based Learning: Temporal Ladder, Hierarchical Mixture, and Causal Tree

Unsupervised learning also includes learning temporal and hierarchical underlying dependence structures, as illustrated in Fig. 29.2b(D). Instead of directly modeling temporal dependence underlying data  $X = [x_1, \dots, x_N]$ , its structure is typically represented in a hidden space, while non-temporal or spatial dependence is represented by a relation from the hidden space to the space where  $X$  is observed, in the ladder structure illustrated in Fig. 29.2b(D(1)).

One typical example is the classic hidden Markov model (**HMM**). Its hidden space is featured by a discrete variable that jumps between a set of discrete values or states  $\{s_j\}$ , with temporal dependence described by the jumping probabilities between the states, typically considering  $p(s_j|s_i)$  of jumping from one state  $s_i$  to another  $s_j$ . The relation from the hidden space to the space of  $X$  is described by  $p(x_t|s_i)$  for the probability that the value of  $x_t$  is emitted from the state  $s_i$ . Classically, the values of  $x_t$  are also a set of labels. The task is learning from  $X = [x_1, \dots, x_N]$  two probability matrices  $\mathbf{Q} = [p(s_j|s_i)]$  and  $\mathbf{E} = [p(x_t|s_i)]$ . Given the number of states, learning is typically implemented to maximize the likelihood  $p(X|\mathbf{Q}, \mathbf{E})$  by the well-known Baum-Welch algorithm.

Another example is the classic state-space model (**SSM**), which has been widely studied in the literature of control theory and signal processing since the 1960s; this has also been called a linear dynamical system with considered with renewed interest since the beginning of the 2000s. As illustrated in Fig. 29.2b(D(2)), its hidden space is featured by an  $m$ -dimensional subspace and temporal dependence is described by one first-order vector autoregressive model as follows

$$\begin{aligned} y_t &= B y_{t-1} + \varepsilon_t, \quad E y_{t-1} \varepsilon_t^T = 0, \\ \varepsilon_t &\approx G(\varepsilon_t|0, \Lambda), \quad \Lambda \text{ is diagonal}, \end{aligned} \quad (29.28)$$

while the spatial dependence is represented by a relation between the coordinates of the state-space and the coordinates of the space of  $X$ , e.g., typically by (29.4).

Though the **EM** algorithm has also been suggested for learning the **SSM** parameters, the performance is usually unsatisfactory because an **SSM** is generally not identifiable due to an indeterminacy of any unknown nonsingular matrix, similar to what was discussed previously with respect to the **FA** in (29.5). Favorably, it has been shown that the indeterminacy of not only any unknown nonsingular matrix but also an unknown orthonormal matrix is usually removed by additionally requiring a diagonal matrix  $B$ , which leads to temporal factor analysis (**TFA**).

**TFA** is an extension of the **FA** by (29.4) with (29.6) replaced by (29.28). As introduced in Sect. 29.3.1, the **FA** is generalized into **NFA** when (29.6) becomes (29.5) with each  $p(y_t^{(j)})$  being non-Gaussian. The **NFA** with a real vector  $y_t$  can be further extended into a temporal **NFA** when (29.5) is also extended by (29.28) with

$$p(\varepsilon_t) = p(\varepsilon_t^{(1)}) \cdots p(\varepsilon_t^{(m)}).$$

Moreover, the **BFA** (i.e., **NFA** with a binary vector  $y_t$ ) can be extended into a temporal **BFA**. Also, **TFA** has been extended into an integration of several **TFA** models coordinated by an **HMM**. For further details readers are referred to Sect. 5.2 of [29.58] for a recent overview on **TFA** and its extensions.

A ladder is merely a special type of tree structure. Hierarchical modeling is one other type of tree structure, as illustrated in Fig. 29.2b(D(3)). Again, the **EM** algorithm has been extended to implement learning on a hierarchical or tree mixture of Gaussians [29.78]. Also, a learning algorithm is available for implementing **BYY** harmony learning with tree configuration determined during learning. A learning algorithm for a three-level hierarchical mixture of Gaussians is shown in Fig. 12 of [29.3], featured by a hierarchical learning flow circling from bottom up as one step and then top down as the other step. Similar to (29.16), where there is a term of  $\Delta$  featuring the difference of **BYY** harmony learning from **EM** learning, there is also such a  $\Delta$  term on each level of hierarchy. If these  $\Delta$  terms are set to be zero, the algorithm degenerates back to the **EM** algorithm. For further details readers are referred to Sect. 5.1 in [29.3] and especially equation (55) therein.

Many applications consider several sets of samples. Each set is known to come from one model or pattern class. Typically, one does unsupervised learning on each set of samples by a hierarchical mixture of Gaussians, and then integrates individual hierarchical models in a supervised way to form a classifier.

Alternatively, we may put together all the individual hierarchical mixtures with each as a branch of one higher level root of a tree, and then do learning as shown in Fig. 12 of [29.3]. The **BYY** harmony learning algorithm (including the **EM** algorithm as its degenerated case) for learning a two-level hierarchical mixture of Gaussians is shown in Sect. 5.3 of [29.58], and especially Fig. 11 therein. This type of learning can be regarded as semi-supervised learning in the sense that each sample has two teaching labels. One is known, indicating which individual hierarchy  $x_t$  comes from, while the other is unknown to be determined, indicating which Gaussian component  $x_t$  comes from. Even generally, this type of learning provides a general formulation that involves the multi-label classification of Sect. 29.2.2 (especially labels with a hierarchy).

There are also real applications that consider a combination of ladder structures and hierarchical structures. For example, what is widely used in speech processing is an **HMM** model with each hidden state associated with a two-level hierarchical Gaussian mixture as illustrated in Fig. 11 of [29.58]. Also, extensions are made with each Gaussian mixture replaced by a mixture of local subspaces or **FA** or **NFA** models. For further details readers are referred to Sect. 5.3 and Fig. 14 of [29.3]. Another example is considering a two-level hierarchical model with both **HMM** for modeling nonstationary temporal dependence and **TFA** for modeling stationary temporal dependence. For further details readers are referred to Sect. 5.2.2 of [29.58].

## 29.4 Reinforcement Learning

Differently to unsupervised learning, reinforcement learning gets guidance from external evaluation. Also, unlike supervised learning in which the teacher clearly specifies the output that corresponds to an input, reinforcement learning is only provided with an evaluative value about the action made. Furthermore, reinforcement learning is featured by a dynamic process in discrete time steps. At each step, upon observing the current environment and getting some input (if any), the learner makes an action and moves to a new state, receiving an award or punish value about the action. The aim is to maximize the total award received.

This section provides a brief tutorial on the basic issues of reinforcement learning, especially **TD** learning and Q-learning. Then, improvements on Q-learning are proposed by replacing its built-in winner-take-all competition mechanism with some unsupervised learning

Another typical tree structure, as illustrated in Fig. 29.2b(D(4)), is a learning probabilistic tree, i.e., a joint distribution of a set of variables on a tree with one node per variable. The most well-known study is structuring such tree models for a given set of bi-valued variables, as done by *Pearl* in 1986 [29.79]. Following this, one study in 1987 [29.80] extends this to construct tree representations of continuous variables. It has been proved that the tree can be structured from the correlations observed between pairs of variables if the visible variables are governed by a tree decomposable joint normal distribution. Moreover, the conditions for tree decomposable normal distribution are less restrictive than those of bi-valued variables.

Nowadays, many advances have been made along this line. Some of the basic results, e.g., (29.15) and (29.17) in [29.80], has become a widely used technique in network construction for detecting whether an edge describes a direct link or a duplicated indirect link. For example, considering the association between two nodes  $i, j$  linked to a third node  $w$  with the correlation coefficients  $\rho_{iw}$  and  $\rho_{jw}$ , we can remove the link  $i, j$  if its correlation coefficient  $\rho_{ij}$  fails to satisfy, i. e.,

$$\rho_{ij} > \rho_{iw}\rho_{wj}. \quad (29.29)$$

Otherwise we may either choose to keep the link  $i, j$ , or let three nodes to be linked to a newly added node and then remove all the original links among the three nodes.

methods. For further reading readers are referred to tutorials and reviews in [29.6, 81, 82].

### 29.4.1 Markov Decision Processes

Reinforcement learning is closely related to Markov decision processes (**MDP**), which consist of a series of states  $s_0, s_1, \dots, s_t, s_{t+1}, \dots$ . At a state  $s_t$ , an action  $a_t = \pi(s_t)$  is selected from the set  $A$  of actions according to a policy  $\pi$ , which makes the environment move to a new state  $s_{t+1}$ , and the reward  $r_{t+1}$  associated with the transition  $(s_t, a_t, s_{t+1})$  is received. The goal is to collect as much reward as possible, that is, to maximize the total reward or return

$$R = \sum_{t=0}^{N-1} r_{t+1},$$

where  $N$  denotes the random time when a terminal state is reached. In the case of nonepisodic problems the return  $R = \sum_{t=0}^{\infty} \gamma^t r_{t+1}$  is considered by a discount factor  $0 \leq \gamma \leq 1$ .

Given an initial distribution based on which the initial state is sampled at random, we can assign the expected return  $E[R|\pi]$  to policy  $\pi$ . Since the actions are selected according to  $\pi$ , the task is to specify an algorithm that can be used to find a policy  $\pi$  to maximize  $E[R]$ . Suppose we know the state transition probability  $p_a(s'|s) = P(s_{t+1} = s'|s_t = s)$  and the corresponding reward  $r_{t+1} = R_a(s'|s)$ , the standard family of algorithms to calculate this optimal policy is featured by iterating the following two steps

$$(1) \quad \pi(s) = \arg \max_a V^a(s), \\ (2) \quad V^\pi(s) = \sum_{s'} p_{\pi(s)}(s'|s)[R_{\pi(s)}(s'|s) + \gamma V(s')], \quad (29.30)$$

with  $V^\pi(s)$  estimating  $E[R|s, \pi]$ . The iteration can be made in one of several variants as follows:

- Doing step (1) once and then repeating step (2) several times or until it converges. Then step (1) is done once again, and so on.
- Doing step (2) by solving a set of linear equations.
- Substituting the calculation of  $\pi(s)$  into the calculation of  $V^*(s) = \max_\pi V^\pi(s)$ , resulting in a combined step

$$V^*(s) = \max_a \left\{ \sum_{s'} p_a(s'|s)[R_a(s'|s) + \gamma V^*(s')] \right\}, \quad (29.31)$$

which is called backward induction and is iterated for all states until it converges to what is called the Bellman equation.

- Preferentially applying the steps to states that are in some way of importance.

Under some mild regularity conditions, all the implementations will reach a policy that achieves these optimal values of  $V^*(s) = \max_\pi V^\pi(s)$  and thus also maximizes the expected return  $E[V^\pi(s)]$ , where  $s$  is a state that is randomly sampled from the underlying distribution.

In the implementation of MDPs we need to know the probability  $p_a(s'|s)$  per action  $a$ . Reinforcement learning avoids obtaining this  $p_a(s'|s)$  with the help

of stochastic approximation. The two most popular examples are temporal difference (TD) learning and Q-learning, respectively. The name TD derives from its use of differences in predictions over successive time steps to drive learning, while the name Q comes from its use of a function that calculates the quality of a state-action combination.

## 29.4.2 TD Learning and Q-Learning

TD learning aims at predicting a measure of the total amount of reward expected over the future. At time  $t$ , we seek an estimate  $\hat{r}_t$  of  $R_t = \sum_{i=1}^{\infty} \gamma^{i-1} r_{t+i}$  with  $0 \leq \gamma < 1$ . Each estimate is a prediction because it involves future values of  $r$ . We can write  $\hat{r}_t = \Pi_t(s_t)$ , where  $\Pi$  is a prediction function. The prediction at any given time step is updated to bring it closer to the prediction of the same quantity at the next step, based on the error correction  $\delta_{t+1} = R_t - \Pi_t(s_t)$ . To obtain  $R_t$  exactly requires waiting for the arrival of all the future values of  $r$ . Instead, we use  $R_t = r_{t+1} + \gamma R_{t+1}$  with  $\Pi_t(s_{t+1})$  as an estimate of  $R_{t+1}$  available at step  $t$ , that is, we have

$$\delta_{t+1} = r_{t+1} + \gamma \Pi_t(s_{t+1}) - \Pi_t(s_t), \quad (29.32)$$

which is termed the temporal difference error (or TD error).

The simplest TD algorithm updates the prediction function  $\Pi_t$  at step  $t$  into a new prediction function  $\Pi_{t+1}$  as follows

$$\Pi_{t+1}(x) = \begin{cases} \Pi_t(x) + \eta \delta_{t+1} & \text{if } x = s_t \\ \Pi_t(x) & \text{otherwise,} \end{cases} \quad (29.33)$$

where  $\eta$  is a learning step size and  $x$  denotes any possible input signal. The simplest format is a prediction function implemented as a lookup table. Suppose that  $s_t$  takes only a finite number of values and that there is an entry in a lookup table to store a prediction for each of these values. At step  $t$ , the state  $s_t$  moves to the next  $s_{t+1}$  based on the current status of the table, e.g., the table entry for  $s_{t+1}$  is the largest across the table, or  $s_{t+1}$  is selected according to a fixed policy. When  $r_{t+1}$  is observed, only the table entry for  $s_t$  changes from its current value of  $\hat{r}_t = \Pi_t(s_t)$  to  $\Pi_t(s_t) + \eta \delta_{t+1}$ .

The algorithm uses a prediction of a later quantity  $\Pi_t(s_{t+1})$  to update a prediction of an earlier quantity  $\Pi_t(s_t)$ . As learning proceeds, later predictions tend to become accurate sooner than earlier ones, resulting in an overall error reduction. This depends on whether an

input sequence has sufficient regularity to make predicting possible. When  $s_t$  comes from the states of a Markov chain, on which the  $r$  values are given by a function of these states, a prediction function may exist that accurately gives the expected value of the quantity  $R$ , for each  $t$ .

Another view of the TD algorithm is that it operates to maintain the following consistency condition

$$\Pi(s_t) = r_{t+1} + \gamma \Pi(s_{t+1}), \quad (29.34)$$

which must be satisfied by correct predictions. By the theory of *Markov* decision processes, any function that satisfies  $R_t = r_{t+1} + \gamma R_{t+1}$  for all  $t$  must actually give the correct predictions. The TD error indicates how far the current prediction function deviates from this condition, and the algorithm acts to reduce this error towards this condition. Actually,  $\Pi_t(s_t) + \eta \delta_{t+1} = (1 - \eta) \Pi_t(s_t) + \eta [r_{t+1} + \gamma \Pi_t(s_{t+1})]$  is a type of stochastic approximation to the value function in (29.30), without directly requiring to know the probability  $p_a(s'|s)$ .

Alternatively, Q-learning calculates the quality of a state-action combination, i.e., estimating  $Q(s_t, a_t)$  of  $R_t$  conditionally on the action  $a_t$  at  $s_t$ . The implementation of Q-learning consists of

$$\begin{aligned} a_t &= \arg \max_{a \in A} Q_t(s_t, a), \\ Q_{t+1}(x, a) &= \begin{cases} Q_t(x, a) + \eta \delta_{t+1}(a) & \text{if } x = s_t, a = a_t \\ Q_t(x, a) & \text{otherwise,} \end{cases} \\ \delta_{t+1}(a) &= r(s_t, a) + \gamma \max_{\ell} Q_t(s_{t+1}, \ell) - Q_t(s_t, a). \end{aligned} \quad (29.35)$$

At  $s_t$ , an action  $a_t \in A$  is obtained in an easy computation, and then makes a move to a new state  $s_{t+1}$ . Receiving the reward  $r_{t+1} = r(s_t, a_t)$  associated with the transition  $(s_t, a_t, s_{t+1})$ , only the table entry for  $s_t$  and  $a_t$  is updated.

The format of  $\delta_{t+1}$  is similar to the one in (29.32) with the prediction  $\Pi_t(s_t)$  replaced by  $Q(s_t, a_t)$  and  $\Pi_t(s_{t+1})$  replaced by  $\max_a Q_t(s_{t+1}, a)$ . Alternatively, we may select  $a_{t+1}$  by a fixed policy and then obtain  $\delta_{t+1}$  with  $\max_a Q_t(s_{t+1}, a)$  replaced by  $Q_t(s_{t+1}, a_{t+1})$ , which leads to a variant of the Q-learning rule called state-action-reward-state-action (**SARSA**). Under some mild regularity conditions, similarly to TD learning, both Q-learning and SARSA converge to prediction functions that make optimal action choices.

Both TD learning and Q-learning have variants and extensions. In the following, we briefly summarize two typical streams:

- In (29.33) and (29.35), only the table entry for  $s_t$  is modified, though  $r_{t+1}$  provides useful information for learning earlier predictions as well. Under the name of eligibility traces, an exponentially decaying memory trace is provided on a number of previous input signals so that each new observation can update the parameters related to these signals.
- In addition to a lookup table, the prediction function can be replaced by a more advanced prediction function. It could be a linear or non-linear regression function  $F_t(\omega_\tau, \theta)$  with input signals  $\omega_\tau = \{x_\tau^{(1)}, \dots, x_\tau^{(m)}\}$ . Each  $x_\tau^{(j)}$  could be either a state or an action or even one additional feature around a state in one eligibility trace, where  $\tau$  can be different from  $t$ . Then, learning adjusts  $\theta$  to reduce the error  $\delta_{t+1}$  or  $\delta_{t+1}(a_t)$ .

### 29.4.3 Improving Q-Learning by Unsupervised Methods

Examining the Q-learning by (29.35), we observe that it shares some common features with the multi-model-based learning introduced in Sect. 29.3. For a set  $A$  of finite many actions, we use the index  $\ell = 1, \dots, k$  to denote each action. Obtaining  $a_t$  in (29.35) is equivalent to obtaining  $p_{\ell,t}$  in (29.9) with  $\varepsilon_{j,t} = -Q_t(s_t, j)$ , that is, a selection is made by winner-take-all (**WTA**) competition. Then, updating  $Q_t(s_t, a)$  in (29.35) can be rewritten as follows

$$\begin{aligned} Q_{t+1}(s_t, \ell) &= Q_t(s_t, \ell) + \eta p_{\ell,t} \delta_{t+1}(\ell), \\ Q_{t+1}(s, \ell) &= Q_t(s, \ell), \text{ for } s \neq s_t, \end{aligned} \quad (29.36)$$

which is similar to the general updating rule by (29.17), with  $p_{\ell,t}$  selecting which column of  $Q$  table to update. This motivates the following improvements on Q-learning, motivated by the multi-model-based learning methods in Sect. 29.3.2.

First, the WTA selection of the above  $p_{\ell,t}$  can be replaced by an estimation of the posteriori probabilities as follows

$$p_{\ell,t} = q(\ell|s_t), \quad q(\ell|s) = e^{Q_t(s, \ell)} / \sum_{j=1}^k e^{Q_t(s, j)}. \quad (29.37)$$

Putting this into (29.38), we improve the weak points incurred from a WTA competition by updating all the columns of the  $Q$  table with the weights by  $p_{\ell,t}$ , as

a counterpart of (29.12) of the well-known **EM** algorithm for learning a finite mixture.

Second,  $\delta_{t+1}(a)$  in (29.35) uses  $\max_a Q_t(s_{t+1}, a)$  as a prediction of the Q-value at  $s_{t+1}$ , also by a **WTA** competition that gives an optimistic choice. Alternatively, we can use the following more reliable one

$$\begin{aligned}\delta_{t+1}(s_t, a_t) &= r(s_t, a_t) + \gamma \Delta\pi_{\ell,t}(s_{t+1}), \\ \Delta\pi_{\ell,t}(s) &= \sum_j q(j|s)Q_t(s, j) - Q_t(s_t, a_t),\end{aligned}\quad (29.38)$$

where  $q(j|s_{t+1})$  is given by (29.37) with  $s = s_{t+1}$  instead of  $s = s_t$ , to obtain  $\Delta\pi_{\ell,t}(s_{t+1})$  with  $q(\ell|s)$ .

Third, instead of  $p_{\ell,t}$  given by (29.37), we may also use a counterpart of (29.16) to implement Q-learning with help of **BYY** harmony learning. That is, we consider

$$p_{\ell,t} = q(\ell|s_t)[1 + \Delta\pi_{\ell,t}(s_t)], \quad (29.39)$$

by which an action is encouraged when its value is higher than the average of all actions, while an action is discouraged when its value is below the average but still not too far away, and then is repelled when its value is far below this average.

Moreover, we may simplify the above  $p_{\ell,t}$  by focusing on a few of major actions, e.g., the winning action  $a_t = \arg \max_a Q_t(s_t, a)$  and its rival action similar to rival penalized competitive learning (**RPCL**) by  $p_{\ell,t}$ , given as follows

$$p_{\ell,t} = \begin{cases} 1, & \ell^* = \arg \max_j Q_t(s_t, j), \\ -\gamma, & \ell = \arg \max_{\ell \neq \ell^*} Q_t(s_t, j), \\ 0, & \text{otherwise,} \end{cases} \quad (29.40)$$

i.e., the winning action is encouraged while its rival is repelled.

**BYY** harmony learning and **RPCL** learning lead to discriminative Q-learning by which actions at each state become more discriminative and thus easier to be selected. As a result, confusing branches in a searching tree will be pruned away. Moreover, we may discard one extra action if we observe that its corresponding

$$\alpha_{\ell}^{\text{new}} = (1 - \eta)\alpha_{\ell}^{\text{new}} + \eta q(\ell|s_t), \quad (29.41)$$

is pushed to zero. Actually, this is the nature of automatic model selection, which controls the complexity of function  $Q(s, j)$ .

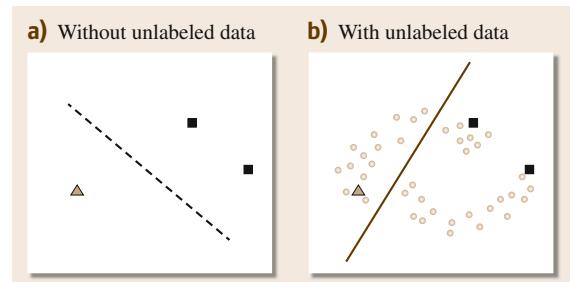

## 29.5 Semi-Supervised Learning

In many real tasks it is easy to obtain a large amount of unlabeled training data but labeling them is expensive because of the requirement of great human effort and expertise or high execution cost. Semi-supervised learning [29.83–86] attempts to exploit unlabeled data to help improve the learning performance without assuming human intervention. In situations where the unlabeled data are exactly the test data, it is also called *transductive learning* [29.87].

Figure 29.3 illustrates why unlabeled data (*gray points*) can be helpful. It can be seen that although both classification boundaries are consistent with labeled data, the boundary obtained by considering unlabeled data is better in generalization. One reason is that the unlabeled data can disclose some information about data distribution which is helpful for model construction.

There are two popular assumptions connecting the distribution information disclosed by unlabeled data with label information. The *cluster assumption* assumes

that data with similar inputs have similar class labels; the *manifold assumption* assumes that data live in a low-dimensional manifold, whereas unlabeled data can help to identify that manifold. The latter can be regarded as a generalization of the former because it is usually assumed that the cluster structure of the data will be more easily found in the lower-dimensional

**Fig. 29.3a,b** Illustration of the usefulness of unlabeled data

manifold. These assumptions are closely related to *low-density separation*, which specifies that the boundary should not go across high-density regions in the instance space.

Many semi-supervised learning methods have been developed. Roughly speaking, they can be categorized into four categories. In *generative methods*, both labeled and unlabeled data are assumed to be generated by the same model, and thus, the unlabeled data can be exploited to model the label estimation or parameter estimation process. For example, if we assume the data come from a mixture model with  $T$  components, i.e.,

$$f(x|\theta) = \sum_{t=1}^T \alpha_t f(x|\theta_t), \quad (29.42)$$

where  $\alpha_t$  is mixing coefficient and  $\theta = \{\theta_t\}$  are the model parameters, then label  $c_i$  can be determined by the mixture component  $m_i$  and the instance  $x_i$  according to the *maximum a posteriori* criterion

$$\arg \max_k \sum_j P(c_i = k|m_i = j, x_i) P(m_i = j|x_i), \quad (29.43)$$

where estimating  $P(c_i = k|m_i = j, x_i)$  requires label information, but unlabeled data can be used to help estimate  $P(m_i = j|x_i)$ , and hence improve the learning performance. Actually, the posterior probability is equivalently given by a *mixture of experts* that will be further addressed next in Sect. 29.6.1.

In *semi-supervised support vector machines (S3VM)*, unlabeled data are used directly to help adjust the decision boundary, as illustrated in Fig. 29.3. Given  $l$  labeled examples and  $u$  unlabeled instances, the goal is usually accomplished by minimizing an

objective

$$\frac{1}{2} \|w\|_{\mathcal{H}}^2 + C_1 \sum_{i=1}^l \ell[y_i, f(x_i)] + C_2 \sum_{j=1}^u \ell[\hat{y}_j, f(x_j)], \quad (29.44)$$

where the first term is structural risk, the second term is empirical risk on the labeled data  $(x_i, y_i)$ , the third term is empirical risk on the unlabeled instances  $x_j$  ( $j = 1, \dots, u$ ) and the estimated outputs  $\hat{y}_j$ , whereas  $C_1/C_2$  balance the contribution of labeled/unlabeled data.

*Graph-based methods* construct a graph whose nodes are the training instances (both labeled and unlabeled), and the edges between nodes reflect a certain relation, such as similarity, between the corresponding examples. Then, the learning process is accomplished by propagating label information on the graph.

*Disagreement-based methods* generate multiple learners and exploit the disagreements among the learners, where unlabeled data serve as a kind of platform for information exchange; if one learner is much more confident on a disagreed unlabeled instance than other learner(s), then it will *teach* other(s) by assigning a predicted *pseudo-label* to the instance. A representative of this category is *co-training* [29.31], which constructs two learners from two different views, and thus is closely related to multi-view learning.

In addition to classification, semi-supervised regression, dimension reduction, clustering, etc., have also been well studied. It is worth mentioning that exploiting unlabeled data does not always improve the performance, and sometimes the performance may be even worse than using only the labeled data. Some recent studies have tried to address this issue under the name of *safe* semi-supervised learning [29.88].

## 29.6 Ensemble Methods

### 29.6.1 Basic Concepts

Ordinary learning methods try to construct one learner from training data, whereas ensemble methods [29.14] try to construct a set of learners and combine them to solve the problem. Such kinds of learning methods are also called *committee-based learning*, *meta-learning*, or *multiple classifier systems*, although ensemble methods have also been found to be helpful in

clustering [29.14, 89, 90] and various tasks other than classification.

Figure 29.4 shows a common ensemble architecture. An ensemble contains a number of *base learners*, or *individual learners*, *component learners*, or *weak learners* because the main purpose of ensemble methods is to generate strong learners by combining learners whose generalization performances are not strong. Base learners can be generated by a *base learning*

*algorithm*, such as a decision tree algorithm, a neural network algorithm, etc., and such ensembles are called *homogeneous* ensembles because they contain homogeneous base learners. An ensemble can also be *heterogeneous* if multiple types of base learners are included.

The generalization ability of an ensemble is often much stronger than that of base learners. Roughly, there are three threads of studies that lead to the state-of-the-art of ensemble methods. The *combining classifiers* thread was mostly studied in the pattern recognition community, where researchers usually focused on the design of powerful combining rules to obtain a strong combined classifier [29.28, 29]. The *mixture of experts* thread generally considered a divide-and-conquer strategy, trying to learn a mixture of parametric models jointly [29.91]. Equation (29.43) is actually a mixture of experts for classification, with  $P(c_i = k | m_i = j, x_i)$  being the individual expert and  $P(m_i = j | x_i)$  the gating net, especially for the one given in [29.72] where the gating net is given by the posteriori of  $\alpha_f(x|\theta_i)$  in (29.42). The *ensembles of weak learners* thread often works on weak learners and tries to design powerful algorithms to boost performance from weak to strong. Readers are referred to [29.30] for a recent survey on *combining classifiers* and *mixture-of-experts* as well as their relations, and to Sect. 5 of [29.86] for a brief overview on all the three threads.

Generally, an ensemble is built in two steps; that is, generating the base learners and then combining them. It is worth noting that the computational cost of constructing an ensemble is often not much larger than creating a single learner. This is because when using a single learner, one usually has to generate multiple versions of the learner for model selection or parameter tuning; this is comparable to generating multiple base learners in ensembles, whereas the computational cost for combining base learners is often small because most combining rules are simple.

The term *boosting* refers to a family of algorithms originated in [29.92], with AdaBoost [29.93] as its rep-

representative. This kind of algorithm is usually provably able to convert weak learners that are just slightly better than random guess to strong learners that have nearly perfect performance.

Algorithm 29.1 shows the pseudo-code of AdaBoost. Roughly speaking, the basic idea of boosting is to let later learners try to correct the mistakes made by earlier learners, and this is accomplished by deriving in each round a new data distribution which makes the earlier mistakes more evident. The base learners should be able to learn with specific distributions; this is usually accomplished by re-weighting or re-sampling the training examples according to the data distribution in each round. Such a learning process is very similar to residual minimization, and it has a close relation to additive models, inspiring an interpretation that AdaBoost is a stagewise estimation procedure for fitting an additive logistic regression model with an exponential loss [29.94]. Notice that AdaBoost was designed for binary classification, but it has many variants for multi-class problems [29.93, 95, 96].

It has been proved [29.93] that the generalization error of AdaBoost is upper bounded by

$$\epsilon \leq \epsilon_D + \tilde{O} \left( \sqrt{\frac{dT}{m}} \right), \quad (29.45)$$

with probability at least  $1 - \delta$ , where  $\epsilon_D$  is the error on the training sample  $D$ ,  $d$  is the VC-dimension of base learners,  $m$  is the number of training samples, and  $\tilde{O}(\cdot)$  is used instead of  $O(\cdot)$  to hide logarithmic terms and constant factors. This generalization bound implies that the complexity  $d$  of base learners and the number  $T$  of learning rounds need to be constrained; otherwise AdaBoost will overfit. Empirical studies, however, show that AdaBoost often seems resistant to overfitting; that is, the test error often tends to decrease even after the training error reaches zero.

---

**Algorithm 29.1 The AdaBoost Algorithm**

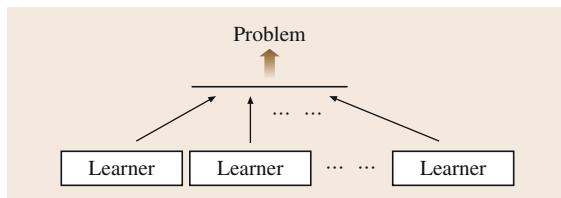

**Input:** data set  $D = \{(x_1, y_1), (x_2, y_2), \dots, (x_m, y_m)\}$ ;  
 Base learning algorithm  $\mathcal{L}$ ; number of learning rounds  $T$

### **Process•**

- ```

1:  $\mathcal{D}_1(x) = 1/m$ . % initialize the weight distribution
2: for  $t = 1, \dots, T$ :
3:    $h_t = \mathcal{L}(D, \mathcal{D}_t)$ ; % train a classifier  $h_t$  from  $D$ 
                                under distribution  $\mathcal{D}_t$ 
4:    $\epsilon_t = P_{x \sim \mathcal{D}_t}(h_t(x) \neq f(x))$ ; % evaluate the error
   of  $h_t$ 
5:   if  $\epsilon_t > 0.5$  then break

```

**Fig. 29.4** A common ensemble architecture

```

6:    $\alpha_t = \frac{1}{2} \ln \left( \frac{1-\epsilon_t}{\epsilon_t} \right);$  % determine the weight of  $h_t$ 
7:    $\mathcal{D}_{t+1}(x) = \frac{\mathcal{D}_t(x) \exp(-\alpha_t f(x) h_t(x))}{Z_t}$  % update
      the distribution, where  $Z_t$  is
      % a normalization factor which enables  $\mathcal{D}_{t+1}$ 
      to be a distribution
8: end
Output:  $H(x) = \text{sign} \left( \sum_{t=1}^T \alpha_t h_t(x) \right)$ 

```

## 29.6.2 Boosting

For binary classification, formally,  $f(x) \in \{-1, +1\}$ , the margin of the classifier  $h$  on the instance  $x$  is defined as  $f(x)h(x)$ , and similarly, the margin of the ensemble  $H(x) = \sum_{t=1}^T \alpha_t h_t(x)$  is  $f(x)H(x) = \sum_{t=1}^T \alpha_t f(x)h_t(x)$ , whereas the *normalized margin* is

$$f(x)H(x) = \frac{\sum_{t=1}^T \alpha_t f(x)h_t(x)}{\sum_{t=1}^T \alpha_t}, \quad (29.46)$$

where  $\alpha_t$  are the weights of base learners. Given any threshold  $\theta > 0$  of margin over the training sample  $D$ , it was proved in [29.97] that the generalization error of the ensemble is bounded with probability at least  $1 - \delta$  by

$$\begin{aligned} \epsilon &\leq 2^T \prod_{t=1}^T \sqrt{\epsilon_t^{1-\theta} (1-\epsilon_t)^{1+\theta}} \\ &+ \tilde{O} \left( \sqrt{\frac{d}{m\theta^2} + \ln \frac{1}{\delta}} \right), \end{aligned} \quad (29.47)$$

where  $\epsilon_t$  is the training error of the base learner  $h_t$ . This bound implies that when other variables are fixed, the larger the margin over the training set, the smaller the generalization error. Thus, [29.97] argued that AdaBoost tends to be resistant to overfitting because it can increase the ensemble margin even after the training error reaches zero.

This margin-based explanation seems reasonable; however, it was later questioned [29.98] by the fact that (29.47) depends heavily on the minimum margin, whereas there are counterexamples where an algorithm is able to produce uniformly larger minimum margins than AdaBoost, but the generalization performance drastically decreases. From then on, there was much debate about whether the margin-based explanation holds; more details can be found in [29.14].

One drawback of AdaBoost lies in the fact that it is very sensitive to noise. Great efforts have been devoted to address this issue [29.99, 100]. For example, RobustBoost [29.101] tries to improve the noise tolerance ability by boosting the normalized classification margin, which was believed to be closely related to the generalization error.

## 29.6.3 Bagging

In contrast to *sequential ensemble methods* such as boosting where the base learners are generated in a sequential style to exploit the *dependence* between the base learners, bagging [29.99] is a kind of *parallel ensemble method* where the base learners are generated in parallel, attempting to exploit the *independence* between the base learners.

The name bagging came from the abbreviation of *Bootstrap AGGRegatING*. Algorithm 29.2 shows its pseudo-code, where  $\mathbb{I}$  is the indicator function. Bagging applies *bootstrap sampling* [29.102] to obtain multiple different data subsets for training the base learners. Given  $m$  training examples, a set of  $m$  training examples is generated by sampling with replacement; some original examples appear more than once, whereas some do not present. By applying the process  $T$  times,  $T$  such sets are obtained, and then each set is used for training a base learner. Bagging can deal with binary as well as multi-class problems by using *majority voting* to combine base learners; it can also be applied to regression by using *averaging* for combination.

### Algorithm 29.2 The Bagging Algorithm

**Input:** Data set  $D = \{(x_1, y_1), (x_2, y_2), \dots, (x_m, y_m)\}$ ;  
Base learning algorithm  $\mathfrak{L}$ ;  
Number of base learners  $T$ .

#### Process:

- 1: **for**  $t = 1, \dots, T$ :
- 2:  $h_t = \mathfrak{L}(D, \mathcal{D}_{bs})$  %  $\mathcal{D}_{bs}$  is bootstrap distribution
- 3: **end**

**Output:**  $H(x) = \arg \max_{y \in Y} \sum_{t=1}^T \mathbb{I}(h_t(x) = y)$

Theoretical analysis [29.99, 103, 104] shows that Bagging is particularly effective with *unstable* base learners (whose performance will change significantly with even slight variation of the training sample), such as decision trees, because it has a tremendous variance reduction effect, whereas it is not wise to apply Bagging to stable learners, such as nearest neighbor classifiers.

A prominent extension of Bagging is the random forest method [29.105], which has been successfully deployed in many real tasks. Random forest incorporates a randomized feature selection process in constructing the individual decision trees. For each individual decision tree, at each step of split selection, it randomly selects a feature subset, and then executes conventional split selection within the feature subset. The recommended size of feature subsets is the logarithm of the number of all features [29.105].

#### 29.6.4 Stacking

Stacking [29.106–108] trains a *meta-learner* (or *second-level learner*), to combine the individual learners (or *first-level learners*). First-level learners are often generated by different learning algorithms, and therefore, stacked ensembles are often heterogeneous, although it is also possible to construct homogeneous stacked ensembles. Also, one similar approach was proposed in IJCNN1991 [29.109], with *meta-learner* referred to by a different name called *associative switch*, which is learned from examples for combining multiple classifiers.

Stacking can be viewed as a generalized framework of many ensemble methods, and can also be regarded as a specific combination method, i.e., *combining by learning*. It uses the original training examples to construct the first-level learners, and then generates a new data set to train the meta-learner, where the first-level learners' outputs are used as input features whereas the original labels are used as labels. Notice that there will be a high risk of overfitting if the exact data that are used to train the first-level learners are also used to generate the new data set for the meta-learner. Hence, it is recommended to exclude the training examples for the first-level learners from the data that are used for the meta-learner, and a cross-validation procedure is usually used.

It is crucial to consider the types of features for the new training data, and the types of learning algorithms for the meta-learner [29.106]. It has been suggested [29.110] to use class probabilities instead of crisp class labels as features for the new data, and to use multi-response linear regression (**MLR**) for the meta-learner. It has also been suggested [29.111] to use different sets of features for the linear regression problems in **MLR**.

If stacking (and many other ensemble methods) is simply viewed as assigning weights to combine different models, then it is closely related to *Bayes model*

*averaging* (**BMA**), which assigns weights to models based on posterior probabilities. In theory, if the correct data generation model is in consideration and if the noise level is low, **BMA** is never worse and often better than stacking. In practice, however, **BMA** rarely performs better than stacking, because the correct data generalization model is usually unknown, whereas **BMA** is quite sensitive to model approximation error [29.112].

#### 29.6.5 Diversity

If the base learners are independent, an amazing combination effect will occur. Taking binary classification, for example, suppose each base learner has an independent generalization error  $\epsilon$  and  $T$  learners are combined via majority voting. Then, the ensemble makes an error only when at least half of its base learners make errors. Thus, by *Hoeffding inequality*, the generalization error of the ensemble is

$$\sum_{k=0}^{\lfloor T/2 \rfloor} \binom{T}{k} (1-\epsilon)^k \epsilon^{T-k} \leq \exp\left(-\frac{1}{2} T (2\epsilon - 1)^2\right), \quad (29.48)$$

which implies that the generalization error decreases exponentially to the ensemble size  $T$ , and ultimately approaches zero as  $T$  approaches infinity.

It is practically impossible to obtain really independent base learners, but it is generally accepted that to construct a good ensemble, the base learners should be as accurate as possible, and as *diverse* as possible. This has also been confirmed by *error-ambiguity decomposition* and *bias-variance-covariance decomposition* [29.113–115]. Generating diverse base learners, however, is not easy, because these learners are generated from the same training data for the same learning problem, and thus they are usually highly correlated. Actually, we need to require that the base learners must not be very poor; otherwise their combination may even worsen the performance.

Usually, combining only accurate learners is often worse than combining some accurate ones together with some relatively weak ones, because the complementarity is more important than pure accuracy. Notice that it is possible to do some selection to construct a smaller but stronger ensemble after obtaining all base learners [29.116], possibly because this way makes it easier to trade off between individual performance and diversity.

Unfortunately, there is not yet a clear understanding about diversity although it is crucial for ensemble methods. Many efforts have been devoted to designing diversity measures, however, none of them is well-

accepted [29.14, 117]. In practice, heuristics are usually employed to generate diversity, and popular strategies include manipulating data samples, input features, learning parameters, and output representations [29.14].

## 29.7 Feature Selection and Extraction

Real-world data are often high-dimensional and contain many spurious features. For example, in face recognition, an image of size  $m \times n$  is often represented as a vector in  $R^{mn}$ , which can be very high-dimensional for typical values of  $m$  and  $n$ . Similarly, biological databases such as microarray data can have thousands or even tens of thousands of genes as features. Such a large number of features can easily lead to the curse of dimensionality and severe overfitting. A simple approach is to manually remove irrelevant features from the data. However, this may not be feasible in practice. Hence, automatic dimensionality reduction techniques, in the form of either feature selection or feature extraction, play a fundamental role in many machine learning problems.

Feature selection selects only a relevant subset of features for use with the model. In feature selection, the features may be scored either individually or as a subset. Not only can feature selection improve the generalization performance of the resultant classifier, the use of fewer features is also less computationally expensive and thus implies faster testing. Moreover, it can eliminate the need to collect a large number of irrelevant and redundant features, and thus reduces cost. The discovery of a small set of highly predictive variables also enhances our understanding of the underlying physical, biological, or natural processes, beyond just the building of accurate *black-box* predictors.

Feature selection and extraction has been a classic topic in the literature of pattern recognition for several decades; many results obtained before the 1980s are systematically summarized in [29.118]. Reviews on further studies in the recent three decades are referred to [29.119–121]. Roughly, feature selection methods can be classified into three main paradigms: filters, wrappers, and the embedded approach [29.120]. Filters score the usefulness of the feature subset obtained as a pre-processing step. Commonly used scores include mutual information and the inter/intra class distance. This filtering step is performed independently of the classifier and is typically least computationally expensive among the three paradigms. Wrappers, on the other

hand, score the feature subsets according to their prediction performance when used with the classifier. In other words, the classifier is trained on each of the candidate feature subsets, and the one with the best score is then selected. However, as the number of candidate feature subsets can be very large, this approach is computationally expensive, though it is also expected to perform better than filters. Both filters and wrappers rely on search strategies to guide the search for the *best* feature subset. While a large number of search strategies can be used, one is often limited to the computationally simple greedy strategies: (i) forward, in which features are added to the candidate set one by one; or (ii) backward, in which one starts with the full feature set and deletes features one by one. Finally, embedded methods combine feature selection with the classifier to create a sparse model. For example, one can use the  $\ell_1$  regularizer which shrinks the coefficients of the useless features to zero, essentially removing them from the model. Another popular algorithm is called recursive feature elimination [29.122] for use with support vector machines. It repeatedly constructs a model and then removes those features with low weights. Empirically, embedded methods are often more efficient than filters and wrappers [29.120].

While most feature selection methods are supervised, there are also recent works on feature selection in the unsupervised learning setting. However, unsupervised feature selection is much more difficult due to the lack of label information to guide the search for relevant features. Most unsupervised feature selection methods are based on the filter approach [29.123–125], though there are also some studies on wrappers [29.126] and embedded approaches [29.124, 127–129].

Recently, feature selection in multi-task learning has been receiving increasing attention. Recall that the  $\ell_1$  regularizer is commonly used to induce feature selection in single-task learning; this is extended to the mixed norms in **MTL**. Specifically, let  $W = [w_1, w_2, \dots, w_T]$ , where  $w_t \in R^d$  is the parameter associated with the  $t$ -th task. To enforce joint sparsity across the  $T$  tasks, the  $\ell_{\infty,1}$  norm of  $W$  is used as the regular-

izer, i.e.,  $\|W\|_{\infty,1} = \sum_{j=1}^d \max_{1 \leq i \leq T} |W_{ji}|$  [29.130]. In other words, one uses an  $\ell_\infty$  norm on the rows of the  $W$  to combine the contributions of each row (feature) from all the tasks, and then combine the features by using the  $\ell_1$  norm, which, because of its sparsity-encouraging property, leads to only a few nonzero rows of  $W$ .

Instead of only selecting a subset from the existing set of features, feature extraction aims at extracting a set of new features from the original features. This can be viewed as performing dimensionality reduction that maps the original features to a new lower-dimensional feature space, while ensuring that the overall structure of the data points remains intact. The unsupervised methods previously introduced in Sect. 29.3.1 can all be used for feature extraction. The classic ones consist of *principal component analysis* (**PCA**) and *principal subspace analysis* (**PSA**), and their complementary counterparts *minor component analysis* (**MCA**) and *minor subspace analysis* (**MSA**), as well as the closely related *factor analysis* (**FA**), while independent component analysis (**ICA**) and *non-Gaussian factor*

*analysis* (**NFA**) are further developments of **PCA** and **FA**, respectively. Another popular further development of **PCA** is kernel principal component analysis (**KPCA**) [29.131].

Moreover, feature extraction and unsupervised learning are coordinately conducted in many learning tasks, such as local factor analysis (**LFA**) in Sect. 29.3.2, nonnegative matrix factorization (**NMF**) and manifold learning in Sect. 29.3.3, temporal and hierarchical learning in Sect. 29.3.4, as well as other latent factor featured methods. Furthermore, the use of supervised information can lead to even better discriminative features for classification problems. Linear discriminant analysis (**LDA**) is the most classic example, which results in the Bayes optimal transform direction in the special case that the two classes are normally distributed with the same covariance. Learning multiple layer perceptron or neural networks can be regarded as nonlinear extensions of **LDA**, with hidden units extracting optimal features for supervised classification and regression.

# 30. Theoretical Methods in Machine Learning

Badong Chen, Weifeng Liu, José C. Principe

The problem of optimization in machine learning is well established but it entails several approximations. The theory of Hilbert spaces, which is principled and well established, helps solve the representation problem in machine learning by providing a rich (universal) class of functions where the optimization can be conducted. Working with functions is cumbersome, but for the class of reproducing kernel Hilbert spaces (**RKHSs**) it is still manageable provided the algorithm is restricted to inner products. The best example is the support vector machine (**SVM**), which is a batch mode algorithm that uses a very efficient (supralinear) optimization procedure. However, the problem of **SVMs** is that they display large memory and computational complexity. For the large-scale data limit, **SVMs** are restrictive because for fast operation the Gram matrix, which increases with the square of the number of samples, must fit in computer memory. The computation in this best-case scenario is also proportional to number of samples square. This is not specific to the **SVM** algorithm and is shared by kernel regression. There are also other relevant data processing scenarios such as streaming data (also called a time series) where the size of the data is unbounded and potentially nonstationary, therefore batch mode is not directly applicable and brings added difficulties.

Online learning in kernel space is more efficient in many practical large scale data applications. As the training data are sequentially presented to the learning system, online kernel learning, in general, requires much less memory and computational bandwidth. The drawback is that online algorithms only converge weakly (in mean square) to the optimal solution, i. e., they only have guaranteed convergence within a ball of radius  $\epsilon$  around the optimum ( $\epsilon$  is controlled by the user). But because the theoretical optimal ML solution has many approximations, this is one more approximation

that is worth exploring practically. The most important recent advance in this field is the development of the kernel adaptive filters (**KAFs**). The **KAF** algorithms are developed in reproducing kernel Hilbert space (**RKHS**), by using the linear structure of this space to implement well-established linear adaptive algorithms (e.g., **LMS**, **RLS**, **APA**, etc.) and to obtain nonlinear filters in the original input space. The main goal of this chapter is to bring closer to readers, from both machine learning and signal processing communities, these new online learning techniques. In this chapter, we focus mainly on the kernel least mean square (**KLMS**), kernel recursive least squares (**KRLSs**), and the kernel affine projection algorithms (**KAPAs**). The derivation of the algorithms and some key aspects, such as the mean-square convergence and the sparsification of the solutions, are discussed. Several illustration examples are also presented to demonstrate the learning performance.

## 30.1 Background Overview

The general goal of machine learning is to build a model from data with the goal of extracting useful structure contained in the data. More specifically, machine learning can be defined as a process by which the topology and the free parameters of a neural network (i.e., the learning machine) are adapted through a process of stimulation by the environment in which the network is embedded [30.1]. There is a wide variety of machine learning algorithms. Based on the desired response of the algorithm or the type of input available during training, machine learning algorithms can be divided into several categories: *supervised learning*, *unsupervised learning*, *semi-supervised learning*, *reinforcement learning*, and so on [30.2]. In this chapter, however, we focus mainly on supervised learning, and in particular, on the regression tasks. The goal of supervised learning is, in general, to infer a function that maps inputs to desired outputs or labels that should have the generalization property, that is, it should perform well on unseen data instances.

In supervised machine learning problems, we assume that the data pairs  $\{x_i, z_i\}$  collected from real-world experiments are stochastic and drawn independently from an unknown probability distribution  $P(X, Z)$  that represents the underlying phenomenon we wish to model. The optimization problem is normally formulated in terms of the expected risk  $R(f)$  defined as  $R(f) = \int L(f(x), z)dP(x, z)$ , where a loss function  $L(f(x), z)$  translates the goal of the analysis, and  $f$  belongs to a functional space. The optimization problem is to find the minimal expected risk  $R(f)$  among all possible functions, i.e.  $f^* = \min_f R(f)$ . Unfortunately, we cannot work with arbitrary functions in our model, so we restrict  $f$  to a mapper class  $F$ , and very likely  $f^* \notin F$ . For instance, if our mapper is linear, then the functional class is the linear set which is small, albeit important, and so we will approximate  $f^*$  by the closest linear function, committing sometimes a large error. But even if the mapper is a multilayer perceptron with fixed topology, the same problem exists although the error will likely be smaller. The best solution is therefore  $f_F^* = \min_{f \in F} R(f)$  and it represents the first source of implementation error experimenters face. But this is not the only problem. We also normally do not know  $P(X, Z)$  in advance (indeed in machine learning this is normally the goal of the analysis). Therefore, we resort to the law of large numbers and approximate the expected risk by  $\hat{R}_N(f) = 1/N \sum_i L(f(x_i), z_i)$  which we call the empirical risk. Therefore, our optimization

goal becomes  $f_N^* = \min_{f \in F} \hat{R}_N(f)$ , which is normally achieved by optimization algorithms. The difference between the optimal solution  $R(f^*)$  and the solution achieved  $R_N(f_N^*)$  with the finite number of samples and the chosen mapper can be written as

$$\begin{aligned} & \hat{R}_N(f_N^*) - R(f^*) \\ &= [R(f_F^*) - R(f^*)] + [\hat{R}_N(f_N^*) - R(f_F^*)], \end{aligned}$$

where the first term is the *approximation error* while the second term is the *estimation error*. The optimization itself is also subject to constraints as we can imagine. The major compromise is how to treat the two terms. Statisticians favor algorithms to decrease as fast as possible the second term (estimation error), while optimization experts concentrate on supra-linear algorithms to minimize the first term (approximation error). But in large-scale data problems, one major consideration is the optimization time under these optimal assumptions, which can become prohibitively large. This paper among others [30.3] defines a third error  $\rho$  called the *optimization error* to approximate the practical optimal solution  $R_N(f_N^*)$  by  $R_N(\tilde{f}_N)$ , provided one can find  $R_N(\tilde{f}_N)$  simply with algorithms that are  $O(N)$  in time and memory usage. Basically, the final solution of  $R_N(\tilde{f}_N)$  will exist in a neighborhood of the optimal solution of radius  $\rho$ .

Let us now explain how the powerful mathematical tool called the **RKHS** has been widely utilized in the areas of machine learning [30.4, 5]. It is well known that the probability of linearly *shattering* data tends to one with the increase in dimensionality of the data space. However, the main bottleneck of this technique was the large number of free parameters of the high-dimensional classifiers, which results in two difficult issues: expensive computation and the need to regularize the solutions. The **RKHS** (also kernel space or feature space) provides a nice way to simplify the computation. The dimension of an **RKHS** can be very high (even infinite), but by the *kernel trick* the calculation in **RKHS** can still be done efficiently in the original input space if the algorithms can be expressed in terms of the inner products. Vapnik proposed a robust regularizer in support vector machine (**SVM**), which promoted the application of **RKHS** in pattern recognition [30.4, 5].

Kernel-based learning algorithms have been successfully applied in batch settings (say **SVM**). The batch kernel learning algorithms, however, usually require significant memory and computational burden

due to the necessity of retaining all the training data and calculating a large Gram matrix. In many practical situations, the online kernel learning (**OKL**) is more efficient. Since the training data are sequentially (one by one) presented to the learning system, **OKL** in general requires much less memory and computational cost. Another key advantage of **OKL** algorithms is that they can easily deal with nonstationary (time varying) environments (i.e., where the data statistics change over time).

Traditional linear adaptive filtering algorithms like the least mean square (**LMS**) and recursive least squares (**RLS**s) are the most well known and simplest online learning algorithms, especially in signal processing community [30.6–8]. In recent years, many researchers devoted to use the **RKHS** to design the optimal nonlinear adaptive filters, namely, the kernel adaptive filters (**KAF**) [30.9]. The **KAF** algorithms are developed in **RKHS**, by using the linear structure (inner product) of this space to implement the well-established linear adaptive algorithms and to obtain (by *kernel trick*) nonlinear filters in the original input space. Up to now, there have been many **KAF** algorithms. Typical examples include the **KLMS** [30.10], kernel affine projection algorithms (**KAPA**) [30.11], kernel recursive least squares (**KRLS**) [30.12], and the extended kernel recursive least squares (**EX-KRLS**s) [30.13]. If the kernel is a Gaussian, these nonlinear filters build a radial basis function (**RBF**) network with a growing structure, where centers are placed at the projected samples and the weights are directly related to the errors at each sample.

The main bottleneck of **KAF** algorithms (and many other **OKL** algorithms) is their growing structure. This drawback will result in increasing memory and computational requirements, especially in continuous adaptation situation where the number of centers grows unbounded. In order to make the **KAF** algorithms practically useful, it is crucial to find a way to curb the network growth and to obtain a compact representation. Some *sparsification* rules can be applied to address this issue [30.9]. According to these sparsification rules,

the new input is accepted as a new center (i.e., inserted into the *center dictionary*) only if it is judged as an *important* input under a certain criterion. Popular sparsification criteria include the novelty criterion (**NC**) [30.14], coherence criterion (**CC**) [30.15], approximate linear dependency (**ALD**) criterion [30.12], surprise criterion (**SC**) [30.16], and so on. In addition, the *quantization* approach can also be used to sparsify the solution and produce a compact network with desirable accuracy [30.17].

Besides the **RKHS**, fundamental concepts and principles from information theory can also be applied in the areas of signal processing and machine learning. For example, information theoretic descriptors like entropy and divergence have been widely used as similarity metrics and optimization criteria in *information theoretic learning (ITL)* [30.18]. These descriptors are particularly useful for nonlinear and non-Gaussian situations since they capture the information content and higher order statistics of signals rather than simply their energy (i.e., second-order statistics like variance and correlation). Recent studies show that the **ITL** is closely related to **RKHS**. The quantity of *correntropy* in **ITL** is in essence a correlation measure in **RKHS** [30.19]. Many **ITL** costs can also be formulated in an **RKHS** induced by the Mercer kernel function defined as the *cross information potential (CIP)* [30.20]. The popular *quadratic information potential (QIP)* can be expressed as a squared norm in this **RKHS**. The estimators of information theoretic quantities can also be reinterpreted in **RKHS**. For example, the nonparametric kernel estimator of the **QIP** can be expressed as a squared norm of the mean vector of the data in kernel space [30.20].

The focus of the present chapter is mainly on a large family of online kernel learning algorithms, the kernel adaptive filters. Several basic learning algorithms are introduced. Some key aspects about these algorithms are discussed, and several illustration examples are presented. Although our focus is on the kernel adaptive filtering, the basic ideas will be applicable to many other online learning methods.

## 30.2 Reproducing Kernel Hilbert Spaces

A Hilbert space is a linear, complete, and normed space equipped with an inner product. A reproducing kernel Hilbert space is a special Hilbert space associated with a kernel  $\kappa$  such that it reproduces (via an in-

ner product) each function  $f$  in the space. Let  $\mathcal{X}$  be a set (usually a compact subset of  $\mathbb{R}^d$ ) and  $\kappa(x, y)$  be a real-valued bivariate function on  $\mathcal{X} \times \mathcal{X}$ . Then the function  $\kappa(x, y)$  is said to be *nonnegative definite* if for

any finite point set  $\{x_i \in \mathcal{X}\}_{i=1}^N$  and for any real number set  $\{\alpha_i \in \mathbb{R}\}_{i=1}^N$ ,

$$\sum_{i=1}^N \sum_{j=1}^N \alpha_i \alpha_j \kappa(x_i, x_j) \geq 0. \quad (30.1)$$

If the above inequality is strict for all nonzero vectors  $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_N]^T$ , the function  $\kappa(x, y)$  is said to be *strictly positive definite (SPD)*. The following theorem shows that any symmetric and nonnegative definite bivariate function  $\kappa(x, y)$  is a *reproducing kernel*.

### Theorem 30.1 (Moore-Aronszajn [30.21, 22])

Any symmetric, nonnegative definite function  $\kappa(x, y)$  defines implicitly a Hilbert space  $\mathcal{H}_k$  that consists of functions on  $\mathcal{X}$  such that:

- 1)  $\forall x \in \mathcal{X}, \kappa(., x) \in \mathcal{H}_k,$
- 2)  $\forall x \in \mathcal{X}, \forall f \in \mathcal{H}_k, f(x) = \langle f, \kappa(., x) \rangle_{\mathcal{H}_k},$   
where  $\langle ., . \rangle_{\mathcal{H}_k}$  denotes the inner product in  $\mathcal{H}_k$ .

Property (2) is the so-called *reproducing property*. In this case, we call  $\kappa(x, y)$  a *reproducing kernel*, and  $\mathcal{H}_k$  an **RKHS** defined by the reproducing kernel  $\kappa(x, y)$ . Usually, the space  $\mathcal{X}$  is also called the input space. Property 1) indicates that each point in the input space  $\mathcal{X}$  can be mapped onto a function in a potentially much higher dimensional **RKHS**  $\mathcal{H}_k$ . The nonlinear mapping from the input space to **RKHS** is defined as  $\Phi(x) = \kappa(., x)$ . In particular, we have

$$\begin{aligned} \langle \Phi(x), \Phi(y) \rangle_{\mathcal{H}_k} &= \langle \kappa(., x), \kappa(., y) \rangle_{\mathcal{H}_k} \\ &= \kappa(x, y). \end{aligned} \quad (30.2)$$

Thus the inner products in high-dimensional **RKHS** can be simply calculated via kernel evaluation. This is normally called the *kernel trick*. Note that the **RKHS** is defined by the selected kernel function, and the similarity between functions in the **RKHS** is also defined by the kernel since it defines the inner product of functions.

The next theorem guarantees the existence of a nonlinear mapping between the input space and a high-dimensional feature space (a vector space in which the training data are embedded).

### Theorem 30.2 (Mercer's [30.23])

Let  $\kappa \in L_\infty(\mathcal{X} \times \mathcal{X})$  be a symmetric bivariate kernel function. If  $\kappa$  is the kernel of a positive integral operator in  $L_2(\mathcal{X})$ , and  $\mathcal{X}$  is a compact subset of  $\mathbb{R}^d$ , then

$$\forall \psi \in L_2(\mathcal{X}): \int_{\mathcal{X}} \kappa(x, y) \psi(x) \psi(y) dx dy \geq 0. \quad (30.3)$$

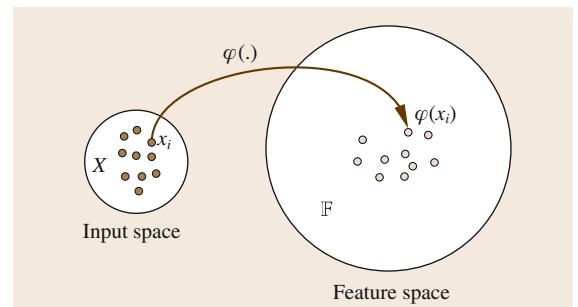

Let  $\varphi_i \in L_2(\mathcal{X})$  be the normalized orthogonal eigenfunctions of the integral operator, and  $\lambda_i$  the corresponding positive eigenvalues. Then

$$\kappa(x, y) = \sum_{i=1}^M \lambda_i \varphi_i(x) \varphi_i(y), \quad (30.4)$$

where  $M \leq \infty$ . Since the eigenvalues are positive, one can readily construct a nonlinear mapping  $\varphi$  from the input space  $\mathcal{X}$  to a feature space  $\mathbb{F}$

$$\begin{aligned} \varphi: \mathcal{X} &\rightarrow \mathbb{F}, \\ \varphi(x) &= \left[ \sqrt{\lambda_1} \varphi_1(x), \sqrt{\lambda_2} \varphi_2(x), \dots \right]^T. \end{aligned} \quad (30.5)$$

The dimension of  $\mathbb{F}$  is  $M$ , i.e., the number of the positive eigenvalues (which can be infinite in the strictly positive definite kernel case).

**Fig. 30.1** Nonlinear map  $\varphi(\cdot)$  between the input space and the feature space

**Table 30.1** Some well-known kernels defined over  $\mathcal{X} \times \mathcal{X}$ ,  $\mathcal{X} \subset \mathbb{R}^d (c > 0, \sigma > 0, p \in \mathbb{N})$

| Kernels                | Expressions                                     |
|------------------------|-------------------------------------------------|
| Polynomial             | $\kappa(x, y) = (c + x^T y)^p$                  |
| Exponential            | $\kappa(x, y) = \exp(x^T y / 2\sigma^2)$        |
| Sigmoid                | $\kappa(x, y) = \tanh(x^T y / \sigma + c)$      |
| Gaussian               | $\kappa(x, y) = \exp(-\ x - y\ ^2 / 2\sigma^2)$ |
| Laplacian              | $\kappa(x, y) = \exp(-\ x - y\  / 2\sigma^2)$   |
| Cosine                 | $\kappa(x, y) = \exp(\angle(x, y))$             |
| Multiquadratic         | $\kappa(x, y) = \sqrt{\ x - y\ ^2 + c}$         |
| Inverse multiquadratic | $\kappa(x, y) = 1 / \sqrt{\ x - y\ ^2 + c}$     |

The feature space  $\mathbb{F}$  is *isometric-isomorphic* to the RKHS  $\mathcal{H}_k$  induced by the kernel. This can be easily recognized by identifying  $\varphi(x) = \Phi(x) = \kappa(.,x)$ . In general, we do not distinguish these two spaces if no confusion arises.

Now the basic idea of kernel-based learning algorithms can be simply described as follows: Via a nonlinear mapping  $\varphi: \mathcal{X} \rightarrow \mathbb{F}$  (or  $\Phi: \mathcal{X} \rightarrow \mathcal{H}_k$ ), the data  $\{x_i \in \mathcal{X}\}_{i=1}^N$  are mapped into a high dimensional (usually  $M \gg d$ ) feature space  $\mathbb{F}$  with a linear structure (Fig. 30.1). Then a learning problem in  $\mathcal{X}$  is solved in  $\mathbb{F}$  instead, by working with  $\{\varphi(x_i) \in \mathbb{F}\}_{i=1}^N$ . As long as an algorithm can be formulated in terms of the inner products in  $\mathbb{F}$ , all the operations can be done in the input space (via kernel evalua-

tions). Because  $\mathbb{F}$  is high dimensional, a simple linear learning algorithm (preferably one expressed solely in terms of inner products) in  $\mathbb{F}$  can solve arbitrarily nonlinear problems in the input space, provided that  $\mathbb{F}$  is rich enough to represent the mapping (the feature space can be *universal* if it is infinite dimensional).

The kernel function  $\kappa$  is a crucial factor in all kernel methods because it defines the similarity between data points. Some well-known kernels are listed in Table 30.1. Among these kernels, the Gaussian kernel is most popular and is, in general, a default choice due to its universal approximating capability (Gaussian kernel is strictly positive definite), desirable smoothness and numerical stability.

## 30.3 Online Learning with Kernel Adaptive Filters

In this section, we discuss several important online kernel learning algorithms, i.e., the kernel adaptive filtering algorithms. Suppose our goal is to learn a continuous input-output mapping  $f: \mathbb{U} \rightarrow \mathbb{D}$  based on a sequence of input-output examples (the so called training data)  $\{\mathbf{u}(i), d(i)\}, i = 1, 2, \dots$ , where  $\mathbb{U} \subset \mathbb{R}^m$  is the input domain,  $\mathbb{D} \subset \mathbb{R}$  is the desired output space. This supervised learning problem can be solved online (sequentially) using an adaptive filter. Figure 30.2 shows a general scheme of an adaptive filter. Usually, an adaptive filter consists of three elements:

- 1) The input-output training data.
- 2) The structure (or topology) of the filter, with a set of unknown parameters (or weights)  $w$ .
- 3) An optimization criterion  $J$  (or cost function).

An adaptive filtering algorithm will adjust the filter parameters so as to minimize the disparity (measured by

the cost function) between the filtering and desired outputs. The filter topology can be a simple linear structure (e.g., the FIR filter) or any nonlinear network structure (e.g., MLPs, RBF, etc.). The cost function is, in general, the mean square error (MSE) or the least-squares (LSS) cost. The adaptive filtering algorithm is usually a gradient-based algorithm.

The great appeal of developing adaptive filters in RKHS is to utilize the linear structure of this space to implement well-established linear adaptive filtering algorithms and to achieve nonlinear filters in the input space. Compared with other nonlinear adaptive filters, the KAFs have several desirable features:

- 1) If choosing a universal kernel (e.g., Gaussian kernel), they are universal approximators.
- 2) Under MSE criterion, the performance surface is still quadratic so gradient descent learning does not suffer from local minima.
- 3) If pruning the redundant features, they have moderate complexity in terms of computation and memory.

Table 30.2 gives the comparison of different adaptive filters [30.9].

### 30.3.1 Kernel Least Mean Square (KLMS) Algorithm

Among the family of the KAF, the KLMS is the simplest, which is derived by directly mapping the linear

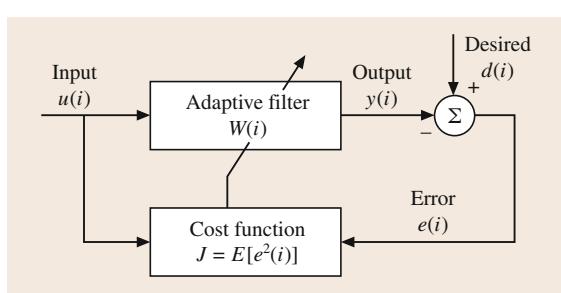

Fig. 30.2 General configuration of an adaptive filter

**Table 30.2** Comparison of different adaptive filters

| Adaptive filters            | Modeling capacity    | Convexity | Complexity  |
|-----------------------------|----------------------|-----------|-------------|
| Linear adaptive filters     | Linear only          | Yes       | Very simple |
| Hammerstein, Weiner models  | Limited nonlinearity | No        | Simple      |
| Volterra, Wiener series     | Universal            | Yes       | Very high   |
| Time-lagged neural networks | Universal            | No        | Modest      |
| Recurrent neural networks   | Universal            | No        | High        |
| Kernel adaptive filters     | Universal            | Yes       | Modest      |
| Recursive Bayesian filters  | Universal            | No        | Very high   |

least mean square (**LMS**) algorithm into **RKHS** [30.10]. Before proceeding, we simply discuss the well-known **LMS** algorithm.

### LMS Algorithm

Usually, the **LMS** algorithm assumes a linear finite impulse response (**FIR**) filter (or transversal filter), whose output, at  $i$  iteration, is simply a linear combination of the input

$$y(i) = \mathbf{w}(i-1)^T \mathbf{u}(i), \quad (30.6)$$

where  $\mathbf{w}(i-1)$  denotes the estimated weight vector at  $(i-1)$  iteration. With the above linear model, the **LMS** algorithm can be given as follows

$$\begin{cases} \mathbf{w}(0) = \mathbf{0}, \\ e(i) = d(i) - \mathbf{w}(i-1)^T \mathbf{u}(i), \\ \mathbf{w}(i) = \mathbf{w}(i-1) + \eta e(i) \mathbf{u}(i), \end{cases} \quad (30.7)$$

where  $e(i) = d(i) - y(i)$  is the prediction error, and  $\eta > 0$  is the step size. The **LMS** algorithm is in essence a stochastic gradient-based algorithm under the instantaneous **MSE** cost  $J(i) = e^2(i)/2$ . In fact, the weight update equation of the **LMS** can be simply derived as

$$\begin{aligned} \mathbf{w}(i) &= \mathbf{w}(i-1) - \eta \frac{\partial}{\partial \mathbf{w}(i-1)} \left( \frac{1}{2} e^2(i) \right) \\ &= \mathbf{w}(i-1) - \eta e(i) \frac{\partial}{\partial \mathbf{w}(i-1)} (d(i) \\ &\quad - \mathbf{w}(i-1)^T \mathbf{u}(i)) \\ &= \mathbf{w}(i-1) + \eta e(i) \mathbf{u}(i). \end{aligned} \quad (30.8)$$

The **LMS** algorithm has been widely applied in adaptive signal processing due to its simplicity and efficiency [30.6–8]. The robustness of the **LMS** has been proven in [30.24], and it has been shown that a single realization of the **LMS** is optimal in the  $H_\infty$  sense. The step size  $\eta$  is a crucial parameter and has significant influence on the learning performance. It controls

the compromise between convergence speed and misadjustment. In practice, the selection of step size should guarantee the stability and convergence rate of the algorithm.

The **LMS** algorithm is sensitive to the input power. In order to guarantee the stability and improve the performance, one often uses the normalized **LMS** (**NLMS**) algorithm, which is a variant of the **LMS** algorithm, where the step-size parameter is normalized by the input power, that is

$$\mathbf{w}(i) = \mathbf{w}(i-1) + \frac{\eta}{\|\mathbf{u}(i)\|^2} e(i) \mathbf{u}(i). \quad (30.9)$$

### KLMS Algorithm

The **LMS** algorithm assumes a linear **FIR** filter, and hence the performance will become very poor if the unknown mapping is highly nonlinear. To overcome this limitation, we are motivated to formulate a *similar* algorithm in a high-dimensional feature space (or equivalent **RKHS**), which is capable of learning arbitrary nonlinear mapping. This is the motivation of the development of the kernel adaptive filtering algorithms.

Let us come back to the previous nonlinear learning problem, i.e., learning a continuous arbitrary input-output mapping  $f$  based on a sequence of input-output examples  $\{\mathbf{u}(i), d(i)\}$ ,  $i = 1, 2, \dots$ . Online learning finds sequentially an estimate of  $f$  such that  $f_i$  (the estimate at iteration  $i$ ) is updated based on the last estimate  $f_{i-1}$  and the current example  $\{\mathbf{u}(i), d(i)\}$ . This recursive process can be done in the feature space. First, we transform the input  $\mathbf{u}(i)$  into a high-dimensional feature space  $\mathbb{F}$  by a kernel-induced nonlinear mapping  $\varphi(\cdot)$ . Second, we assume a linear model in the feature space, which is in the form similar to the linear model in (30.6)

$$y(i) = \mathbf{Q}(i-1)^T \varphi(i), \quad (30.10)$$

where  $\varphi(i) = \varphi(\mathbf{u}(i))$  is the mapped *feature vector* from the input space to the feature space,  $\mathbf{Q}(i-1)$  denotes a high-dimensional weight vector in feature space.

Third, we develop a *linear* adaptive filtering algorithm based on the model (30.10) and the transformed training data  $\{\varphi(i), d(i)\}$ ,  $i = 1, 2, \dots$ . If we can formulate this *linear* adaptive algorithm in terms of the inner products, we will obtain a nonlinear adaptive algorithm in input space, namely the kernel adaptive filtering algorithm.

Performing the LMS algorithm on the model (30.10) with new example sequence  $\{\varphi(i), d(i)\}$  yields the KLMS algorithm [30.10]

$$\begin{cases} \Omega(0) = \mathbf{0}, \\ e(i) = d(i) - \Omega(i-1)^T \varphi(i), \\ \Omega(i) = \Omega(i-1) + \eta e(i) \varphi(i). \end{cases} \quad (30.11)$$

The KLMS is very similar to the LMS algorithm, except for the dimensionality (or richness) of the projection space. By identifying  $\varphi(u) = \kappa(u, .)$ , one can easily obtain the learning rule in the input space

$$\begin{cases} f_0 = 0, \\ e(i) = d(i) - f_{i-1}(u(i)), \\ f_i = f_{i-1} + \eta e(i) \kappa(u(i), .). \end{cases} \quad (30.12)$$

The KLMS can be viewed as the solution of the following regularized least squares problem

$$\min_{f_i \in \mathcal{H}_k} (y(i) - f_i(u(i)))^2 + \frac{1-\eta}{\eta} \|f_i - f_{i-1}\|_{\mathcal{H}_k}^2. \quad (30.13)$$

The above formula can be rewritten as

$$\min_{\Delta f_i \in \mathcal{H}_k} (e(i) - \Delta f_i(u(i)))^2 + \frac{1-\eta}{\eta} \|\Delta f_i\|_{\mathcal{H}_k}^2, \quad (30.14)$$

where  $\Delta f_i = f_i - f_{i-1}$ . From (30.14), we observe:

- 1) The learning of KLMS at iteration  $i$  is equivalent to solving a regularized least squares problem, in which the previous estimate  $f_{i-1}$  is frozen, and only the adjustment term  $\Delta f_i$  is solved.
- 2) In this least squares problem, there is only one training example involved. i.e.,  $\{u(i), e(i)\}$ .
- 3) The regularization factor is directly related to the step size via  $\gamma = (1-\eta)/\eta$ .

It has been proven in [30.10] that the KLMS has *self-regularization* property, i.e., the step size plays a similar role as the regularization parameter.

Given an input  $u$ , the output of the KLMS filter, at iteration  $i$ , will be

$$f_i(u) = \eta \sum_{j=1}^i e(j) \kappa(u(j), u). \quad (30.15)$$

If the kernel is a radial kernel (e.g., Gaussian kernel), the KLMS creates a growing RBF network by allocating a new kernel unit for every new example with input  $u(i)$  as the center and  $\eta e(i)$  as the coefficient. The network topology of the KLMS filter is shown in Fig. 30.3. The procedure of KLMS is summarized in Algorithm 30.1.

It is also straightforward to derive the normalized KLMS algorithm. The weight update equation of normalized KLMS will be

$$\begin{aligned} \Omega(i) &= \Omega(i-1) + \frac{\eta}{\|\varphi(i)\|^2} e(i) \varphi(i) \\ &= \Omega(i-1) + \frac{\eta}{\kappa(u(i), u(i))} e(i) \varphi(i). \end{aligned} \quad (30.16)$$

If the kernel function is the Gaussian kernel (Table 30.1), we have  $\kappa(u(i), u(i)) \equiv 1$ . In this case, the KLMS is automatically normalized.

#### Algorithm 30.1 Kernel Least Mean Square Algorithm

*Initialization:*

Choose kernel  $\kappa$  and step size  $\eta$

$a_1 = \eta d(1)$ ,  $C(1) = \{u(1)\}$ ,  $f_1 = a_1 \kappa(u(1), .)$

*Computation:*

**while**  $\{u(i), d(i)\}$  ( $i > 1$ ) available **do**

- 1) Compute the filter output:  $f_{i-1}(u(i)) = \sum_{j=1}^{i-1} a_j \kappa(u(i), u(j))$
- 2) Compute the error:  $e(i) = d(i) - f_{i-1}(u(i))$
- 3) Store the new center:  $C(i) = \{C(i-1), u(i)\}$

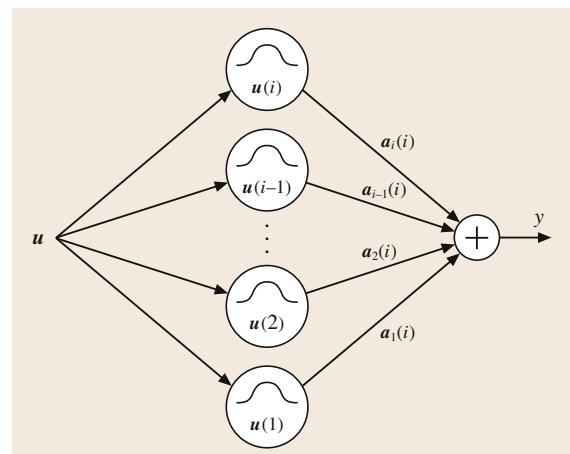

Fig. 30.3 The network topology of the KLMS filter

4) Compute and store the new coefficient:  $\mathbf{a}_i = \eta e(i)$

**end while**

(where  $\mathbf{a}$  denotes the coefficient vector and  $C(i)$  denotes the dictionary at  $i$  iteration)

The **KLMS** is a simple kernel learning algorithm, which requires  $O(i)$  operations per iteration. The role of the step size  $\eta$  in **KLMS** remains, in principle, the same as the step size in traditional **LMS**. Specifically, it controls the compromise between convergence speed and misadjustment. The step-size parameter in **KLMS** is also directly related to the *optimization error* introduced in [30.3].

In **KLMS**, the kernel is usually chosen to be a Gaussian kernel. The kernel size (or kernel bandwidth)  $\sigma$  in the Gaussian kernel is a crucial parameter that controls the degree of smoothing and consequently has significant influence on the learning performance. In practice, the kernel size can be set manually, or estimated by rule-based methods (e.g., Silverman's rule [30.25]), or determined automatically using cross-validation.

### Mean Square Convergence Performance

The mean square convergence analysis is very important for adaptive filters. For linear adaptive filters, much research has been done in this area and significant results have been achieved. For nonlinear adaptive filters, the mean square convergence analysis is, in general, rather complicated and little studied. The mean square convergence analysis of the **KLMS** is, however, relatively tractable since it is a simple linear algorithm in high-dimensional feature space, and hence its convergence analysis is much similar to those of the classical linear adaptive filters [30.26]. In the following, we discuss the mean square convergence performance of the **KLMS**.

Let us consider the case of nonlinear system identification where the output data  $\{d(i)\}$  are related to the input vectors  $\{\mathbf{u}(i)\}$  via

$$d(i) = f^*(\mathbf{u}(i)) + v(i), \quad (30.17)$$

where  $f^*(\cdot)$  denotes the unknown nonlinear mapping that needs to be estimated,  $v(i)$  stands for the measurement noise. Suppose the selected kernel is a *universal* kernel (i.e., strictly positive definite kernel). Then, according to the *universal approximation* prop-

erty [30.27], there is a weight vector  $\mathbf{Q}^* \in \mathbb{F}$  such that

$$d(i) = \mathbf{Q}^{*T} \varphi(i) + v(i). \quad (30.18)$$

The prediction error  $e(i)$  can thus be expressed as

$$e(i) = \tilde{\mathbf{Q}}(i-1)^T \varphi(i) + v(i) = e_a(i) + v(i), \quad (30.19)$$

where  $\tilde{\mathbf{Q}}(i-1) = \mathbf{Q}^* - \mathbf{Q}(i-1)$  is the *weight error vector* in  $\mathbb{F}$ ,  $e_a(i) \triangleq \tilde{\mathbf{Q}}(i-1)^T \varphi(i)$  is the a priori error at iteration  $i$ .

Subtracting  $\mathbf{Q}^*$  from both sides of the weight update equation  $\mathbf{Q}(i) = \mathbf{Q}(i-1) + \eta e(i) \varphi(i)$ , we get

$$\tilde{\mathbf{Q}}(i) = \tilde{\mathbf{Q}}(i-1) - \eta e(i) \varphi(i). \quad (30.20)$$

Define the a posteriori error  $e_p(i) \triangleq \tilde{\mathbf{Q}}(i)^T \varphi(i)$ . Then we have

$$e_p(i) = e_a(i) + (\tilde{\mathbf{Q}}(i)^T - \tilde{\mathbf{Q}}(i-1)^T) \varphi(i). \quad (30.21)$$

By incorporating (30.20),

$$\begin{aligned} e_p(i) &= e_a(i) - \eta e(i) \varphi(i)^T \varphi(i) \\ &= e_a(i) - \eta e(i) \kappa(\mathbf{u}(i), \mathbf{u}(i)). \end{aligned} \quad (30.22)$$

Combining (30.20) and (30.22), and eliminating the prediction error  $e(i)$ , yields

$$\tilde{\mathbf{Q}}(i) = \tilde{\mathbf{Q}}(i-1) + \frac{(e_p(i) - e_a(i)) \varphi(i)}{\kappa(\mathbf{u}(i), \mathbf{u}(i))}. \quad (30.23)$$

Squaring both sides of (30.23), and after some straightforward manipulations, we obtain

$$\begin{aligned} \|\tilde{\mathbf{Q}}(i)\|^2 + \frac{e_a^2(i)}{\kappa(\mathbf{u}(i), \mathbf{u}(i))} \\ = \|\tilde{\mathbf{Q}}(i-1)\|^2 + \frac{e_p^2(i)}{\kappa(\mathbf{u}(i), \mathbf{u}(i))}, \end{aligned} \quad (30.24)$$

where  $\|\tilde{\mathbf{Q}}(i)\|^2 = \tilde{\mathbf{Q}}(i)^T \tilde{\mathbf{Q}}(i)$  is the *weight error power (WEP)* in feature space  $\mathbb{F}$ . Further, taking expectations of both sides of (30.24) yields

$$\begin{aligned} E[\|\tilde{\mathbf{Q}}(i)\|^2] + E\left[\frac{e_a^2(i)}{\kappa(\mathbf{u}(i), \mathbf{u}(i))}\right] \\ = E[\|\tilde{\mathbf{Q}}(i-1)\|^2] + E\left[\frac{e_p^2(i)}{\kappa(\mathbf{u}(i), \mathbf{u}(i))}\right]. \end{aligned} \quad (30.25)$$

The above equation is referred to as the *energy conservation relation* in feature space [30.26], which shows how the **WEP** in feature space evolves in time. The expression of this fundamental relation is in the form similar to those of the energy conservation relation for classical linear adaptive filters [30.28–30]. In fact, this is not surprising, since the **KLMS** is a linear (but high-dimensional) adaptive algorithm in feature space.

Substituting  $e_p(i) = e_a(i) - \eta e(i)\kappa(\mathbf{u}(i), \mathbf{u}(i))$  into the energy conservation relation (30.25) yields

$$\begin{aligned} E[\|\tilde{\Omega}(i)\|^2] &= E[\|\tilde{\Omega}(i-1)\|^2] - 2\eta E[e_a(i)e(i)] \\ &\quad + \eta^2 E[e(i)^2 \kappa(\mathbf{u}(i), \mathbf{u}(i))]. \end{aligned} \quad (30.26)$$

When choosing Gaussian kernel, we have  $\kappa(\mathbf{u}(i), \mathbf{u}(i)) \equiv 1$ , and hence

$$\begin{aligned} E[\|\tilde{\Omega}(i)\|^2] &= E[\|\tilde{\Omega}(i-1)\|^2] \\ &\quad - 2\eta E[e_a(i)e(i)] + \eta^2 E[e^2(i)]. \end{aligned} \quad (30.27)$$

Gaussian kernel is a normalized and *shift-invariant* kernel, which makes the analysis much simpler. Since Gaussian kernel is also a default kernel in **KLMS**, in the following, we will focus on Gaussian kernel and use (30.27) to analyze the mean square convergence behavior of the **KLMS**. It is straightforward to generalize the discussion to arbitrary shift-invariant kernels. In the following, we give an assumption that will be used in the analysis.

#### **Assumption 30.1 A1**

The noise  $v(i)$  is zero-mean, independent, identically distributed (**i.i.d.**), and independent of the a priori estimation error  $e_a(i)$ .

The above assumption is commonly used in convergence analysis for classical linear adaptive filtering algorithms [30.8]. A sufficient condition for the independence between  $v(i)$  and  $e_a(i)$  is the independence between  $v(i)$  and the input sequence  $\{\mathbf{u}(i)\}$ .

Combining (30.27) and assumption A1, we have

$$\begin{aligned} E[\|\tilde{\Omega}(i)\|^2] &= E[\|\tilde{\Omega}(i-1)\|^2] - 2\eta E[e_a^2(i)] \\ &\quad + \eta^2 (E[e_a^2(i)] + \xi_v^2), \end{aligned} \quad (30.28)$$

where  $\xi_v^2$  denotes the noise power (variance). It is worth noting that Eq. (30.28) depends on the noise  $v(i)$  through  $\xi_v^2$  only.

**A Sufficient Condition for Mean Square Convergence.** From (30.28), one can easily derive

$$\begin{aligned} E[\|\tilde{\Omega}(i)\|^2] &\leq E[\|\tilde{\Omega}(i-1)\|^2] \\ &\Leftrightarrow -2\eta E[e_a^2(i)] + \eta^2 (E[e_a^2(i)] + \xi_v^2) \leq 0 \\ &\Leftrightarrow \eta \leq \frac{2E[e_a^2(i)]}{E[e_a^2(i)] + \xi_v^2}. \end{aligned} \quad (30.29)$$

Thus, if we choose the step size such that  $\forall i, \eta \leq 2E[e_a^2(i)]/(E[e_a^2(i)] + \xi_v^2)$ , the **WEP** in feature space will be monotonically decreasing (and hence convergent). This sufficient condition for the mean square convergence is, interestingly, identical to that of the normalized **LMS** algorithm. The essential reason for this is that the Gaussian kernel is a shift-invariant and normalized kernel ( $\kappa(\mathbf{u}, \mathbf{u}) \equiv 1$ ). From (30.29), one can also observe that, when the noise power  $\xi_v^2$  is very small, the upper bound on step size will be approximately equal to 2.0.

**Steady-State Mean Square Performance.** Take the limit of Eq. (30.28) as  $i \rightarrow \infty$ ,

$$\begin{aligned} \lim_{i \rightarrow \infty} E[\|\tilde{\Omega}(i)\|^2] &= \lim_{i \rightarrow \infty} E[\|\tilde{\Omega}(i-1)\|^2] \\ &\quad - 2\eta \lim_{i \rightarrow \infty} E[e_a^2(i)] \\ &\quad + \eta^2 \left( \lim_{i \rightarrow \infty} E[e_a^2(i)] + \xi_v^2 \right). \end{aligned} \quad (30.30)$$

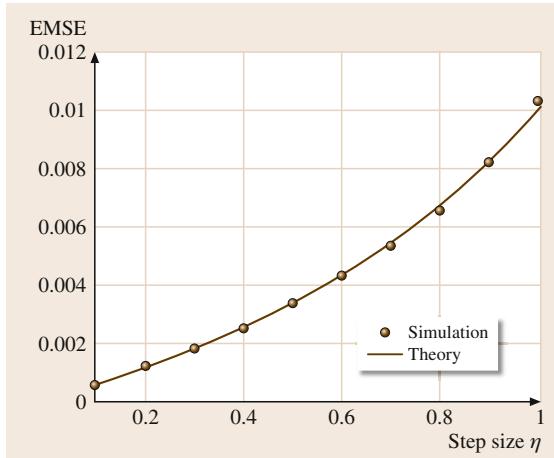

If the **WEP** in feature space reaches a steady-state value, i.e.,  $\lim_{i \rightarrow \infty} E[\|\tilde{\Omega}(i)\|^2] = \lim_{i \rightarrow \infty} E[\|\tilde{\Omega}(i-1)\|^2]$ , we have

$$-2\eta \lim_{i \rightarrow \infty} E[e_a^2(i)] + \eta^2 \left( \lim_{i \rightarrow \infty} E[e_a^2(i)] + \xi_v^2 \right) = 0. \quad (30.31)$$

It follows that

$$\lim_{i \rightarrow \infty} E[e_a^2(i)] = \frac{\eta \xi_v^2}{2 - \eta}. \quad (30.32)$$

The a priori error power  $E[e_a^2(i)]$  is also referred to as the *excess mean square error* (**EMSE**) in the adaptive filtering community. From (30.32), we see that the steady-state **EMSE** of **KLMS** depends only on the step

**Fig. 30.4** Simulated and theoretical EMSE versus step size

size and noise variance, and is NOT related to the kernel size and the unknown nonlinear mapping. We should point out here that, although the kernel size does not affect the KLMS steady-state accuracy, it has crucial influence on the convergence rate. In most practical situations, the training data are finite and the algorithm can never reach the steady state. In these cases, the kernel size also has significant influence on the final accuracy (not the steady-state accuracy).

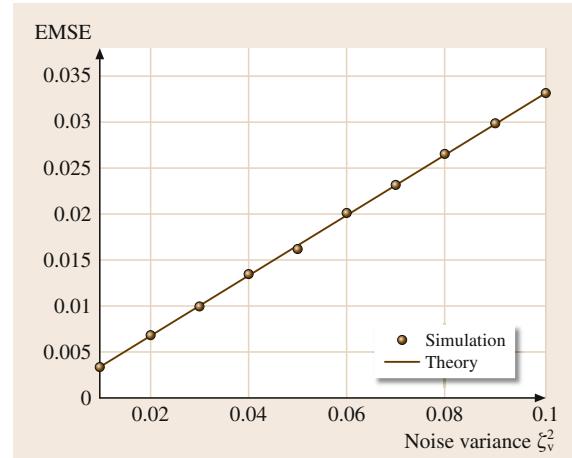

We present here a simple simulation example to verify the obtained theoretical results. Suppose that the training data are generated by the following nonlinear system [30.26]

$$d(i) = \sin(u(i)) + 0.5u(i-1) - 0.1u^2(i-2) + v(i). \quad (30.33)$$

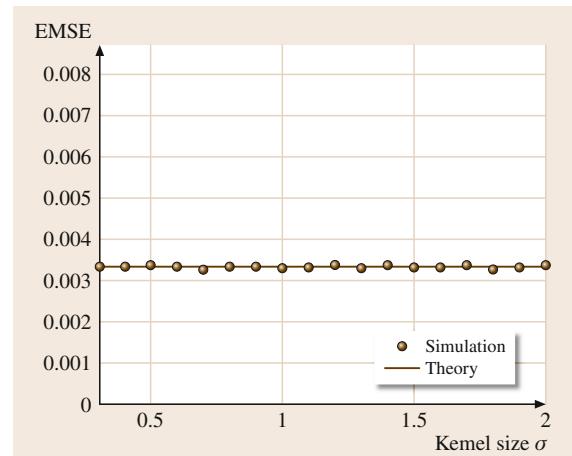

The input sequence  $\{u(i)\}$  is assumed to be a white Gaussian process with variance 1.0, and  $\{v(i)\}$  is a zero-mean white noise that is independent of  $\{u(i)\}$ . In the simulation, except mentioned otherwise, the step size is set at  $\eta = 0.5$ , the noise variance is  $\xi_v^2 = 0.01$ , and the kernel size is  $\sigma = 1.0$ . For different values of the step size, noise variance, and kernel size, the simulated and theoretical EMSE are illustrated in Figs. 30.4–30.6. Evidently, the experimental and theoretical results agree very well.

#### Network Size Control

The KLMS filter network grows rapidly with each new sample following a nonparametric approach. Due to finite resources one must cut the growing structure of the filter and constrain the network size (number of the

**Fig. 30.5** Simulated and theoretical EMSE versus noise variance

**Fig. 30.6** Simulated and theoretical EMSE versus kernel size

centers). Some *sparsification* methods can be applied to cope with this issue. According to these methods, new samples are inserted into the dictionary, only if they satisfy a certain *sparsification criterion*. In the following, we briefly discuss several useful sparsification criteria.

Suppose at  $i$  iteration, the dictionary is  $C(i) = \{c_1, c_1, \dots, c_{m_i}\}$ , and the coefficient vector  $a(i) = \{a_1, a_2, \dots, a_{m_i}\}$ , where  $c_j$  is the  $j$ th center,  $a_j$  is the  $j$ th coefficient, and  $m_i$  the dictionary size (or network size) at  $i$  iteration. In this case, the learned mapping is

$$f_i(\cdot) = \sum_{j=1}^{m_i} a_j(i) \kappa(c_j, u). \quad (30.34)$$

When a new example  $\{\mathbf{u}(i+1), d(i+1)\}$  is presented, the learning system needs to decide whether  $\mathbf{u}(i+1)$  should be inserted into the dictionary. This decision procedure is, in general, based on some sparsification criterion.

**Novelty Criterion.** Platt's NC [30.14] first computes the distance of  $\mathbf{u}(i+1)$  to the present dictionary

$$\text{dis}_1 = \min_{c_j \in C(i)} \|\mathbf{u}(i+1) - \mathbf{c}_j\|. \quad (30.35)$$

If  $\text{dis}_1$  is smaller than some preset threshold  $\delta_1 (\delta_1 > 0)$ ,  $\mathbf{u}(i+1)$  will not be added into the dictionary. Otherwise, it computes the prediction error  $e(i+1) = d(i+1) - f_i(\mathbf{u}(i+1))$ . Only if the magnitude of the prediction error is larger than another preset threshold  $\delta_2 (\delta_2 > 0)$ ,  $\mathbf{u}(i+1)$  will be accepted as a new center. If the input domain  $\mathbb{U}$  is a compact subset, the NC criterion always produces a dictionary with finite elements.

**Coherence Criterion.** According to the CC [30.15], the input  $\mathbf{u}(i+1)$  will be inserted into the dictionary if its coherence remains below a given threshold  $\mu_0$ , that is

$$\max_{c_j \in C(i)} |\kappa(\mathbf{u}(i+1), \mathbf{u}(c_j))| \leq \mu_0. \quad (30.36)$$

**ALD Criterion.** The ALD uses the distance of the new input to the linear span of the current dictionary in feature space, that is [30.12]

$$\text{dis}_2 = \min_{\forall b} \left\| \boldsymbol{\varphi}(\mathbf{u}(i+1)) - \sum_{c_j \in C(i)} b_j \boldsymbol{\varphi}(\mathbf{c}_j) \right\|. \quad (30.37)$$

ALD is computationally expensive especially when the dictionary size  $m_i$  is very large. In order to simplify the computation, one can use the following approximate distance

$$\text{dis}_3 = \min_{\forall b, \forall c_j \in C(i)} \|\boldsymbol{\varphi}(\mathbf{u}(i+1)) - b \boldsymbol{\varphi}(\mathbf{c}_j)\|. \quad (30.38)$$

**Surprise Criterion.** Surprise is a subjective information measure of an example  $\{\mathbf{u}, d\}$  with respect to a learning system  $\mathcal{L}$ , which is defined as the negative log likelihood of the example given the learning system's estimate on the data distribution [30.16]

$$S_{\mathcal{L}}(\mathbf{u}, d) = -\ln p(\mathbf{u}, d | \mathcal{L}), \quad (30.39)$$

where  $p(\mathbf{u}, d | \mathcal{L})$  is the subjective probability of  $(\mathbf{u}, d)$  hypothesized by  $\mathcal{L}$ . The surprise  $S_{\mathcal{L}}(\mathbf{u}, d)$  measures how surprising the exemplar is to the learning system. The surprise of the new example  $\{\mathbf{u}(i+1), d(i+1)\}$  is

$$\begin{aligned} S_{\mathcal{L}(i)}(\mathbf{u}(i+1), d(i+1)) \\ = -\ln p(\mathbf{u}(i+1), d(i+1) | \mathcal{L}(i)), \end{aligned} \quad (30.40)$$

where  $\mathcal{L}(i)$  denotes the present learning system. To simplify notation, one can write  $S_{\mathcal{L}(i)}(\mathbf{u}(i+1), d(i+1))$  as  $S(i+1)$ .

By the definition, if surprise  $S(i+1)$  is large, the new example  $\{\mathbf{u}(i+1), d(i+1)\}$  contains something new for the system to learn or it is suspicious. Otherwise, if surprise  $S(i+1)$  is very small, the new datum is well expected by the learning system  $\mathcal{L}(i)$  and thus contains little information to be learned. Usually one can classify the new example into three categories

$$\begin{cases} \text{abnormal: } S(i+1) > T_1, \\ \text{learnable: } T_1 \geq S(i+1) \geq T_2, \\ \text{redundant: } S(i+1) < T_2, \end{cases} \quad (30.41)$$

where  $T_1$  and  $T_2$  are threshold parameters. The choice of the thresholds and learning strategies defines the characteristics of the learning system. In general, a new center will be added only if the example is learnable, i.e.,  $T_1 \geq S(i+1) \geq T_2$ .

Besides the aforementioned sparsification methods, there is another technique, called the *quantization approach*, to reduce the network size of KLMS. By quantization approach, the input space is quantized, if the quantization of the new input has already been assigned a center, no new center will be added, while the coefficient of that center will be updated. This new algorithm is called the quantized KLMS (QKLMS) algorithm [30.17]. The mapping update equation of the QKLMS can be simply expressed as

$$\begin{cases} f_0 = 0, \\ e(i) = d(i) - f_{i-1}(\mathbf{u}(i)), \\ f_i = f_{i-1} + \eta e(i) \kappa(Q[\mathbf{u}(i)], .), \end{cases} \quad (30.42)$$

where  $Q[.]$  is a quantization operator over input space. A simple online vector quantization (VQ) method has also been proposed in [30.17]. The QKLMS algorithm (with simple online VQ) is described in Algorithm 30.2.

---

**Algorithm 30.2 Quantized Kernel Least Mean Square Algorithm**

**Initialization:**

Choose kernel  $\kappa$ , step size  $\eta$ , quantization size  $\varepsilon$   
 $\mathbf{a}_1 = \eta d(1)$ ,  $\mathbf{C}(1) = \{\mathbf{u}(1)\}$ ,  $f_1 = \mathbf{a}_1 \kappa(\mathbf{u}(1), \cdot)$

**Computation:**

**while**  $\{\mathbf{u}(i), d(i)\} (i > 1)$  available **do**

1) Compute the prediction error

$$e(i) = d(i) - \sum_{j=1}^{\text{size}(\mathbf{C}(i-1))} \mathbf{a}_j(i-1) \kappa(\mathbf{C}_j(i-1), \mathbf{u}(i))$$

2) Compute the distance between  $\mathbf{u}(i)$  and  $\mathbf{C}(i-1)$

$$\text{dis}(\mathbf{u}(i), \mathbf{C}(i-1)) = \|\mathbf{u}(i) - \mathbf{C}_{j^*}(i-1)\|$$

where

$$j^* = \underset{1 \leq j \leq \text{size}(\mathbf{C}(i-1))}{\operatorname{argmin}} \|\mathbf{u}(i) - \mathbf{C}_j(i-1)\|$$

3) **if**  $\text{dis}(\mathbf{u}(i), \mathbf{C}(i-1)) \leq \varepsilon$ , **then**

$$\mathbf{C}(i) = \mathbf{C}(i-1), \quad \mathbf{a}_{j^*}(i) = \mathbf{a}_{j^*}(i-1) + \eta e(i)$$

**else**

$$\mathbf{C}(i) = \{\mathbf{C}(i-1), \mathbf{u}(i)\}, \quad \mathbf{a}(i) = [\mathbf{a}(i-1), \eta e(i)]$$

**end if**

**end while**

(where  $\mathbf{C}_j(i-1)$  denotes the  $j$ th element of the dictionary  $\mathbf{C}(i-1)$ ).

---

### Kernel Maximum Correntropy (KMC) Algorithm

Like most conventional adaptive filtering algorithms, the **KLMS** adopts the **MSE** as the optimality cost function. The **MSE** is mathematically tractable, computationally simple, and optimal for linear Gaussian systems. However, **MSE** may be a poor cost for nonlinear or/and non-Gaussian (e.g., heavy-tail distributions) situations, since it constraints only the second-order statistics. To cope with this problem, one may use a non-**MSE** cost, such as a higher order statistics, or an *information theoretic criterion* (entropy, correntropy, divergence, etc.). In particular, the *kernel maximum correntropy (KMC)* algorithm has been developed in [30.31], which is derived by applying the *maximum correntropy criterion* (MCC) to **KLMS**.

The correntropy defines a new correlation function between two random variables. Let  $X$  and  $Y$  be two random variables with the same dimensions, the cor-

rentropy is defined by [30.19]

$$V(X, Y) = E_{XY}[\kappa_{\text{corr}}(X, Y)] \\ = \int \kappa_{\text{corr}}(x, y) dF_{XY}(x, y), \quad (30.43)$$

where  $\kappa_{\text{corr}}(\cdot, \cdot)$  is a Mercer kernel (usually Gaussian kernel), and  $F_{XY}(x, y)$  denotes the joint distribution function of  $X$ ,  $Y$ . Since any Mercer kernel induces a nonlinear mapping  $\varphi(\cdot)$  from the input space to a high-dimensional (possibly infinite) feature space, and the inner product of two points  $\varphi(X)$  and  $\varphi(Y)$  in feature space can be implicitly computed by using the Mercer kernel, so the correntropy (30.43) can alternatively be expressed as

$$V(X, Y) = E[\langle \varphi(X), \varphi(Y) \rangle], \quad (30.44)$$

where  $\langle \cdot, \cdot \rangle$  denotes the inner product in the feature space induced by  $\kappa_{\text{corr}}(\cdot, \cdot)$ . Clearly, correntropy is a generalized correlation function and it is also positive definite, i.e., it defines a new **RKHS** for inference. By a simple Taylor series expansion on the kernel, one can see that correntropy provides a number that is the sum of all the statistical moments expressed by the kernel. In many applications, this sum may be sufficient to quantify better than correlation the relationships of interest and it is much simpler to estimate than the higher order statistical moments. Therefore, it can be considered a new type of statistical descriptor and a new cost function for adaptive system training.

Under MCC criterion, the learning cost function is  $V(d(i), y(i)) = E[\kappa_{\text{corr}}(d(i), y(i))]$ . Dropping the expectation operator, one obtains the instantaneous cost function  $\tilde{V}(d(i), y(i)) = \kappa_{\text{corr}}(d(i), y(i))$ . Thus, a *stochastic gradient algorithm* in **RKHS**  $\mathcal{H}_k$  (which is induced by  $\kappa$ , NOT by  $\kappa_{\text{corr}}$ ) can be readily derived as follows

$$f_i = f_{i-1} + \eta \frac{\partial}{\partial f_{i-1}} \tilde{V}(d(i), y(i)) \\ = f_{i-1} + \eta \frac{\partial}{\partial f_{i-1}} \kappa_{\text{corr}}(d(i), y(i)) \\ = f_{i-1} + \eta \frac{\partial}{\partial y(i)} \kappa_{\text{corr}}(d(i), y(i)) \frac{\partial}{\partial f_{i-1}} y(i) \\ = f_{i-1} + \eta \frac{\partial}{\partial y(i)} \kappa_{\text{corr}}(d(i), \\ y(i)) \frac{\partial}{\partial f_{i-1}} \langle f_{i-1} | \kappa(\mathbf{u}(i), \cdot) \rangle_{\mathcal{H}_k} \\ = f_{i-1} + \eta \frac{\partial}{\partial y(i)} \kappa_{\text{corr}}(d(i), y(i)) \kappa(\mathbf{u}(i), \cdot), \quad (30.45)$$

where  $\partial/\partial f_{i-1}$  denotes *Frechet's* differential. This algorithm is called the **KMC** algorithm. If  $\kappa_{\text{corr}}(\cdot, \cdot)$  is a Gaussian kernel, i.e.,  $\kappa_{\text{corr}}(d(i), y(i)) = \exp(-(e(i)^2/2\sigma^2))$ , then **KMC** (30.45) becomes

$$\begin{aligned} f_i &= f_{i-1} + \eta \frac{\partial}{\partial y(i)} \exp\left(-\frac{e(i)^2}{2\sigma^2}\right) \kappa(\mathbf{u}(i), \cdot) \\ &= f_{i-1} + \frac{\eta}{\sigma^2} \exp\left(-\frac{e(i)^2}{2\sigma^2}\right) e(i) \kappa(\mathbf{u}(i), \cdot). \end{aligned} \quad (30.46)$$

The algorithm of (30.46) is, in fact, a **KLMS** algorithm with step size  $\eta' = \frac{\eta}{\sigma^2} \exp(-(e(i)^2/2\sigma^2))$ .

To achieve a better performance, one should select a suitable kernel size for correntropy. Note that there may be two kernel sizes in **KMC**: the kernel size for the **RKHS** of filter and the kernel size for the cost function. Here we talk about the latter. A kernel size update rule has been proposed in [30.32], which is

$$\sigma(i+1) = \alpha\sigma(i) + (1-\alpha)\sqrt{\frac{\beta_G}{\beta_e}}\sigma_e^2, \quad (30.47)$$

where  $\sigma(i)$  denotes the kernel size of correntropy at iteration  $i$ ,  $0 \leq \alpha \leq 1$  is a forgetting factor,  $\beta_G$  is the kurtosis of the Gaussian distribution (i.e.,  $\beta_G = 3$ ), and  $\beta_e$  and  $\sigma_e^2$  are, respectively, the kurtosis and variance of the prediction error.

### 30.3.2 Kernel Recursive Least Squares (**KRLS**) Algorithm

The *recursive least squares* (**RLS**) is another popular algorithm in the traditional linear adaptive filtering literature, which recursively updates the estimated autocorrelation matrix of the input signal vector and the cross-correlation vector between the input vector and the desired response. The convergence rate of **RLS** is, in general, much faster than the **LMS** algorithm. This improvement in performance, however, is achieved at the expense of an increase in computational complexity. Similar to the **LMS** algorithm, the **RLS** algorithm can also be *kernelized*. Next, we will discuss the **KRLS** algorithm [30.12]. The derivation of **KRLS** is based on a least squares formulation in the feature space.

Based on a sequence of available examples (up to and including time  $i-1$ )  $\{\mathbf{u}(j), d(j)\}_{j=1}^{i-1}$ , the regularized least squares regression in  $\mathcal{H}_k$  can be formulated as

$$\min_{f \in \mathcal{H}_k} \sum_{j=1}^{i-1} (d(j) - f(\mathbf{u}(j)))^2 + \gamma \|f\|_{\mathcal{H}_k}^2, \quad (30.48)$$

where  $\gamma \geq 0$  is the regularization factor that controls the smoothness of the solution (to avoid overfitting). Note that in **KLMS**, the step size performs a similar role as the regularization factor (*self-regularization property*), and hence there is no need to add explicitly a regularization factor in **KLMS**.

By the representer theorem [30.33], the function  $f$  in  $\mathcal{H}_k$  minimizing (30.48) can be expressed as a linear combination of the kernels in terms of the available data

$$f(\cdot) = \sum_{j=1}^{i-1} \alpha_j \kappa(\mathbf{u}(j), \cdot). \quad (30.49)$$

The learning problem can also be defined as finding  $\boldsymbol{\alpha} \in \mathbb{R}^{i-1}$  that minimizes

$$\begin{aligned} \min_{\boldsymbol{\alpha}(i-1) \in \mathbb{R}^{i-1}} & \| \mathbf{d}(i-1) - \mathbf{K}(i-1)\boldsymbol{\alpha}(i-1) \|^2 \\ & + \gamma \boldsymbol{\alpha}(i-1)^T \mathbf{K}(i-1) \boldsymbol{\alpha}(i-1), \end{aligned} \quad (30.50)$$

where  $\boldsymbol{\alpha}(i-1) = [\alpha_1, \dots, \alpha_{i-1}]^T$ ,  $\mathbf{d}(i-1) = [d(1), \dots, d(i-1)]^T$ , and  $\mathbf{K}(i-1) \in \mathbb{R}^{(i-1) \times (i-1)}$  is the Gram matrix with elements  $\mathbf{K}_{jk} = \kappa(\mathbf{u}(j), \mathbf{u}(k))$ ,  $j, k = 1, 2, \dots, i-1$ . The solution of (30.50) will be

$$\boldsymbol{\alpha}^* = (\gamma \mathbf{I} + \mathbf{K}(i-1))^{-1} \mathbf{d}(i-1), \quad (30.51)$$

where  $\mathbf{I}$  denotes an identity matrix with appropriate dimension. Of course, the above least squares problem can alternatively be formulated in feature space  $\mathbb{F}$

$$\min_{\boldsymbol{\Omega} \in \mathbb{F}} \sum_{j=1}^{i-1} (d(j) - \boldsymbol{\Omega}^T \boldsymbol{\varphi}(j))^2 + \gamma \|\boldsymbol{\Omega}\|^2 \quad (30.52)$$

The solution of (30.52) can be derived as [30.9]

$$\begin{aligned} \boldsymbol{\Omega}^* &= \boldsymbol{\Phi}(i-1) \boldsymbol{\alpha}^* \\ &= \boldsymbol{\Phi}(i-1) (\gamma \mathbf{I} + \mathbf{K}(i-1))^{-1} \mathbf{d}(i-1), \end{aligned} \quad (30.53)$$

where  $\boldsymbol{\Phi}(i-1) = [\boldsymbol{\varphi}(1), \dots, \boldsymbol{\varphi}(i-1)]$  (Hence the Gram matrix  $\mathbf{K}$  can also be expressed as  $\mathbf{K} = \boldsymbol{\Phi}^T \boldsymbol{\Phi}$ ). The **KRLS** algorithm will update this solution recursively as new data  $(\mathbf{u}(i), d(i))$  become available.

When the new data  $(\mathbf{u}(i), d(i))$  are available, the optimal solution of (30.53) becomes

$$\boldsymbol{\Omega}^* = \boldsymbol{\Phi}(i) (\gamma \mathbf{I} + \mathbf{K}(i))^{-1} \mathbf{d}(i). \quad (30.54)$$

Denote

$$\mathbf{Q}(i) = (\gamma \mathbf{I} + \mathbf{K}(i))^{-1} = (\gamma \mathbf{I} + \boldsymbol{\Phi}(i)^T \boldsymbol{\Phi}(i))^{-1}. \quad (30.55)$$

It is easy to see

$$\mathbf{Q}(i)^{-1} = \begin{bmatrix} \mathbf{Q}(i-1)^{-1} & \mathbf{h}(i) \\ \mathbf{h}(i)^T & \gamma + \boldsymbol{\varphi}(i)^T \boldsymbol{\varphi}(i) \end{bmatrix}, \quad (30.56)$$

where  $\mathbf{h}(i) = \boldsymbol{\Phi}(i-1)^T \boldsymbol{\varphi}(i)$ . Using the block matrix inversion identity [30.9], one can derive

$$\mathbf{Q}(i) = r(i)^{-1} \begin{bmatrix} \mathbf{Q}(i-1)r(i) + z(i)z(i)^T & -z(i) \\ -z(i)^T & 1 \end{bmatrix}, \quad (30.57)$$

where  $z(i) = \mathbf{Q}(i-1)\mathbf{h}(i)$ ,  $r(i) = \gamma + \kappa(\mathbf{u}(i), \mathbf{u}(i)) - z(i)^T \mathbf{h}(i)$ . Then the coefficient vector can be updated as

$$\begin{aligned} \boldsymbol{\alpha}^*(i) &= \mathbf{Q}(i)\mathbf{d}(i) \\ &= r(i)^{-1} \begin{bmatrix} \mathbf{Q}(i-1)r(i) + z(i)z(i)^T & -z(i) \\ -z(i)^T & 1 \end{bmatrix} \\ &\quad \begin{bmatrix} \mathbf{d}(i-1) \\ \mathbf{d}(i) \end{bmatrix} \\ &= \begin{bmatrix} \boldsymbol{\alpha}^*(i-1) - z(i)r(i)^{-1}e(i) \\ r(i)^{-1}e(i) \end{bmatrix}, \end{aligned} \quad (30.58)$$

where  $e(i) = d(i) - \mathbf{h}(i)^T \boldsymbol{\alpha}^*(i-1)$  is the prediction error.

Now we have obtained a recursive algorithm to solve the kernel least squares problem, namely, the **KRLS** algorithm (see Algorithm 30.3). The computational cost of **KRLS** is  $O(i^2)$  per iteration. The **KRLS** also produces a network with linear growth. All the previously mentioned *sparsification* or *quantization* approaches can still be applied to curb the network growth. Notice that the algorithm presented here is just the basic **KRLS** algorithm. There are many variants or extensions of **KRLS**, including the exponentially weighted **KRLS** (**EW-KRLS**) [30.9], sliding window **KRLS** (**SW-KRLS**) [30.34], fixed-budget **KRLS** (**FB-KRLS**) [30.35], extended **KRLS** (**EX-KRLS**) [30.13], and so on.

### Algorithm 30.3 Kernel Recursive Least Squares Algorithm

#### Initialization:

Set the regularization parameter  $\gamma > 0$

$$\mathbf{C}(1) = \{\mathbf{u}(1)\}, \quad \mathbf{Q}(1) = [\kappa(\mathbf{u}(1), \mathbf{u}(1)) + \gamma]^{-1},$$

$$\boldsymbol{\alpha}^*(1) = \mathbf{Q}(1)\mathbf{d}(1)$$

#### Computation:

**while**  $\{\mathbf{u}(i), y(i)\}$  ( $i > 1$ ) available **do**

$$\mathbf{h}(i) = [\kappa(\mathbf{u}(i), \mathbf{u}(1)), \dots, \kappa(\mathbf{u}(i), \mathbf{u}(i-1))]^T$$

$$z(i) = \mathbf{Q}(i-1)\mathbf{h}(i)$$

$$r(i) = \gamma + \kappa(\mathbf{u}(i), \mathbf{u}(i)) - z(i)^T \mathbf{h}(i)$$

$$\mathbf{Q}(i) = r(i)^{-1} \begin{bmatrix} \mathbf{Q}(i-1)r(i) + z(i)z(i)^T & -z(i) \\ -z(i)^T & 1 \end{bmatrix}$$

$$e(i) = d(i) - \mathbf{h}(i)^T \boldsymbol{\alpha}^*(i-1)$$

$$\boldsymbol{\alpha}^*(i) = \begin{bmatrix} \boldsymbol{\alpha}^*(i-1) - z(i)r(i)^{-1}e(i) \\ r(i)^{-1}e(i) \end{bmatrix}$$

**end while**

(where  $\mathbf{C}_j(i-1)$  denotes the  $j$ th element of the dictionary  $\mathbf{C}(i-1)$ ).

### 30.3.3 Kernel Affine Projection Algorithms (KAPA)

The **KAPA** algorithms are nonlinear extensions of the conventional *affine projection algorithms* (**APAs**) in kernel space, which include the **KLMS** and **KRLS** as special cases [30.9]. Before presenting the **KAPA** algorithms, we give a brief introduction of the **APA** algorithms.

Let  $d$  be a zero-mean scalar-valued random variable, and  $\mathbf{u}$  be a zero-mean  $m \times 1$  random variable with a positive-definite covariance matrix  $R_{\mathbf{u}} = E[\mathbf{u}\mathbf{u}^T]$ . Denote  $r_{du}$  the cross-covariance vector  $r_{du} = E[d\mathbf{u}]$ . Then the weight vector  $\mathbf{w}$  that solves

$$\min_{\mathbf{w} \in \mathbb{R}^m} E|d - \mathbf{w}^T \mathbf{u}|^2 + \lambda \|\mathbf{w}\|^2, \quad (30.59)$$

is given by

$$\mathbf{w}^* = (\lambda \mathbf{I} + R_{\mathbf{u}})^{-1} r_{du}.$$

The solution  $\mathbf{w}^*$  of (30.59) can also be recursively solved using a common gradient-based method

$$\begin{aligned} \mathbf{w}(i) &= \mathbf{w}(i-1) + \eta[r_{du} - (\lambda \mathbf{I} + R_{\mathbf{u}})\mathbf{w}(i-1)] \\ &= (1 - \eta\lambda)\mathbf{w}(i-1) + \eta[r_{du} - R_{\mathbf{u}}\mathbf{w}(i-1)], \end{aligned} \quad (30.60)$$

**Table 30.3** Weight update equations of four **KAPA** algorithms

| Algorithms | Update equations                                                                                                 |
|------------|------------------------------------------------------------------------------------------------------------------|
| KAPA-1     | $\Omega(i) = \Omega(i-1) + \eta\Phi(i)[d(i) - \Phi(i)^T\Omega(i-1)]$                                             |
| KAPA-2     | $\Omega(i) = \Omega(i-1) + \eta\Phi(i)(\epsilon\mathbf{I} + \Phi(i)^T\Phi(i))^{-1}[d(i) - \Phi(i)^T\Omega(i-1)]$ |
| KAPA-3     | $\Omega(i) = (1-\eta\lambda)\Omega(i-1) + \eta\Phi(i)[d(i) - \Phi(i)^T\Omega(i-1)]$                              |
| KAPA-4     | $\Omega(i) = (1-\eta)\Omega(i-1) + \eta\Phi(i)(\lambda\mathbf{I} + \Phi(i)^T\Phi(i))^{-1}d(i)$                   |

**Table 30.4** Several kernel learning algorithms related to **KAPA** (30.64)

| Algorithms             | Relation to KAPA                |
|------------------------|---------------------------------|
| KLMS [30.10]           | KAPA-1 ( $L=1$ )                |
| NKLMS [30.9]           | KAPA-2 ( $L=1$ )                |
| NORMA [30.36]          | KAPA-3 ( $L=1$ )                |
| Kernel Adaline [30.37] | KAPA-1 ( $L=N$ )                |
| RA-RBF [30.38]         | KAPA-3 ( $\eta\lambda=1, L=N$ ) |
| SW-KRLS [30.34]        | KAPA-4 ( $\eta=1$ )             |
| RegNet [30.39]         | KAPA-4 ( $\eta=1, L=N$ )        |

or Newton's recursion (for the case  $\lambda \neq 0$ )

$$\begin{aligned} w(i) &= w(i-1) + \eta(\lambda\mathbf{I} + R_u)^{-1} \\ &\quad \times [r_{du} - (\lambda\mathbf{I} + R_u)w(i-1)] \\ &= (1-\eta)w(i-1) + \eta(\lambda\mathbf{I} + R_u)^{-1}r_{du}. \end{aligned} \quad (30.61)$$

If the regularization factor  $\lambda = 0$ , Newton's recursion should be

$$w(i) = w(i-1) + \eta(\epsilon\mathbf{I} + R_u)^{-1}[r_{du} - R_u w(i-1)], \quad (30.62)$$

where  $\epsilon$  is a small positive number to avoid numerical instability.

Suppose we have access to the observations (training examples) of  $\mathbf{u}$  and  $d$ :  $\{\mathbf{u}(i), d(i)\}, i = 1, 2, \dots$ . Then the **APA** algorithms can be easily derived by approximating  $R_u$  and  $r_{du}$  in Algorithms (30.60)–(30.62). Based on the  $L$  most recent observations, the covariance matrix  $R_u$  and the cross-covariance vector  $r_{du}$  can be simply approximated by

$$\begin{cases} \hat{R}_u = \frac{1}{L}\mathbf{U}(i)\mathbf{U}(i)^T, \\ \hat{r}_{du} = \frac{1}{L}\mathbf{U}(i)d(i), \end{cases} \quad (30.63)$$

where

$$\begin{aligned} \mathbf{U}(i) &= [\mathbf{u}(i-L+1), \dots, \mathbf{u}(i)]_{m \times L}, \\ d(i) &= [d(i-L+1), \dots, d(i)]^T. \end{aligned}$$

Combining (30.60) and (30.63) yields

$$w(i) = (1-\eta\lambda)w(i-1) + \eta\mathbf{U}(i)[d(i) - \mathbf{U}(i)^T w(i-1)].$$

When  $\lambda = 0$ , (30.64) becomes

$$w(i) = w(i-1) + \eta\mathbf{U}(i)[d(i) - \mathbf{U}(i)^T w(i-1)]. \quad (30.65)$$

Similarly, combining (30.61) and (30.63), we have

$$\begin{aligned} w(i) &= (1-\eta)w(i-1) \\ &\quad + \eta(\lambda\mathbf{I} + \mathbf{U}(i)\mathbf{U}(i)^T)^{-1}\mathbf{U}(i)d(i) \\ &= (1-\eta)w(i-1) \\ &\quad + \eta\mathbf{U}(i)(\lambda\mathbf{I} + \mathbf{U}(i)^T\mathbf{U}(i))^{-1}d(i), \end{aligned} \quad (30.66)$$

where the second equation comes from the *matrix inverse lemma*.

Further, using the approximations of (30.63), algorithm (30.62) becomes

$$\begin{aligned} w(i) &= w(i-1) + \eta(\epsilon\mathbf{I} + \mathbf{U}(i)\mathbf{U}(i)^T)^{-1} \\ &\quad \times \mathbf{U}(i)[d(i) - \mathbf{U}(i)^T w(i-1)]. \end{aligned} \quad (30.67)$$

Algorithm (30.67) is equivalent to (by the matrix inverse lemma)

$$\begin{aligned} w(i) &= w(i-1) + \eta\mathbf{U}(i)(\epsilon\mathbf{I} + \mathbf{U}(i)^T\mathbf{U}(i))^{-1} \\ &\quad \times [d(i) - \mathbf{U}(i)^T w(i-1)]. \end{aligned} \quad (30.68)$$

Algorithms (30.65), (30.68), (30.64), and (30.66) are, respectively, referred to as the **APA-1**, **APA-2**, **APA-3**, and **APA-4** algorithms.

Reformulating the above **APA** algorithms in feature space yields the **KAPA** algorithms [30.11], whose weight update equations are summarized in Table 30.3.

The **KAPA** algorithms are directly related to many other **OKL** algorithms [30.9]. Typical examples are presented in Table 30.4.

## 30.4 Illustration Examples

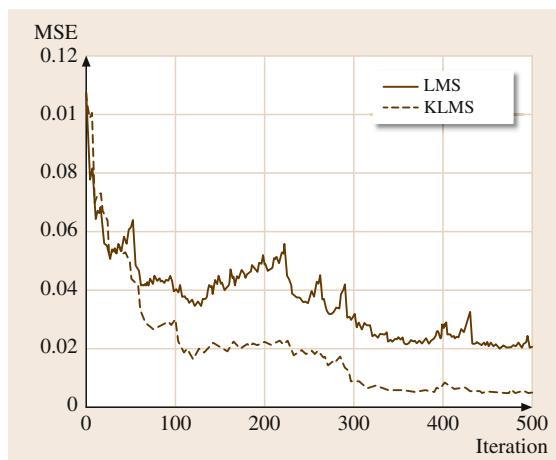

### 30.4.1 Chaotic Time Series Prediction

#### Mackey–Glass (MG) Time Series

First, we consider the Mackey–Glass time series. The time sequence is generated (with a sampling period  $T = 6\text{ s}$ ) from the following time-delay differential equation [30.9]

$$\frac{dx(t)}{dt} = -bx(t) + \frac{ax(t-\tau)}{1+x(t-\tau)^10}, \quad (30.69)$$

where  $b = 0.1$ ,  $a = 0.2$ , and  $\tau = 30$ . The 10 most recent values ( $\mathbf{u}(i) = [x(i-10), \dots, x(i-1)]^T$ ) in the past are used as the input to predict the present value  $x(i)$ . A segment of 500 samples is used as the training data and another 100 as the testing data. The data are corrupted by additive Gaussian noise with zero mean and variance 0.0016. Figure 30.7 shows the learning curves of LMS and KLMS algorithms. Evidently, the KLMS converges

**Fig. 30.7** Learning curves of LMS and KLMS in MG time series prediction (adopted from [30.9])

**Table 30.5** Performance comparison among LMS, KLMS, and RN

| Algorithms            | Training MSE        | Testing MSE         |
|-----------------------|---------------------|---------------------|
| LMS                   | $0.021 \pm 0.002$   | $0.026 \pm 0.007$   |
| KLMS ( $\eta = 0.1$ ) | $0.0074 \pm 0.0003$ | $0.0069 \pm 0.0008$ |
| KLMS ( $\eta = 0.2$ ) | $0.0054 \pm 0.0004$ | $0.0056 \pm 0.0008$ |
| KLMS ( $\eta = 0.6$ ) | $0.0062 \pm 0.0012$ | $0.0058 \pm 0.0017$ |
| RN ( $\lambda = 0$ )  | $0 \pm 0$           | $0.012 \pm 0.004$   |
| RN ( $\lambda = 1$ )  | $0.0038 \pm 0.0002$ | $0.0039 \pm 0.0008$ |
| RN ( $\lambda = 10$ ) | $0.011 \pm 0.0001$  | $0.010 \pm 0.0003$  |

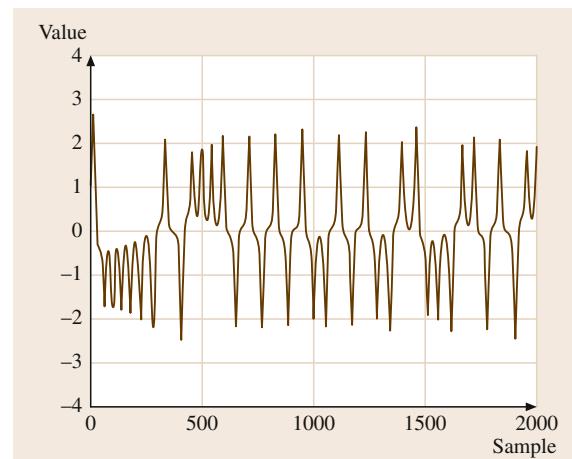

to a much smaller value of the testing MSE. This is an expected result as the MG time series is a nonlinear system. In the simulation, the Gaussian kernel is used, and the kernel parameter ( $a = 1/(2\sigma^2)$ ) is set at  $a = 1.0$ . The step sizes of the LMS and KLMS are both set at 0.2. Table 30.5 presents the performance comparison among LMS, KLMS with different step sizes, and regularization network (RN) with different regularization parameters. The performance of KLMS is much better than LMS and is comparable to RN with the best regularization. This is indeed surprising since RN is a batch mode kernel regression method while KLMS is a simple stochastic gradient algorithm in RKHS.

#### Lorenz Time Series

Next, we consider the Lorenz chaotic time series, generated from a nonlinear, three-dimensional dynamic system [30.17]

$$\begin{cases} \frac{dx}{dt} = -\beta x + yz, \\ \frac{dy}{dt} = \delta(z-y), \\ \frac{dz}{dt} = -xy + \rho y - z, \end{cases} \quad (30.70)$$

where the parameters are  $\beta = 8/3$ ,  $\delta = 10$ , and  $\rho = 28$ . The sample data are obtained using the first-order approximation with step size 0.01. The state  $x$  is picked for short-term prediction task. The signal is preprocessed to be zero mean and unit variance (Fig. 30.8).

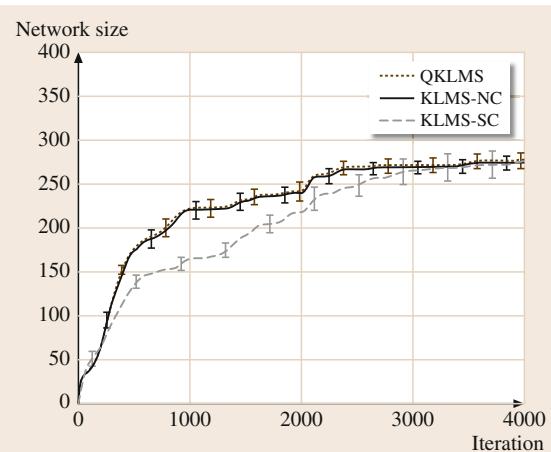

**Fig. 30.8** A segment of the processed Lorenz time series

We use the previous five consecutive samples  $\mathbf{u}(i) = [x(i-5), \dots, x(i-1)]^T$  to predict the current sample  $x(i)$ . The performances of **QKLMS**, **KLMS-NC**, **KLMS-SC**, and the standard **KLMS** are compared. Here, **KLMS-NC** and **KLMS-SC** denote the sparsified **KLMS** with, respectively, the novelty and surprise criterion. The Gaussian kernel with the kernel parameter  $a = 1.0$  is used. The step sizes are all set at  $\eta = 0.1$ , and the other parameters are tuned such that all the algorithms except **KLMS** yield almost the same final network size (Fig. 30.9). Figure 30.10 shows the average learning curves over 100 simulation runs with different segments of the signal, where the testing MSE

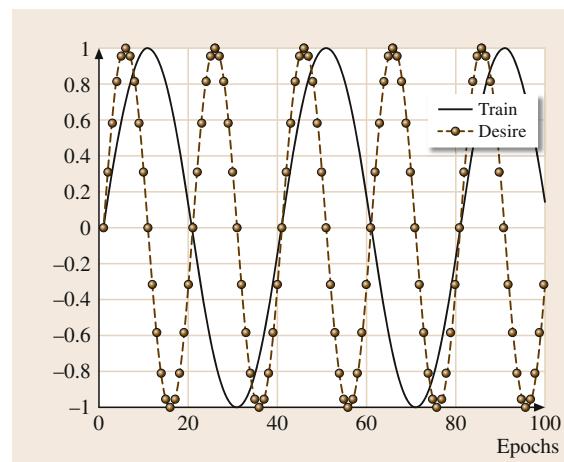

is calculated based on 200 test data (the filter is fixed in the testing phase). Simulation results clearly indicate that the **QKLMS** exhibits much better performance, achieving almost the same testing MSE as the **KLMS** but with small network size.

### 30.4.2 Frequency Doubling

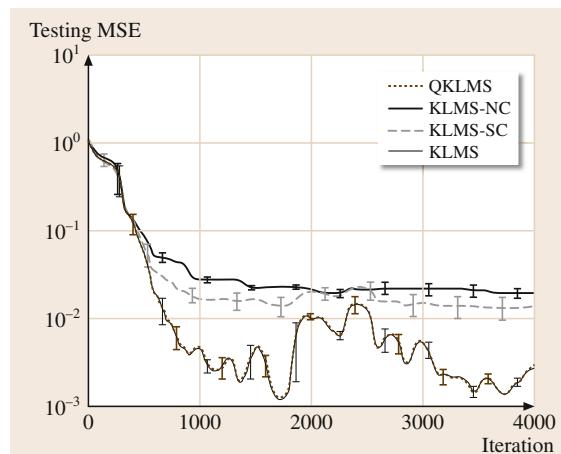

In frequency doubling, both the input and desired data for the learning system are sine waves with frequencies  $f_0$  and  $2f_0$ , respectively (Fig. 30.11). In this example, 1500 samples are used as the training data and another 200 as the testing data. The data are cor-

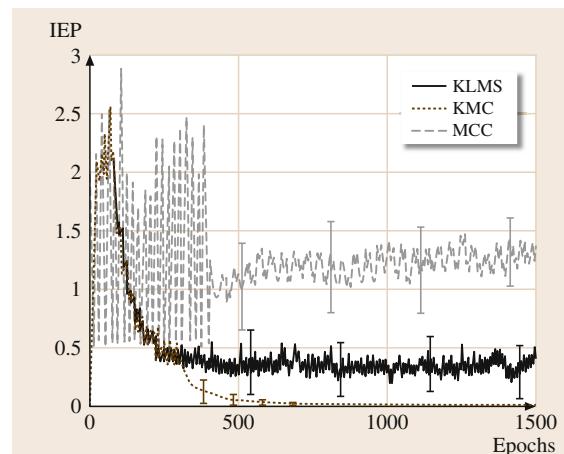

**Fig. 30.9** Network sizes of **QKLMS**, **KLMS-NC**, and **KLMS-SC** in Lorenz time series prediction

**Fig. 30.11** Simulation data in frequency doubling (adopted from [30.31])

**Fig. 30.10** Learning curves of **QKLMS**, **KLMS-NC**, **KLMS-SC**, and **KLMS** in Lorenz time series prediction

**Fig. 30.12** Learning curves of **KLMS**, **KMC**, and **MCC** in frequency doubling (adopted from [30.31])

rupted by an impulsive mixture Gaussian noise, with probability density function  $p(x) \approx 0.9\mathcal{N}(0, 0.01) + 0.1\mathcal{N}(2, 0.01)$  [30.31]. Let the dimension of the input vector be 2. Figure 30.12 shows the average learning curves of KLMS, KMC, and MCC (adaptive FIR filter under MCC criterion). It is clear that the KMC algorithm outperforms both KLMS and MCC algorithms. Simulation results suggest that the KMC algorithm performs well under impulsive noise environment.

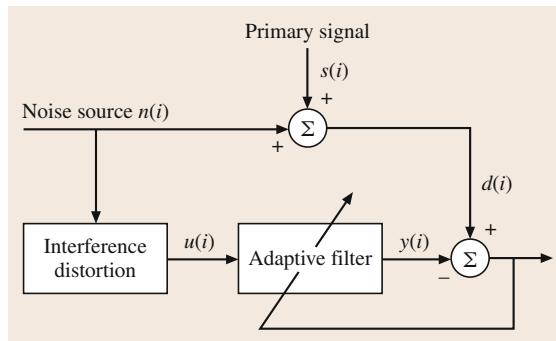

Fig. 30.13 Basic structure of the noise cancellation system

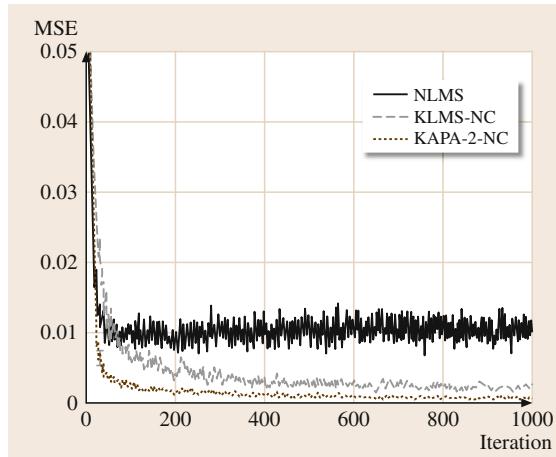

Fig. 30.14 Average learning curves of NLMS, KLMS-NC, and KAPA-2-NC in noise cancellation (adopted from [30.9])

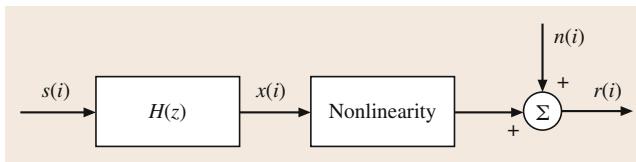

Fig. 30.15 Basic structure of the nonlinear channel

### 30.4.3 Noise Cancellation

Noise cancellation is very important in signal processing where an unknown interference has to be removed based on some reference measurement. Figure 30.13 shows the basic structure of a noise cancellation system. The goal of the noise cancellation is to use the reference measurement  $u(i)$  as the input to the adaptive filter and to obtain the filter output  $y(i)$  as an estimate of the unknown noise source  $n(i)$ , such that the noise can be subtracted from the noisy measurement  $d(i)$  to improve the signal-to-noise ratio (SNR).

In this example, the noise source is assumed to be white and uniformly distributed over  $[-0.5, 0.5]$ . Further, the nonlinear interference distortion function is

$$u(i) = n(i) - 0.2u(i-1) - u(i-1)n(i-1) \quad (30.71) \\ + 0.1n(i-1) + 0.4u(i-2).$$

During the training phase the primary signal is assumed to be  $s(i) = 0$ , that is, the system simply tries to reconstruct the noise source from the reference measurement. We use the NLMS, KLMS-NC, KAPA-2-NC ( $L = 10$ ) algorithms. The average learning curves over 200 Monte Carlo simulations are illustrated in Fig. 30.14. In the simulation, the step sizes for NLMS, KLMS-NC, and KAPA-2-NC are 0.2, 0.5, and 0.2, respectively. The Gaussian kernel is used for both KLMS-NC and KAPA-2-NC with kernel parameter  $a = 1.0$ . The tolerance parameters for KLMS-NC and KAPA-2-NC are  $\delta_1 = 0.15$  and  $\delta_2 = 0.01$ . The noise reduction (NR) factor, defined as

$$10 \log_{10} \frac{E[n(i)^2]}{E[n(i) - y(i)]^2},$$

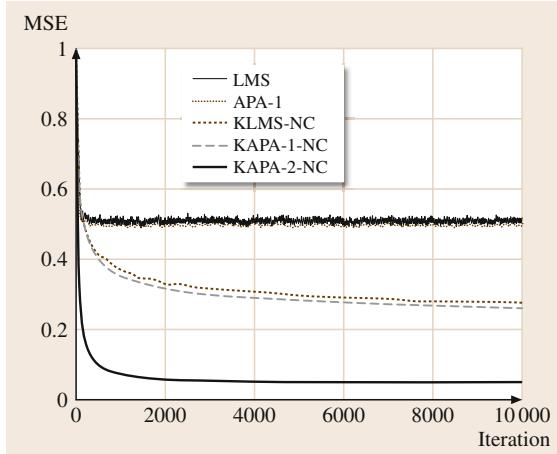

and the corresponding final network sizes are listed in Table 30.6. The performance improvement of KAPA over KLMS is obvious.

### 30.4.4 Nonlinear Channel Equalization

The final example is on nonlinear channel equalization, where the nonlinear channel consists of a serial connection of a linear filter  $H(z)$  and a static nonlinearity (Fig. 30.15). The problem setting is as follows:

Table 30.6 Performance comparison of NLMS, KLMS, and KAPA-2 in noise cancellation

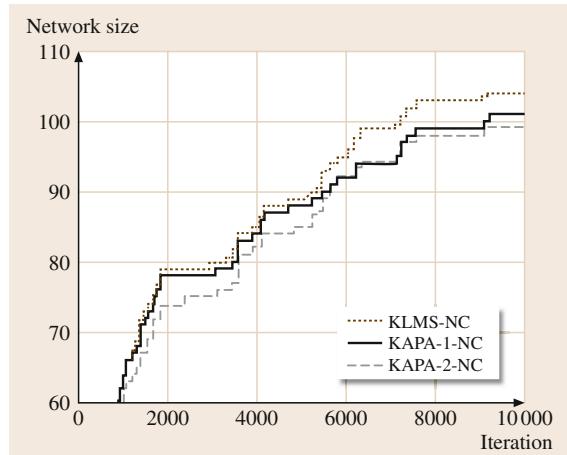

| Algorithms | Network size | NR (dB)          |
|------------|--------------|------------------|
| NLMS       | N/A          | $9.09 \pm 0.45$  |
| KLMS-NC    | $407 \pm 14$ | $15.58 \pm 0.48$ |
| KAPA-2-NC  | $370 \pm 14$ | $21.99 \pm 0.80$ |

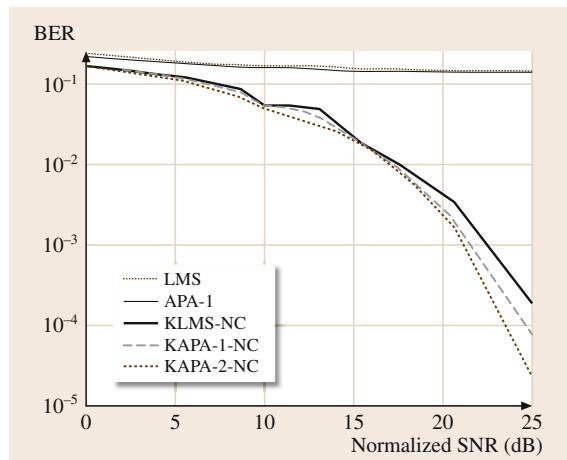

**Fig. 30.16** Learning curves of LMS, APA-1, KLMS-NC, KAPA-1-NC, and KAPA-2-NC in nonlinear channel equalization (adopted from [30.9])

A binary signal  $\{s(1), s(2), \dots, s(N)\}$  is fed into a nonlinear channel. At the receiver end of the channel, the signal is further corrupted by additive i.i.d. Gaussian noise, and then is observed as  $\{r(1), r(2), \dots, r(N)\}$ . The objective of channel equalization is to learn an *inverse filter* that recovers the original signal with as low an error rate as possible. This problem can be formulated as a regression problem with input-output training data  $\{(r(t+D), r(t+D-1), \dots, r(t+D-l+1)), s(t)\}$ , where  $l$  is the time embedding length, and  $D$  is the equalization time lag. In this example, the nonlinear channel is defined by  $x(t) = s(t) + 0.5s(t-1)$ ,  $r(t) = x(t) - 0.9x(t)^2 + n(t)$ , where  $n(t)$  is a white Gaussian noise with variance  $\sigma^2$ .

We compare the performance of LMS, APA-1, KLMS-NC, KAPA-1-NC ( $L = 10$ ) and KAPA-2-NC ( $L = 10$ ). The noise variance is assumed to be 0.01.  $l = 3$ , and  $D = 2$  in the equalizer. For KLMS-NC, KAPA-1-NC and KAPA-2-NC, the Gaussian kernel with kernel parameter 1.0 is used, and the NC is employed with  $\delta_1 = 0.26$ ,  $\delta_2 = 0.08$ . Figure 30.16 shows the average learning curves over 50 Monte Carlo simulations, where the MSE is calculated between the continuous output (i.e., before taking the hard decision) and the desired signal. Figure 30.17 plots the dynamic changes of the network sizes during the training. In addition, different noise variances are set. To

**Fig. 30.17** Network sizes of KLMS-NC, KAPA-1-NC, and KAPA-2-NC over training in nonlinear channel equalization (adopted from [30.9])

**Fig. 30.18** Performance comparison of LMS, APA-1, KLMS-NC, KAPA-1-NC, and KAPA-2-NC with different SNR in nonlinear channel equalization (adopted from [30.9])

make the comparison fair, we tune the NC parameters ( $\delta_1$  and  $\delta_2$ ) to make the network size almost the same (around 100) in each scenario. The simulation results in terms of bit error rate (BER) are presented in Fig. 30.18, where the normalized SNR is defined as  $10 \log_{10}(1/\sigma^2)$ .

## 30.5 Conclusion

Online learning has found its place in a wide range of applications, especially in situations where the number of training data is extremely large or the data statistics change fast over time. Recent studies suggest that many online learning algorithms can be efficiently extended to kernel space, provided that these algorithms can be expressed in terms of inner products, since the inner products in high-dimensional kernel space can be simply calculated using the kernel function in input space. At present, most of the well-known linear adaptive filtering algorithms, such as the LMS, RLS, and APA, have been *kernelized*. These new algorithms, namely the kernel adaptive filtering algorithms, can solve incrementally arbitrary nonlinear problems in the input space, if the kernel space is rich (high-dimensional) enough to

represent the mapping. In general, KAFs naturally create a growing RBF network, learning the network topology and adapting the free parameters directly from data at the same time. However, by sparsifying the solution one can achieve a compact model with small network size even in continuous adaptation situations.

Illustration examples, including chaotic time series prediction, frequency doubling, noise cancellation, and nonlinear channel equalization, have been presented to demonstrate the performance and usefulness of the kernel adaptive filtering algorithms.

The use of the kernel trick and online sparsification techniques to develop other online learning algorithms (supervised, unsupervised, and reinforcement) is a promising direction for future research.

# 31. Probabilistic Modeling in Machine Learning

# Probabilistic

Davide Bacciu, Paulo J.G. Lisboa, Alessandro Sperduti, Thomas Villmann

Probabilistic methods are the heart of machine learning. This chapter shows links between core principles of information theory and probabilistic methods, with a short overview of historical and current examples of unsupervised and inferential models. Probabilistic models are introduced as a powerful idiom to describe the world, using random variables as building blocks held together by probabilistic relationships. The chapter discusses how such probabilistic interactions can be mapped to directed and undirected graph structures, which are the Bayesian and Markov networks. We show how these networks are subsumed by the broader class of the probabilistic graphical models, a general framework that provides concepts and methodological tools to encode, manipulate and process probabilistic knowledge in a computationally efficient way. The chapter then introduces, in more detail, two topical methodologies that are central to probabilistic modeling in machine learning. First, it discusses latent variable models, a probabilistic approach to capture complex relationships between a large number of observable and measurable events (data, in general), under the assumption that these are generated by an unknown, nonobservable process. We show how the parameters of a probabilistic model involving such nonobservable information can be efficiently estimated using the concepts underlying the expectation–maximization algorithms. Second, the chapter introduces a notable example

of latent variable model, that is of particular relevance for representing the time evolution of sequence data, that is the hidden Markov model. The chapter ends with a discussion on advanced approaches for modeling complex data-generating processes comprising nontrivial probabilistic interactions between latent variables and observed information.

## 31.1 Probabilistic and Information-Theoretic Methods

Information theory is closely connected to probability theory and statistics. In particular, the standard definition of information contained in a random variable  $X$  with a probability density function  $P(X)$  is well known to be  $I(X) = -\log(P(X))$ , with the correspond-

ing *Shannon entropy*, in differential form, given by the average information

$$H(P) = - \int P(X) \log(P(X)) dx . \quad (31.1)$$

One of the fundamental theorems of information theory, the second Gibbs theorem, states that the normal distribution achieves maximum entropy, hence maximal average information from all distributions with known variance. To show this in the univariate case, consider the normal distribution in the standard form

$$P(X) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(X-\mu)^2}{2\sigma^2}\right).$$

It is straightforward to show that for the natural logarithm

$$\begin{aligned} - \int P(X) \log(P(X)) dx &= \frac{1}{2} + \log(\sqrt{2\pi\sigma^2}) \\ &= - \int G(X) \log(G(X)) dx, \end{aligned}$$

where  $G(X)$  is any arbitrary density function with variance  $\int G(X)(X-\mu)^2 dx = \sigma^2$ . Therefore, the difference in average information between the two density functions necessarily observes the following

$$\begin{aligned} &- \int P(X) \log(P(X)) dx + \int G(X) \log(G(X)) dx \\ &= - \int G(X) \log(P(X)) dx + \int G(X) \log(G(X)) dx \\ &= - \int G(X) \log\left(\frac{P(X)}{G(X)}\right) dx \\ &\geq \int G(X) \left(1 - \frac{P(X)}{G(X)}\right) dx = 0 \end{aligned}$$

using Jensen's inequality  $\log(x) \leq x - 1$  and the normalization property  $\int P(X) = \int Q(X) = 1$ . This is a particular instance of Gibbs inequality and proves that the asymptotic distribution of the *central limit theorem* also maximizes entropy.

This led, in probability theory, to the definition of natural measures of dissimilarity closely related to the expectation of information difference, e.g., the *Kullback–Leibler (KL)* divergence [31.1]

$$D_{\text{KL}}(P||Q) = \int P(X) \log\left(\frac{P(X)}{Q(X)}\right) dx, \quad (31.2)$$

as generalized distances between probability distributions  $P$  and  $Q$ .

The *KL* divergence occurs frequently in machine learning, where the development of learning strategies links information theory with statistical and biologically motivated concepts. For instance, the perceptron

model was established as a simple but mathematically tractable model of a biological neuron as the smallest information processing unit in brains [31.2]. Recognition that gradient descent provided a pragmatic but effective solution to the credit assignment problem, namely which values the hidden nodes should have, led to the multilayer perceptron as powerful computational tools for classification and regression. Initially *maximum likelihood* optimization was used for parameter estimation, following the tried and tested statistical concepts of normally distributed errors leading to a sum-of-squares loss function in regression and, for classification, the Bernoulli distribution for binary data and the so-called cross-entropy (31.2) for multinomial class assignments, the latter two likelihood functions measuring information divergence averaged over the true distribution given by the empirical class labels.

Information theoretic aspects (e.g., mutual information) were also considered in neural models in order to avoid overtraining [31.3], for instance in Boltzmann networks which directly mirror information principles in statistical mechanics [31.4]. Related approaches are used currently for deep learning models, where information principles drive the feature representations [31.5].

The correspondence between maximum entropy and maximum likelihood outlined above is just one aspect of the application of information-theoretic concepts in machine learning. The next section outlines further developments linked first to source identification through blind signal separation and matrix factorization methods. These concepts from signal processing identify important degrees of freedom that may be used as hidden variables in probabilistic models, discussed later in the chapter. Furthermore, the application of information-theoretic methods extends also to the automatic identification of prototypes for use in compact data representations that include *dictionaries* defined by methods such as vector quantization, typically with unsupervised approaches.

Supervised methods are introduced as probabilistic models, focusing first on discriminative methods. This indicates that the maximum likelihood approach is limited in its predictive power in generalization to out-of-sample data, because it allows models to be generated with very little bias but with considerable variance – for a more detailed discussion of this point refer [31.6]. What this means in practice is that flexible models such as neural networks are prone to overfitting unless the complexity of the model is controlled along with the extent to which the model fits the data. The

latter is described by the likelihood, but the model complexity can be controlled in a number of different ways. In probabilistic models an efficient framework to maximize the generality of probabilistic inference models is to apply the maximum a posteriori (**MAP**) framework which optimizes the posterior probability of the model parameters given the data but also given prior distributions for the parameters, typically limiting their size by assuming a zero-centred normal distribution as the prior. This is the basis of the method of *automatic relevance determination*, explained in Sect. 31.2.

While discriminative models are efficient approximators for nonlinear response functions, both in regression and in the estimation of class conditional density functions, they are difficult to interpret and can generally be considered as black boxes, meaning that they are not readily interpreted to give insights about the data. A topical and widely used alternative approach is to model the joint distribution of the data directly. This is ideally done by factorization into subgraphs into which the multivariate structure of the data is broken-up using strict conditional independence requirements, as discussed in Sect. 31.2. Inference can then proceed using Bayes theorem introduced in (31.6).

An alternative approach to modeling the joint distribution of the covariates is to use the mutual correlation in the data to identify important degrees of freedom that may be *hidden* in the sense that they are not directly observed. This generates *latent variable* representations that naturally fit into the framework of probabilistic modeling. However, the introduction of additional variables also introduces complexity into the optimization process for estimating their values. This leads naturally to the introduction of *expectation maximization* (**EM**), a general approach of particular value for estimating mixture models, discussed in Sect. 31.3.

So far the modeling methodologies focus on snapshots of the data, without taking into consideration the time evolution of the covariates. To do this requires explicit parametrization, for which arguably the most widely used probabilistic approach is *hidden Markov models* (**HMM**). These models are build on the concepts of conditional independence, latent variables, and expectation maximization to model the time evolution of sequences of covariate measurements, in the last substantive Sect. 31.4

### 31.1.1 Information-Theoretic Methods

While the statistical properties of perceptrons are widely investigated [31.6], the more difficult prob-

lem of establishing statistical independence is becoming increasingly important and novel algorithms have been presented during the last decade [31.7]. Their applicability is enormous, ranging from variable selection, to *blind source separation* (**BSS**) and statistical causality. Frequently, the difficult question of statistical dependence in data is replaced by the easier consideration of estimation and application of data correlations for learning strategies. A recent approach tries to determine independence by generalized correlation functions [31.8]. In this context of decorrelation and independence, **BSS** and nonnegative matrix factorizations [31.9] of data channels are based on statistical deconvolution. A comprehensive overview for **BSS**, independent component analysis (**ICA**) and nonnegative matrix and tensor factorization (**NMF**) can be found in [31.10–12], respectively. Different aspects can be investigated, like **ICA** and **BSS** maximizing conditional probabilities [31.11]. A relevant connection exists between **NMF** and probabilistic graphical models comprising hidden variables [31.13], which is briefly discussed in Sect. 31.3.4.

Other recent approaches in this field incorporate information theoretic principles directly: Pham [31.14] investigated **BSS** based on mutual information, whereas [31.15] applied  $\beta$ -divergences. The *infomax* principle for **ICA** was considered in depth [31.16], as was the problem of learning overcomplete data representations and performing overcomplete noisy blind source separation, e.g., the sparse coding neural gas (**SCNG**) [31.17]. Recent results including modern divergences (generalized  $\alpha$ - $\beta$ -divergences) were recently published [31.18]. Obviously, information theoretic divergence measures like Rényi-divergences (belonging to the family of  $\alpha$ -divergences) capture directly the statistical information contained in the data, as expressed by the probability density function [31.19, 20]. This property can be used for unsupervised model estimation for instance in vector quantization, when divergences are used as dissimilarity measure [31.21].

Information optimum vector quantization by prototypes is a widely investigated topic in clustering and data compression, based on the optimization of the  $\gamma$ -reconstruction error

$$E_{VQ}(\gamma) = \int \|v - w(v)\|_E^\gamma P(V=v) dv,$$

where  $P(V=v)$  is the data density of the vector data  $v$  and  $\|v - w(v)\|_E$  is the Euclidean distance of the data vector and the prototype  $w(v)$  representing it. One of

the key results concerning information theoretic principles for vector quantization is *Zador's magnification law* [31.22]: if the data vectors  $\mathbf{v}$  are given in  $q$ -dimensional Euclidean space, then the magnification law  $\rho \sim P^\alpha$  holds. Here,  $\rho(\mathbf{w})$  is the prototype density with the magnification factor

$$\alpha = \frac{q}{q + \gamma}.$$

This is the basic principle of vector quantization based on Euclidean distances. For different schemes like self-organizing maps, *Neural Gas* variants with slightly different magnification factors are obtained depending on the choice of neighborhood cooperation scheme applied during prototype adaptation [31.23–25]. Information optimum magnification for  $\alpha = 1$  is equivalent to maximum mutual information [31.22]. Yet, it is possible to control the magnification for most of these algorithms by different strategies like localized or frequency sensitive competitive learning. For an overview, we refer to [31.23]. If the Euclidean distance is replaced by divergence measures, optimum magnification  $\alpha = 1$  can also be achieved by maximum entropy learning [31.26], or by the utilization of correntropy [31.27]. Vector quantization algorithms directly derived from information theoretic principles based on Rényi entropies are intensively studied in [31.28], also highlighting its connection to graph clustering and Mercer kernel-based learning [31.29].

Other information theoretic vector quantizers optimize the mutual information between data and prototypes, or the respective **KL** divergence, instead of minimizing a reconstruction error [31.30]. Based on this principle, several data embedding, or dimensionality reduction techniques, have been developed as alternatives to multidimensional scaling. These approaches are frequently used to visualize data. Prominent examples are *stochastic neighborhood embedding* (**SNE**) [31.31] or variants thereof: for instance, t-SNE uses outlier-robust Student-*t*-distributions for data characterization instead of Gaussians [31.32]. The generalization to other divergences than **KL** can be found in [31.33].

Another role for information theory in machine learning is in *feature selection*. Removing irrelevant or redundant features not only leads to a simplification of the model and a reduced requirement for data acquisition, but it is also central for maximizing the generality of the model when it is applied to future data. Most feature selection approaches are supervised schemes, hence using class information or expected regression

values. Strategies to achieve this goal can be classical Bayesian inference schemes of which *automatic relevance determination* (**ARD**) is a good example (described further in Sect. 31.2), or statistical approaches based on mutual correlation or covariances [31.34, 35]. An alternative approach to feature selection is to use *mutual information*

$$I(X, Y) = D_{\text{KL}}(J(X, Y) \| P(X)Q(Y))$$

between random variables  $X$  and  $Y$  with probability densities  $P$  and  $Q$ , respectively, and joint density  $J$  [31.36]. Here, the features are treated as random variables to be compared and mutual information measures the information loss resulting from removal of variables from the model. Learning classification together with feature weighting in vector quantization is known as *relevance learning* [31.37]. Recent developments to introduce sparseness according to information theoretic constraints are discussed in [31.38, 39].

Information-theoretic measures such as mutual information, can be explicitly estimated from data [31.40]. This is used in the context of vectorial data analysis to obtain consistent and reliable estimators with topographic maps or kernels [31.41]. Further applications of information theoretic learning also use Rényi entropy

$$H_a(P) = \frac{1}{1-\alpha} \log \left( \int (P(X))^\alpha \, dx \right)$$

as a cost function instead of the mean squared error, resorting, for computational efficiency, to Parzen estimators [31.42] or nearest neighbor entropy estimation models. For effective computation of an approximate of the mutual information  $I(X, Y)$ , the quadratic Rényi entropy  $H_2(p)$  or the closely related information energy are common choices [31.43]. Parzen window-based estimators for some information theoretic cost functions have also been shown to be cost functions in a corresponding Mercer kernel space [31.44]. In particular, a classification rule based on an information theoretic criterion has been shown to correspond to a linear classifier in the kernel space. This leads to the formulation of the support vector machine (**SVM**) from information theory principles.

### 31.1.2 Probabilistic Models

Kernel models are known for having excellent discrimination performance, but they are typically not well

calibrated. This is because they are designed to be efficient binary class allocation models rather than estimators of the posterior probability for membership of each class  $C$ . As an example, **SVMs** allocate inputs to classes on the basis on a binary-valued indicator variable that generally does not have a link function to a probability density estimate. This type of models is known as discriminative models, a well-known variant being Fisher's linear discriminant. As the name implies, the central model is linear in the covariates,

$$y = w^T x$$

optimizing, for binary classification, a discriminant function derived from the mean  $m_i$  and variance  $s_i$  of each class (i.e.,  $i = 1, 2$ ), namely

$$J(w) = \frac{(m_1 - m_2)^2}{s_1^2 + s_2^2}.$$

In general, given the two data cohorts, the covariance matrix of the data  $S$  has a strict decomposition into within- and between-class covariance matrices as  $S = S_w + S_b$ . For an overall data mean vector  $m$  and a total of  $N_j$  data points in each class, these matrices are given by

$$\begin{aligned} S &= \sum_{i=1}^N ((x_i - m)^T (x_i - m)), \\ S_w &= \sum_{j=1}^2 \sum_{i=1}^{N_j} ((x_i - m_j)^T (x_i - m_j)), \\ S_b &= \sum_{j=1}^2 (N_j (m_j - m)^T (m_j - m)). \end{aligned}$$

The solution to the optimization of  $J(w)$  is

$$w \propto S_w^{-1} (m_2 - m_1),$$

where the inverse of the within-class covariance matrix  $S_w$  positions the discriminant hyperplane so as to minimize the overlap between the projections of the data points in each class onto the direction of the weight  $w$ . This illustrates the observation that, in general, this projection will not be calibrated with a probabilistic estimate such as the logit

$$\text{logit}(P(C|X)) = \log \left( \frac{P(C|X)}{1 - P(C|X)} \right).$$

The correct calibration is found in a class of generalized linear models of the form

$$y(x) = f(w^T x + w_0),$$

where  $f(\cdot)$  is known as the *activation function* in machine learning and its inverse is called a *link function* by statisticians [31.6]. Perhaps the best-known choice of activation is the sigmoid function, where the probabilistic model becomes logistic regression and the linear index  $w^T x$  represents exactly the logit ( $P(C|X)$ ). This is very widely used and a generally well-calibrated model, even when severe class imbalance is present.

It is often quoted that generalized linear models are limited by the discriminant forms determined by the linear scores, which must therefore be hyperplanes. However, this ignores the observation that, in most practical applications, suitable attribute representations are defined using domain knowledge, typically by binning variables into discrete states. This turns the probabilistic estimators into linear-in-the-parameter models with significant discrimination potential for nonlinearly separable data. In effect, if the link function is properly tuned to the noise structure of the data and in particular when there are larger numbers of independent covariates, well-designed generalized linear models are competitive with flexible machine learning models, the more so as the limitation of using a linear-in-the-parameters scoring index now works as a form of regularization limiting the complexity of the model. Moreover, the linear index provides a strong element of interpretability whose importance to application domain experts cannot be overestimated. Notwithstanding the power of machine learning, generalized linear models should always be used as benchmarks to set against nonlinear models.

An alternative to probabilistic linear models is the wide range of flexible direct estimators of  $P(C|X)$  among which arguably the most widely used model remains the multilayer perceptron (**MLP**). Similarly to linear statistical models, however, it is important to note that the estimation of class conditional probabilities with an **MLP** is contingent on using a correct activation function at the output node together with a suitable choice of loss function, which must be one of the entropy functions outlined in the previous section. So, in binary classification, the log-likelihood function with a Bernoulli distribution should be used in conjunction with a sigmoid activation function. In the multinomial case, we would need an extension of the sigmoid function, the softmax activation, together

with the cross-entropy as the loss function, since this is the correct measure of the divergence between the estimated and observed probability density functions. Similarly, for nonlinear regression, the activation function should be linear with the usual sum-of-squares error function, provided the inherent noise in the data can be assumed to be normally distributed with zero mean, since this is where the loss function is derived from. In the event where the noise variance, for instance, is dependent on the covariates, heteroscedastic noise models must be used to derive appropriate loss functions [31.6].

While the strength of neural networks is their universal approximation capability, in the sense of fitting any multivariate surface to an arbitrarily small error, this flexibility also makes them prone to overfitting, potentially resulting in data models with little bias but large variance, in direct contrast to generalized linear models. In both cases, it is necessary to control the complexity of the model and this is best done by adding a penalty term to enforce the principle of parsimony, colloquially known as Occam's razor (*lex parsimoniae*). Arguably, the most commonly used and effective scheme is to apply Bayes' theory at the level of fitting the model parameters, then to the regularization hyperparameters, and finally to model selection itself.

As we saw previously, the output of the **MLP** represents a direct estimate of the posterior probability of class membership  $P(C|X)$ . This approach can be generalized for the analysis of longitudinal data where each individual subject is follow up over a period of time starting with a defined recruitment point and ending either at the end of a defined observation period or when an event of interest is observed, whichever occurs first. This is often called *survival modeling* and is typically used to estimate event rates in the presence of censorship, e.g., where the outcome of interest, for instance recovery from an illness, is observed in some subjects for only part of the allowed period of follow-up due to other events taking over, such as another condition setting-in, which prevent the observer from ever knowing whether or not the subject would have recovered from the original illness, which is the event of interest. For discrete time, these models can be estimated using the standard **MLP** with an additional input node coding the time intervals. The output of the **MLP** again represents a conditional probability, but now the probability of the subject surviving each time interval given that the subject survived until the start of the time interval. This defines the hazard function  $h_l(\mathbf{x}_i)$ , for subject with covariate vector  $\mathbf{x}_i$  and predictions over the  $l$ th discrete

time interval, which is given by

$$h_l(\mathbf{x}_i) = P(T \leq t_l | T > t_{l-1}, \mathbf{x}_i).$$

For a single event of interest, i.e., a single *risk factor*, the log-likelihood function exactly mirrors that used in binary classification, treating as independent the probability estimates for each of the  $N$  subjects and over the discrete time intervals where the subject was observed, i.e., up to the end of the follow-up period or until censorship. This leads to the following loss function

$$L_B = \prod_{i=1}^N \prod_{l=1}^{l_i} \left\{ h_l(\mathbf{x}_i)^{d_{il}} [1 - h_l(\mathbf{x}_i)]^{(1-d_{il})} \right\}, \quad (31.3)$$

where the binary indicator variable  $d_{il} = 0$  if the event of interest was not observed for the subject during the specific time interval, and is 1 otherwise. This loss function is known as a partial likelihood, since it is measured only over time periods where the outcomes for each subject are observed, an approach that has been extended to the multinomial case to provide a rigorous treatment of censorship with flexible models in the context known as competing risks [31.45].

Application of the Bayesian regularization framework consists in maximizing the posterior probability for the model parameters  $w$ , given the data set  $\mathcal{D}$ , the regularization hyperparameters  $\alpha$  and the choice of the model structure, e.g., selected covariates  $H$ , namely

$$P(w|\mathcal{D}, \alpha, H) = \frac{P(\mathcal{D}|w, \alpha, H)P(w|\alpha, H)}{P(\mathcal{D}|\alpha, H)}. \quad (31.4)$$

The first term on the right-hand side of Eq. (31.4) denotes the probability of the model fitting the data, represented by the exponential of the entropy term discussed in the introduction and defined for longitudinal data by (31.3), hence

$$P(\mathcal{D}|w, \alpha, H) = e^{-L_B}.$$

The second term in (31.4) represents a *prior* distribution of the model parameters typically with a quadratic loss term corresponding to independent zero-mean univariate Gaussian distributions, sometimes called weight decay terms. A particularly efficient implementation of Bayesian regularization is to assign a separate weight decay term to each covariate, indexing the covariates by  $m$  of which there are  $N_\alpha$ , with the  $N_m$  hidden nodes indexed by  $n$ . This allows each covariate to be separately turned on or off depending on how informative it is

for fitting the observations about the outcome variable, a process known as *automatic relevance determination (ARD)* [31.4]. Expressed in full, this gives

$$P(w|\alpha, H) = \frac{e^{-G(w, \alpha)}}{Z_w(\alpha)}, \quad \text{where } G(w, \alpha) \\ = \frac{1}{2} \sum_{m=1}^{N_\alpha} \alpha_m \sum_{n=1}^{N_m} w_{mn}^2 \quad \text{and} \quad Z_w = \prod_{m=1}^{N_\alpha} \left( \frac{2\pi}{\alpha_m} \right)^{\frac{N_m}{2}}.$$

In principle, the best values for the regularization hyperparameters, i.e., the weight decay parameters  $\alpha$ , are those which minimize their *posterior* probability

$$P(\alpha|\mathcal{D}, H) = \frac{P(\mathcal{D}|\alpha, H)P(\alpha|H)}{P(\mathcal{D}|H)}.$$

However, the denominator of (31.4) cannot be obtained in closed form, so a Laplace approximation is typically around a stationary point in the loss function as a function of the weights. This amounts to a local Taylor expansion of

$$P(\mathcal{D}|\alpha, H) = \int P(\mathcal{D}|w, \alpha, H)P(w|\alpha, H)dw \\ = \int \frac{e^{-S(w, \alpha)}}{Z_w(\alpha)} dw,$$

where the linear term in the weights vanishes because of stationarity leading to

$$S^*(w, \alpha) \approx S(w^{\text{MP}}, \alpha) + \frac{1}{2}(w - w^{\text{MP}})^T A(w - w^{\text{MP}}),$$

from which the posterior probability for the hyperparameter results

$$P(\alpha|\mathcal{D}, H) \propto \frac{e^{-S(w^{\text{MP}}, \alpha)}}{Z_w(\alpha)} (2\pi)^{\frac{N_w}{2}} \det(A)^{-1/2}.$$

In practice, what this means is that the log-odds ratio, given by the activation of the output node of the **MLP** can be assumed to have a univariate normal distribution whose variance is given by the Hessian of the matrix  $S$  with respect to the weights;  $g$  is the gradient of the activation  $a$  with respect to the weights, namely

$$P(a|X, \mathcal{D}) = \frac{1}{1} (2\pi s^2)^{1/2} e^{-\left(\frac{(a-a_{\text{MP}})^2}{2s^2}\right)}$$

with  $a_{\text{MP}}$  denoting the most probable value of the activation function, i.e., the direct output of the **MLP** without marginalization, and

$$s^2(x) = g^T A^{-1} g.$$

The so-called marginalized estimate of the **MLP** output is now the posterior distribution integrated over the activation  $a$ . In the above expression,  $g$  is the gradient of the activation with respect to the network weights and  $A$  is the corresponding Hessian; hence the matrix of second partial derivatives. For binary classification and single-risks modeling, this is given by a neat analytical expression

$$h(x_i, l) = \int g(a)P(a|X_i = x_i, l, \mathcal{D})da \\ = g\left(\frac{a^{\text{MP}}(x_i, l)}{\sqrt{1 + (\pi/8)g^T A^{-1} g}}\right) \quad (31.5)$$

with  $g(\cdot)$  denoting the sigmoid function. This adjustment to the original **MLP** output, i.e.,  $a^{\text{MP}}$ , shows the regularization process in operation: stationary points, where the weights are well defined, have small variance  $s^2$  and therefore their value remains almost unchanged. Conversely, flat valleys in the loss function, where stationary points for the weights have broad Gaussian distributions, are penalized by reducing the value of the argument of the sigmoid function in (31.5) toward nil, reflecting an increase in uncertainty by shifting the **MLP** output toward the *don't know* threshold.

A probabilistic alternative to discriminative approaches consists of generative models, where Bayes' theorem is once again put into practice to estimate the *posterior* probability of class membership  $P(C_k|X)$ , from the *class conditional density* functions  $P(X|C_k)$  and *prior* probabilities for the classes  $P(C_k)$ , that is

$$P(C_k|X) = \frac{P(X|C_k)P(C_k)}{\sum_k P(X|C_k)P(C_k)}, \quad (31.6)$$

where classes are indexed by  $k$  and the sum-rule has been used to expand the denominator. Suitable models for the probability density functions (**pdf**) of the data given each class will depend on the nature of the data. However, it is straightforward to show for two classes that if the **pdfs** are normal distributions with equal variance, then the posterior probability will have exactly the functional form of the logistic regression model. This can be taken as an explanation in probabilistic terms of the potential limitations of this linear model, since different classes in practice tend to have distinct variances, even when that data sets for each class are approximately normally distributed. A natural

extension of this approach is to use a mixture of Gaussian distributions. This is a very flexible model that can parameterize also multimodal density functions. In the interest of space, we refer the interested reader to a standard textbook [31.6].

The two approaches of discriminative and generative models may be combined by using generative models to build kernels. These kernels define similarity between two covariate vectors  $\mathbf{x}$  and  $\mathbf{x}'$  by correlation between the respective pdfs, with the values of the kernel function given by  $k(\mathbf{x}, \mathbf{x}') = P(X = \mathbf{x}) \cdot P(X' = \mathbf{x}')$  for suitable choices of the probability functions. A ker-

nel so designed will naturally form a Gram matrix. Such kernels lead naturally to the use of latent variables

$$k(\mathbf{x}, \mathbf{x}') = \sum_i P(X = \mathbf{x}|Z = i)P(X' = \mathbf{x}'|Z = i) \\ \times P(Z = i),$$

with weighting coefficients  $P(Z)$  reflecting the strength of the latent variable  $Z$  indexed by  $i$ . An example of this approach in practice will be seen in the HMMs later in this chapter (see Sect. 31.4.2).

## 31.2 Graphical Models

In this section, we give a basic introduction to *graphical models*, a general framework for dealing with uncertainty in a computationally efficient way. Probabilistic models that we treat in the next sections belong to this framework. Here, we introduce the two main classes of graphical models, Bayesian and Markov networks, discussing different methods for performing probabilistic inference. Specific instances of learning within this framework, are given in the next two sections. For the sake of presentation, here we limit our presentation to discrete random variables; however, graphical models can be defined on continuous variables or mixed variables. The material covered in this section is based on [31.6, 46, 47].

A graphical model allows us to represent a family of joint probability distributions in terms of a directed or undirected graph, where nodes are associated with random variables, and edges represent some form of direct probabilistic interaction between variables. Being able to compactly represent the joint probability distribution of a set of random variables  $\mathcal{X} = \{X_1, \dots, X_n\}$  is very important: any probabilistic query involving the variables  $X_1, \dots, X_n$  can be answered by knowing their joint probability distribution  $P(X_1, \dots, X_n)$ . For example, assume variables to be discrete, and suppose we want to know the posterior probability of  $X_1$  and  $X_2$  given all the other variables, i. e.,  $P(X_1, X_2|X_3, \dots, X_n)$ . We can easily answer this query by computing

$$P(X_1, X_2|X_3, \dots, X_n) \\ = \frac{P(X_1, \dots, X_n)}{\sum_{\substack{X_1 \in \text{dom}(X_1) \\ X_2 \in \text{dom}(X_2)}} P(X_1 = x_1, X_2 = x_2, X_3, \dots, X_n)}.$$

Unfortunately, storing the joint probability values associated with all the different assignments  $x_1, \dots, x_n$  is not feasible: if  $d_i$  is the size of  $\text{dom}(X_i)$ , all the different assignments are  $\prod_{i=1}^n d_i$ , i. e., an exponential number of entries. This situation, however, constitutes the worst case. In fact, in many application domains, independence properties allow us to factorize the joint distribution into compact parts which can be stored efficiently. Graphical models provide the *language* to compactly represent these factors, enabling in many cases inference and learning over a compact parameterization of the joint distribution as graphical manipulations.

Graphical models can be characterized according to the type of probabilistic interaction between variables they model. Directed graphs (*Bayesian networks*) are used to express causal relationships between random variables (i. e., *cause*  $\rightarrow$  *effect* relationships), while undirected graphs (*Markov networks*) are better suited to express probabilistic constraints among subset of variables to which it is difficult to ascribe a directionality (graphical models containing both directed and undirected edges are possible; however, they will not be covered here). In both cases, the joint distribution is factorized according to the notion of *conditional independence*.

### Definition 31.1 Conditional Independence

Let  $\mathcal{X}$ ,  $\mathcal{Y}$ ,  $\mathcal{Z}$  be sets of random variables with  $X_i \in \mathcal{X}$ ,  $Y_i \in \mathcal{Y}$ ,  $Z_i \in \mathcal{Z}$ .  $\mathcal{X}$  is conditionally independent of  $\mathcal{Y}$  given  $\mathcal{Z}$  (denoted as  $\mathcal{X} \perp\!\!\!\perp \mathcal{Y}|\mathcal{Z}$ ) in a distribution  $P$  if, for all values  $x_i \in \text{dom}(X_i)$ ,  $y_i \in \text{dom}(Y_i)$ ,  $z_i \in \text{dom}(Z_i)$

$$P(\mathcal{X} = \mathbf{x}, \mathcal{Y} = \mathbf{y}|\mathcal{Z} = \mathbf{z}) = P(\mathcal{X} = \mathbf{x}|\mathcal{Z} = \mathbf{z}) \\ \times P(\mathcal{Y} = \mathbf{y}|\mathcal{Z} = \mathbf{z}),$$

where  $\mathcal{X} = \mathbf{x}$  denotes  $X_1 = x_1, \dots, X_{n_X} = x_{n_X}$ ,  $\mathcal{Y} = \mathbf{y}$  denotes  $Y_1 = y_1, \dots, Y_{n_Y} = y_{n_Y}$ ,  $\mathcal{Z} = \mathbf{z}$  denotes  $Z_1 = z_1, \dots, Z_{n_Z} = z_{n_Z}$ , and  $n_X = |\mathcal{X}|$ ,  $n_Y = |\mathcal{Y}|$ ,  $n_Z = |\mathcal{Z}|$ .

It is not difficult to see that if  $\mathcal{X} \perp\!\!\!\perp \mathcal{Y}|\mathcal{Z}$ , then it is also true that  $P(\mathcal{X}|\mathcal{Y}, \mathcal{Z}) = P(\mathcal{X}|\mathcal{Z})$ . In fact, using the product rule for probabilities, we have  $P(\mathcal{X}, \mathcal{Y}|\mathcal{Z}) = P(\mathcal{X}|\mathcal{Y}, \mathcal{Z})P(\mathcal{Y}|\mathcal{Z})$ .

In the following, we will discuss how conditional independence is used within Bayesian and Markov networks to factorize the joint distribution. Inference and learning will be discussed as well.

### 31.2.1 Bayesian Networks

Bayesian networks are directed acyclic graphs used to model causal relationships between random variables: an edge  $X_1 \rightarrow X_2$  is used to express the fact that variable  $X_1$  (*cause*) influences variable  $X_2$  (*effect*). The combination of this interpretation in conjunction with the exploitation of conditional independence, where applicable, allows the efficient probabilistic modeling of many relevant application domains. In general, the product rule can be used to factorize the joint distribution of variables  $X_1, X_2, X_3, \dots, X_n$  as

$$P(X_1, X_2, X_3, \dots, X_n) = \prod_{i=1}^n P(X_i|X_1, X_2, \dots, X_{i-1}). \quad (31.7)$$

The conditional independence relationships can be used to *simplify* the form of each factor in (31.7), i.e., by eliminating variables from the conditioning part, thus drastically reducing the number of probability values that need to be specified to define the factor. For example, if we assume that all the variables are Boolean, then the number of entries needed to define  $P(X_n|X_1, X_2, \dots, X_{n-1})$  would be  $2^{n-1}$ . If we consider a simple scenario in which the variable  $X_n$  is dependent only on  $X_{n-1}$ , the corresponding simplified factor becomes  $P(X_n|X_1, X_2, \dots, X_{n-1}) = P(X_n|X_{n-1})$ , which only requires two entries.

The *naïve Bayes* model used in classification tasks can be understood as a Bayesian network, where the variable associated with the class label  $C$  is the cause and the variables  $X_1, \dots, X_n$  used to describe the attributes of the current input are the effects. The underlying conditional independence assumption is fairly simplistic, but allows a very parsimonious factorization of the joint distribution. By assuming that the class label does not depend on the attributes, and that the at-

tributes are conditionally independent with respect to each other given the class label, i.e.,  $\forall i, j P(X_i, X_j|C) = P(X_i|C)P(X_j|C)$ , *naïve Bayes* factorizes the joint distribution as

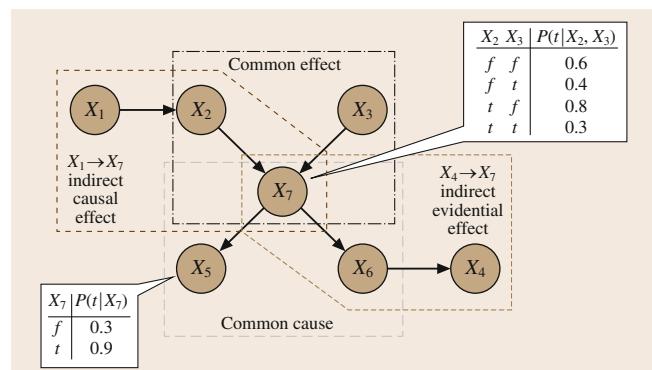

$$P(C, X_1, X_2, X_3, \dots, X_n) = P(C) \prod_{i=1}^n P(X_i|C).$$

The details of this model are not discussed in this chapter, but a good didactic reference is [31.6].

In general, after simplification via conditional independence, factors are in the form  $P(X_i|X_{j_1}, \dots, X_{j_k})$ , where  $X_{j_1}, \dots, X_{j_k}$  are denoted as *parents* of  $X_i$ , and the notation  $\text{pa}(X_i)$  is used with the following meaning  $\text{pa}(X_i) = \{X_{j_1}, \dots, X_{j_k}\}$ . The factor associated with variable  $X_i$  can thus be rewritten as  $P(X_i|\text{pa}(X_i))$  and the joint distribution as

$$P(X_1, X_2, X_3, \dots, X_n) = \prod_{i=1}^n P(X_i|\text{pa}(X_i)). \quad (31.8)$$

The graphical representation of a Bayesian network is shown in Fig. 31.1. The graphical model includes one node for each involved variable. Moreover, a variable that is conditioned (effect) with respect to a parent one (cause) receives a directed edge from that variable. For example, in the Bayesian network represented in Fig. 31.1, we have  $\text{pa}(X_7) = \{X_2, X_3\}$ , i.e., the set constituted by the two nodes from which  $X_7$  receives an edge. This means that the factor associated with  $X_7$  is  $P(X_7|X_2, X_3)$ . In Fig. 31.1, we have reported one popular way to specify the parameters of  $P(X_7|X_2, X_3)$  when the involved variables are discrete, i.e., the *conditional*

**Fig. 31.1** An example of Bayesian network. Conditional probability tables are shown only for variables  $X_5$  and  $X_7$ . Different types of probabilistic influence among variables are highlighted

*probability distribution table* (CPD table). The CPD of  $X_7$  in Fig. 31.1, for instance, reports the probability of  $X_7 = t$ , given each possible assignment of values to its parents. The CPD table associated with  $X_5$  is reported as well. By using the CPD tables associated to all nodes, the joint distribution can be rewritten as

$$\begin{aligned} P(X_1, \dots, X_7) &= P(X_1)P(X_3)P(X_2|X_1)P(X_7|X_2, X_3) \\ &\quad \times P(X_5|X_7)P(X_6|X_7)P(X_4|X_6). \end{aligned}$$

Note that different distributions can be obtained by using different values for the entries of the CPD tables. Thus, a Bayesian network is actually representing a family of distributions: all the distributions that are consistent with the conditional independence assumptions used to simplify the factors. In fact, up to now, we have discussed how starting from a *universal* decomposition of the joint distribution via the product rule (note that such decomposition is not unique as it depends on the presentation order assigned to the variables), a set of conditional independence assumptions can be used to simplify the factors, leading to the corresponding graphical representation given by the Bayesian network. An important question, however, is whether the topological structure of a Bayesian network allows for the direct identification of other (conditional) independence relationships, i.e., whether there exist other (conditional) independence relationships that *must* hold for *any* joint distribution  $P$  that is compatible with the structure of a specific Bayesian network (note that additional relationships may hold only for *some* specific distributions, i.e., some specific assignment of values to the entries of the CPD tables). As we will see later, the answer to this question is important to devise general-purpose inference algorithms on Bayesian networks. A general procedure, called *d-separation* (directed separation), can answer the question. It is based on the observation that two variables are not independent if one can influence the other via one or more paths in the graph. Let us exemplify this concept on the Bayesian network reported in Fig. 31.1, where we have highlighted four different basic cases:

1. *Indirect causal effect*:  $X_1$  can influence  $X_7$  via  $X_2$  if and only if  $X_2$  is not observed (a variable is said to be observed if the value assigned to that variable is known).
2. *Indirect evidential effect*:  $X_4$  can influence  $X_7$  via  $X_6$  if and only if  $X_6$  is not observed.
3. *Common cause*:  $X_5$  can influence  $X_6$  (and viceversa) via  $X_7$  if and only if  $X_7$  is not observed.

4. *Common effect*:  $X_2$  can influence  $X_3$  (and viceversa) if and only if either  $X_7$  or one of  $X_7$ 's descendants (in this case,  $X_5, X_6, X_4$ ) is observed.

The topological structure encountered in the *common effect* is called *v-structure* and it plays a relevant role in the *d-separation* procedure. In general, it is clear from above that probabilistic influence does not follow edge direction. Thus, when considering a longer trail, e.g., the path from  $X_1$  to  $X_4$ , we have to consider whether each part of the trail allows probabilistic influence to flow or not (according to the four basic cases described above).

### Definition 31.2 Active Trail

Let  $X_1, \dots, X_k$  be a trail in a Bayesian network  $\mathbf{G}$ , and  $\mathcal{E}$  be a subset of observed variables in  $\mathbf{G}$ . The trail  $X_1, \dots, X_k$  is active given  $\mathcal{E}$  if:

- Whenever a *v-structure*  $X_{i-1} \rightarrow X_i \leftarrow X_{i+1}$  does occur,  $X_i$  or one of its descendants belong to  $\mathcal{E}$ ;
- No other node along the trail belongs to  $\mathcal{E}$ .

Of course, by definition, if  $X_1 \in \mathcal{E}$  or  $X_n \in \mathcal{E}$  the trail is not active. Examples of active/not active trails from the Bayesian network represented in Fig. 31.1 are: the trail  $X_1, X_2, X_7, X_6, X_4$  is active given the set  $\mathcal{E} = \{X_3, X_5\}$ , while it is not active whenever either  $X_2$  or  $X_7$  or  $X_6$  belongs to  $\mathcal{E}$ ; on the other hand, the trail  $X_1, X_2, X_7, X_3$  is active if  $X_2 \notin \mathcal{E}$  and either  $X_7$  or  $X_5$  or  $X_6$  or  $X_4$  belongs to  $\mathcal{E}$ .

The Bayesian network represented in Fig. 31.1 does not allow more than one trail between any couple of nodes. In general, however, two nodes may have several trails connecting them and one node can influence the other one as long as there exist at least one active trail among them. This intuition is captured by the definition of the concept of *d-separation*.

### Definition 31.3 d-Separation

Let  $\mathcal{X}, \mathcal{Y}, \mathcal{Z}$  be nonintersecting sets of nodes of a Bayesian network.  $\mathcal{X}$  and  $\mathcal{Y}$  are *d-separated* given  $\mathcal{Z}$  if there is no active trail between any node  $X \in \mathcal{X}$  and  $Y \in \mathcal{Y}$  given  $\mathcal{Z}$ .

The *d-separation* test can be used to precisely characterize the independence relationships which hold for probabilistic distributions that factorize according to the given Bayesian network.

In the following, we introduce another class of graphical models, i. e., Markov networks, which are described by undirected graphs.

### 31.2.2 Markov Networks

Directed edges in Bayesian networks are suited to describe causal relationships between random variables. In many cases, however, the probabilistic interaction between two variables is not directional. In these cases, it is natural to consider *undirected graphs*, i. e., *Markov networks*. An undirected edge between variables  $X$  and  $Y$  represents a probabilistic constraint between the two variables. On the other hand, if  $X$  and  $Y$  are not connected, then we can state a conditional independence assertion involving them if and only if there are no active trails connecting them in the graph. Note that, since edges are now undirected, a trail is not active if and only if any of the variables in the trail is observed. This leads us to discuss which kind of joint distribution factorization a Markov network does represent.

If we go back to the concept of active trail, it is clear that if we consider a subset  $S$  of fully connected nodes in the undirected graph, i. e., nodes in  $S$  are connected to each other, then any  $X, Y \in S$  will be connected by so many trails involving nodes in  $S \setminus \{X, Y\}$  that it is wise to consider a single factor  $\phi_S$  involving all nodes in  $S$ . Technically,  $S$  is called a *clique*, and we are actually interested in *maximal cliques*, i. e., cliques which cannot be extended in size by considering another node of the graph. For example, the maximal cliques of the Markov network given in Fig. 31.2 are

$$\begin{aligned} c_1 &= \{X_1, X_3, X_5\}, c_2 = \{X_1, X_2\}, \\ c_3 &= \{X_2, X_4\}, c_4 = \{X_3, X_4\}. \end{aligned}$$

Note that, while  $\{X_1, X_5\}$  is a clique, it is not maximal since we can add  $X_3$  obtaining a larger clique.

A different factor can be associated with each maximal clique  $c_i$ . By using a global normalization constant for the joint distribution factorization, a factor associated with a clique  $c_i$  can be modeled by a *potential function*  $\phi_{c_i}(\cdot)$ , i. e., any nonnegative function (see Fig. 31.2 for involving Boolean variables). Thus, the factorization of the joint distribution for the example in Fig. 31.2 is

$$\begin{aligned} P(X_1, X_2, X_3, X_4, X_5) &= \frac{1}{Z} \phi_{c_1}(X_1, X_3, X_5) \phi_{c_2}(X_1, X_2) \\ &\quad \times \phi_{c_3}(X_2, X_4) \phi_{c_4}(X_3, X_4), \end{aligned}$$

where the normalization constant

$$\begin{aligned} Z = \sum_{\forall i, x_i \in X_i} &\phi_{c_1}(X_1, X_3, X_5) \phi_{c_2}(X_1, X_2) \\ &\times \phi_{c_3}(X_2, X_4) \phi_{c_4}(X_3, X_4) \end{aligned}$$

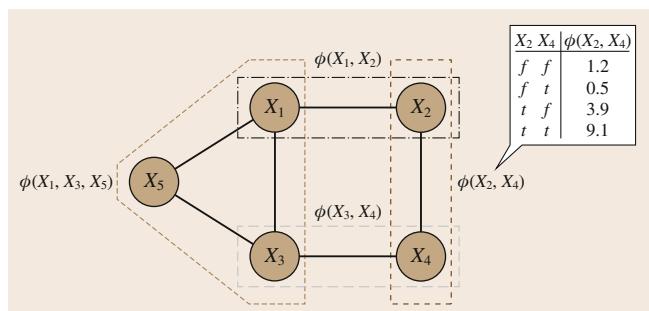

is called the *partition function*. If with  $\mathbf{x}$  we denote an assignment of values to the variables  $X_1, \dots, X_n$  and with  $\mathbf{x}_{c_i}$  the corresponding assignments associated with variables in the clique  $c_i$ , the general formulas for a Markov network are

$$P(X_1, \dots, X_n) = \frac{1}{Z} \prod_{\forall i, c_i} \phi_{c_i}(\mathbf{x}_{c_i}),$$

where

$$Z = \sum_{\mathbf{x}} \prod_{\forall i, c_i} \phi_{c_i}(\mathbf{x}_{c_i}).$$

If the potential functions are restricted to be strictly positive, then it is possible to find a precise correspondence between factorization and conditional independence. In fact, if we consider the set of all possible distributions defined over variables of a given Markov network, then the set of such distributions that are consistent with the conditional independence statements that can be derived by using the adapted concept of active trails and  $d$ -separation coincides with the set of distributions that can be expressed as a factorization of the form given above with respect to maximal cliques of the network (*Hammersley–Clifford theorem*).

**Fig. 31.2** An example of Markov network involving five variables. Maximal cliques and corresponding potential functions are highlighted. An example of potential function is given for clique  $\{X_2, X_4\}$ , where we have assumed that  $X_2$  and  $X_4$  are Boolean variables

For practical reasons, it is convenient to express a strictly positive potential function as a *Boltzmann distribution*, i. e.,

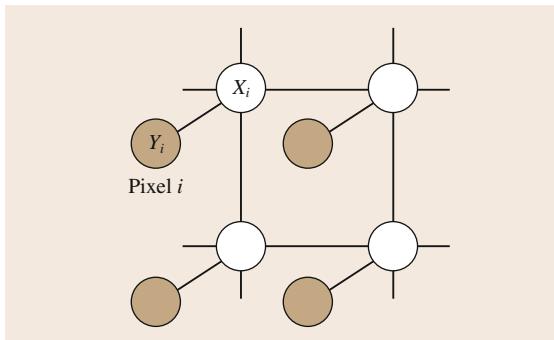

$$\phi_{c_i}(\mathbf{x}_{c_i}) = e^{-E(\mathbf{x}_{c_i})},$$

where  $E(\mathbf{x}_{c_i})$  is called an *energy function*. Since the joint distribution is the product of potentials, the total energy is obtained by adding the energy functions of each of the maximal cliques. Energy functions are very useful since, in the absence of a specific probabilistic interpretation for the potential functions, assignments of values that have high probability can be given low energies, while less probable assignments will correspond to high energies.

Let us give an example of application of Markov networks: image de-noising. The task is to remove noise from a binary image  $\mathcal{Y}$  where the pixels  $Y_i$  are  $-1$  or  $+1$ . Each observed pixel  $Y_i$  is obtained by a noise-free image  $\mathcal{X}$  with pixels  $X_i$  where, with some small probability, the sign of the pixel is flipped. Since neighboring pixels in the noise-free image are strongly correlated, as well as the two variables  $Y_i$  and  $X_i$ , due to the small flipping probability, we can use a Markov network like the one depicted in Fig. 31.3 to capture this knowledge. The total energy function encoding such prior knowledge would be

$$E(\mathcal{X}, \mathcal{Y}) = -\beta \sum_{X_i, X_j \in \mathcal{X}} X_i X_j - \eta \sum_{X_i \in \mathcal{X}, Y_i \in \mathcal{Y}} X_i Y_i,$$

where all the maximal cliques are considered and couples of pixels with the same sign get lower energy values. Since we are interested in removing noise from

**Fig. 31.3** A Markov network for image de-noising.  $Y_i$  is the binary variable representing the state of pixel  $i$  in the noisy observed image, while  $X_i$  refers to the noise-free image

the observed pixels  $Y_i$ , we add a bias toward pixel values that have one particular sign, by summing a term  $hX_i$  to the energy function for each pixel in the noise-free image

$$E(\mathcal{X}, \mathcal{Y}) = h \sum_{X_i \in \mathcal{X}} X_i - \beta \sum_{X_i, X_j \in \mathcal{X}} X_i X_j - \eta \sum_{X_i \in \mathcal{X}, Y_i \in \mathcal{Y}} X_i Y_i.$$

Note that this operation is legal since it corresponds to multiplying the potential function, which are arbitrary nonnegative functions, by a nonnegative function.

The factorized joint distribution over  $\mathcal{Y}$  and  $\mathcal{X}$  is then defined as

$$P(\mathcal{X}, \mathcal{Y}) = \frac{1}{Z} e^{-E(\mathcal{X}, \mathcal{Y})}.$$

Probabilistic inference can now be performed by clamping the value of  $\mathcal{Y}$  to the observed image, which implicitly corresponds to a conditional distribution  $P(\mathcal{X}|\mathcal{Y})$  over free images, and by computing the assignments to  $\mathcal{X}$  that minimizes the total energy of the Markov model, i. e., the assignment of values to pixels of  $\mathcal{X}$  with highest probability given the observed image  $\mathcal{Y}$ . The resulting assignment of values to  $\mathcal{X}$  will return the (presumed) noise-free version of  $\mathcal{Y}$ .

In the following, we briefly present different approaches to perform probabilistic inference in Bayesian and Markov networks.

### 31.2.3 Inference

Performing probabilistic inference in a graphical model over a set of random variables  $\mathcal{X}$  means being able to answer any probabilistic query involving  $\mathcal{X}$ . Since a graphical model, either a Bayesian or a Markov network, describes a factorization of the joint distribution, any probabilistic query can be answered, so the problem reduces to find efficient procedures to perform inference. In the following, we report some of the most typical form of queries:

- *Conditional:* In this case, we are interested in computing  $P(\mathcal{Y}|\mathcal{E} = \mathbf{e})$ , where  $\mathcal{Y}, \mathcal{E} \subseteq \mathcal{X}$ , with  $\mathcal{Y} \cap \mathcal{E} = \emptyset$ , where  $\mathcal{Y}$  are the *query* variables and  $\mathcal{E} = \{E_1, \dots, E_k\}$  are the *evidence* variables for which specific values  $\mathbf{e} = \{e_1, \dots, e_k\}$  have been observed.
- *Most probable assignment:* Given evidence  $\mathcal{E} = \mathbf{e}$ , we are interested in computing the most likely assignment  $\mathbf{y}^*$  to  $\mathcal{Y} \subseteq \mathcal{X} \setminus \mathcal{E}$ . There are two main variants for this kind of query: *most probable explanation* (**MPE**) and *maximum a posteriori* (**MAP**).

A **MPE** query must solve the problem

$$\mathbf{y}^* = \arg \max_{\mathbf{y}} P(\mathcal{Y} = \mathbf{y}, \mathcal{E} = \mathbf{e}),$$

where  $\mathcal{Y} = \mathcal{X} \setminus \mathcal{E}$ , while a **MAP** query must solve the problem

$$\mathbf{y}^* = \arg \max_{\mathbf{y}} \sum_{\mathbf{z}} P(\mathcal{Y} = \mathbf{y}, \mathcal{Z} = \mathbf{z} | \mathcal{E} = \mathbf{e}),$$

where  $\mathcal{Z} = \mathcal{X} \setminus \mathcal{E} \setminus \mathcal{Y}$ .

From the point of view of inference, both directed and undirected networks can be treated in the same way. In fact, directed networks can be converted to undirected networks. This is done by observing that factors in directed networks can be understood as factors corresponding to cliques in an undirected graph obtained by mutually connecting all the parents of each node by new undirected edges and by dropping direction from the original directed edges. This procedure is known as *moralization* and the resulting undirected graph is the *moral* graph. By this means, all the variables involved in factors of the directed graph (e.g., CPTs) will be contained in corresponding cliques of the moral graph. Thus, we can focus on undirected graphs.

From a computational point of view, in the worst case, probabilistic inference is difficult: every type of probabilistic inference in graphical models is  $\mathcal{NP}$ -hard or harder. Specifically, the complexity of inference is related to a topological property of the graphical network called *treenwidth*. Approximate inference methods have been devised to deal with such computational complexity. Unfortunately, approximate inference turns out to be hard, in the worst case. Nevertheless, if the *treenwidth* of the graphical network is not too large (e.g., in polytrees), exact inference can be performed in a reasonable amount of time. Moreover, in many practical cases, approximate inference is efficient and adequate.

There are three major approaches to perform inference: *exact* algorithms, *sampling* algorithms, and *variational* algorithms. The former tries to compute the exact probabilities while avoiding repeated computations. The second approach aims to efficiently approximate probabilities by sampling, in a smart way, the universe of events. Finally, the third approach allows us to treat both exact and approximate inference within the same conceptual framework. In the following, we briefly sketch the main ideas underpinning these approaches.

### Exact Algorithms

Let us illustrate one of the basic ideas of exact algorithms, i.e., *variable elimination*, by using the Markov network shown in Fig. 31.2, where we assume all variables to be Boolean. Suppose we are interested in computing the marginal probability  $P(X_2)$ . We can get it by summing the factorized joint distribution over the remaining variables

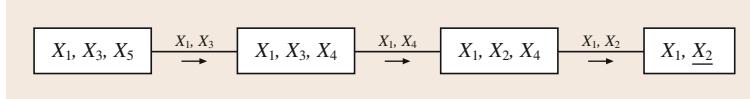

$$P(X_2) = \sum_{x_1} \sum_{x_3} \sum_{x_4} \sum_{x_5} \frac{1}{Z} \phi(X_1, X_3, X_5) \\ \times \phi(X_1, X_2) \phi(X_2, X_4) \phi(X_3, X_4).$$

Naïve computation of the above equation would require  $O(2^5)$  operations, since each summand involves five Boolean variables. However, we can rearrange the summands in a smarter way

$$P(X_2) = \frac{1}{Z} \sum_{x_1} \phi(X_1, X_2) \sum_{x_4} \phi(X_2, X_4) \sum_{x_3} \phi(X_3, X_4) \\ \times \sum_{x_5} \phi(X_1, X_3, X_5) \\ = \frac{1}{Z} \sum_{x_1} \phi(X_1, X_2) \sum_{x_4} \phi(X_2, X_4) \\ \times \sum_{x_3} \phi(X_3, X_4) m_5(X_1, X_3) \\ = \frac{1}{Z} \sum_{x_1} \phi(X_1, X_2) \sum_{x_4} \phi(X_2, X_4) m_3(X_1, X_4) \\ = \frac{1}{Z} \sum_{x_1} \phi(X_1, X_2) m_4(X_1, X_2) \\ = \frac{1}{Z} m_1(X_2),$$

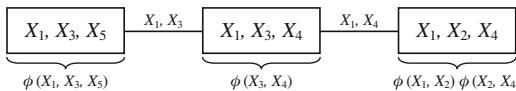

where the  $m_i$  terms are the intermediate factors obtained by summation on variable  $X_i$ . Note that  $Z$  can be computed by summing on variable  $X_2$ . Moreover, the total computational complexity reduces to  $O(2^3)$  since no more than three variables occur together in any summand. In general, the maximal number of variables that occur in any summand is determined by the elimination order. Since many different elimination orders may be used, the lowest complexity is obtained by the order that minimizes this maximal number, which is related to the *treenwidth* of the graph. Unfortunately, finding the optimal elimination order is  $\mathcal{NP}$ -hard.

One positive aspect of the elimination approach is that it also works for continuous variables since

**Fig. 31.4** Example of cluster graph, where the direction of the flow of computation is shown under each edge, while the scope of the computed factor transmitted to the other node after variable elimination is shown over each edge

it is only based on the topology of the graph. However, the elimination procedure returns only a single marginal probability, while it is often of interest to compute more than one marginal probability. Luckily, we can generalize the idea to efficiently compute all the single marginals. Here we give some hints on how to do it. Consider the sequence of intermediate factors generated in the example above. They can be indexed by the variables in their scope, i.e.,  $\psi_{1,3,5} = \phi(X_1, X_3, X_5)$ ,  $\psi_{1,3,4} = \phi(X_3, X_4)m_5(X_1, X_3)$ ,  $\psi_{1,2,4} = \phi(X_2, X_4)m_3(X_1, X_4)$ ,  $\psi_{1,2} = \phi(X_1, X_2)m_4(X_1, X_2)$ . Graphically, we can represent them via a *cluster graph*, where each node is associated with a subset of variables (i.e., the scope of intermediate factors) and the undirected edges *support* the flow of computation of the elimination process. In our example, the cluster graph is shown in Fig. 31.4, where we have shown the direction of the flow of computation under each edge, and the scope of the computed factor *transmitted* to the other node after variable elimination over each edge. The variable  $X_2$  in the rightmost node is underlined to remark that it is the *target* of the flow of computation. In general, since each edge is associated with a variable elimination, it is not difficult to realize that the cluster graph is in fact a tree (called *clique tree* or *junction tree*). This structure can also be used for computing other marginals. In order to see that, we have to observe that the scope of the rightmost node is a subset of the scope of the node at its left, so it can be merged with this last node; moreover, each *initial potential* must be associated with a node with consistent scope, e.g.,

Now, suppose we want to compute  $P(X_3)$  by eliminating all the other variables. We have to select a node which contains  $X_3$  in its scope, e.g., the middle node. The flow of computation should now converge toward that node, as shown in

Any elimination order consistent with the above flow will do the work, e.g., we first consider the leftmost node and eliminate  $X_5$  by transmitting the *message*

$$m_5(X_1, X_3) = \sum_{x_5} \phi(X_1, X_3, X_5)$$

to the middle node. Then, we do the same for the rightmost node, by eliminating  $X_2$  and transmitting the message

$$m_2(X_1, X_4) = \sum_{x_2} \phi(X_1, X_2)\phi(X_2, X_4).$$

Finally, the middle node can merge the two received messages with the local potential obtaining

$$\phi(X_3, X_4)m_5(X_1, X_3)m_2(X_1, X_4),$$

which is an unnormalized version of the joint distribution  $P(X_1, X_3, X_4)$ . Marginal  $P(X_3)$  can then be computed by summing out  $X_1$  and  $X_4$  and normalizing the result. Note that the same flow can be used to compute  $P(X_1)$  and  $P(X_4)$ : in the first case, the final stage will sum out  $X_3$  and  $X_4$ , while in the second case it will sum out  $X_1$  and  $X_3$ .

In general, *all* the factors needed by *all* the nodes to compute the marginals of the variables in their scope, can be computed by a *sum-product message passing* scheme where, having selected an arbitrary node as *root*, messages are transmitted from the leaves up to the root and then back from the root to the leaves. If evidence is present, *restricted* potentials (i.e., potentials where evidence variables are bound to the observed values) are used. MEP and MAP queries can be answered by using a *max-sum algorithm*, which is a variation of the sum-product algorithm exploiting a *trellis* over all the values the variables can take. The message passing scheme sketched above can also be implemented using *division*, giving raise to the *Belief Update* algorithm.

### Sampling Algorithms

The strategy adopted by sampling algorithms to perform (approximate) inference is to approximate the joint distribution via estimates computed on a set of

*representative* instantiations of all, or some of, the variables of the graphical model. Unlike exact inference, some techniques are specialized for directed networks. For example, a simple approach to estimate the joint probability in a Bayesian network is *Forward Sampling*. It starts by considering any topological ordering of the variables, e.g., for the network in Fig. 31.1 the order  $X_1, X_3, X_2, X_7, X_5, X_6, X_4$  will do the job. Then random samples are generated by following the order and by picking a value for each variable according to its distribution. Note that variables with conditional distributions will be considered only when specific values for their parents have already been generated, so that the conditional probability for those variables is fully specified. Once  $M$  full samples are generated in this way, the probability of a specific event  $P(\mathcal{E} = \mathbf{e})$  is estimated as the fraction of samples where variables in  $\mathcal{E}$  take values  $\mathbf{e}$ . If the query is of the form  $P(Y|\mathcal{E} = \mathbf{e})$ , samples which are not consistent with the evidence are rejected (*rejection sampling*) and the remaining samples used to estimate the conditional distribution on variables  $Y$ . With this approach, however, a large amount of generated samples are discarded.

An improvement on this aspect is given by the *likelihood weighting* algorithm, which is based on the observation that evidence variables can be forced to assume *only* the observed values in a sample as long as the sample is weighted by the likelihood of the evidence. This means that a weight is associated with each sample and the weight is given by the product of all the posterior probabilities corresponding to the observed values for the evidence variables, i.e.,

$$w_{\text{sample}} = \prod_{E_i \in \mathcal{E}} P(E_i = e_i | \text{pa}(E_i)).$$

Estimates are then computed considering weighted samples. Likelihood weighting turns out to be a special case of a more general approach called *importance sampling* which aims at estimating the expectation of a function relative to some distribution.

Improved sampling methods, which can also be applied to Markov networks, are given by *Markov chain Monte Carlo* methods. Unlike the methods described so far, these methods generate a *sequence* of samples, in such a way that later samples are generated by distributions that provably approximate with increasing precision the target posterior probability (i.e., the query  $P(Y|\mathcal{E} = \mathbf{e})$ ).

The simpler method uses *Gibbs sampling*: an initial assignment of values for the unobserved variables

is generated from an initial distribution; subsequently, in turn, each unobserved variable is sampled using the posterior probability *given* the current sample for all other variables. This distribution can be computed efficiently by using only factors associated with the *Markov blanket*, i.e., the neighbors of the variable to be resampled in the Markov network (in Bayesian networks, the Markov blanket of a node is given by the set of its parents, its children and the parents of its children). Using the theory of *Markov chains* (discussed in Sect. 31.4.1), it is possible to show that, under some assumptions, the sequence of generated distributions converges to a stationary distribution, where the fraction of time in which a specific assignment of values to variables (sample) does occur in the sequence is exactly proportional to the posterior probability of that assignment.

A drawback of Gibbs sampling is that it uses only *local moves* (i.e., resampling of a single variable), leading to very slow convergence for assignments with low probability. More effective methods, based on the *Metropolis–Hastings* approach, enable for a broader range of moves. Further, more advanced approaches allow us to consider partial assignments in conjunction with a closed-form distribution for unassigned variables. Others use deterministic methods to explicitly search for high-probability assignments to approximate the joint distribution.

### Variational Algorithms

Probabilistic inference can be formulated as a constrained optimization problem. This allows both to rediscover exact inference algorithms, such as the ones we have briefly discussed above, and to design approximated inference algorithms, by simplifying either the objective function to optimize and/or the admissible region for optimization. The possibility to devise theoretically founded approximation algorithms is particularly appealing in cases where the joint distribution is characterized by a factorization with associated large treewidth. Research in this area has been recently very active, yielding to several interesting results. Here we do not have the space for a proper technical treatment, so we try to give only a brief introduction to the main ideas.

Variational approaches are based on the idea of approximating an intractable probabilistic distribution with a simpler one, which allows for inference. This simpler distribution is selected from a family of tractable distributions, as the distribution that is the *best* approximation to the desired one. Can we define a mea-

sure of the quality of the approximation that can be used for the minimization process? A good measure is the **KL**-divergence introduced in (31.2). Let us denote a distribution that factorizes according to the graphical model  $\mathcal{G}$  as

$$P_{\mathcal{G}}(\mathcal{X}) = \frac{1}{Z} \prod_{\forall i, c_i} \phi_{c_i}(\mathbf{x}_{c_i}) \quad (31.9)$$

and let  $Q(\mathcal{X})$  be a member of the tractable distributions we use to approximate  $P_{\mathcal{G}}(\mathcal{X})$ . Then, a nice feature of **KL**-divergence is that it allows us to efficiently solve the optimization problem

$$\arg \min_{Q(\mathcal{X})} D_{\text{KL}}(Q(\mathcal{X}) \| P_{\mathcal{G}}(\mathcal{X}))$$

without requiring to perform inference in  $P_{\mathcal{G}}(\mathcal{X})$ . In fact, using the factorization of  $P_{\mathcal{G}}(\mathcal{X})$  in (31.9), it is not difficult to show that

$$\begin{aligned} D_{\text{KL}}(Q(\mathcal{X}) \| P_{\mathcal{G}}(\mathcal{X})) &= \log Z - \sum_{\forall i, c_i} \mathbb{E}_Q[\log \phi_{c_i}] \\ &\quad + \mathbb{E}_Q[\log Q(\mathcal{X})], \end{aligned} \quad (31.10)$$

and, since  $\log Z$  does not depend on  $Q(\mathcal{X})$ , minimizing  $D_{\text{KL}}(Q(\mathcal{X}) \| P_{\mathcal{G}}(\mathcal{X}))$  is equivalent to maximizing the *energy functional* term

$$\sum_{\forall i, c_i} \mathbb{E}_Q[\log \phi_{c_i}] - \mathbb{E}_Q[\log Q(\mathcal{X})].$$

Following from the definition in (31.1),  $H_Q(\mathcal{X}) = -\mathbb{E}_Q[\log Q(\mathcal{X})]$  is the entropy of  $Q$ , while the first term in (31.10) is referred to as *energy term*.

Different variational methods correspond to different strategies for optimizing the energy functional. The

name *variational* is used since all of them adopt the general strategy of reformulating the optimization problem by introducing new variational parameters to be used for optimization. In particular, each specific choice of values for the variational parameters expresses one member, i. e.,  $Q(\mathcal{X})$ , of the family of tractable distributions we want to use. The optimization procedure searches the space of variational parameters to find the  $Q^*(\mathcal{X})$  that best approximates  $P_{\mathcal{G}}(\mathcal{X})$ . It is important to understand that the family of tractable distributions will actually correspond to a set of constraints, involving the variational parameters that must be satisfied while maximizing the energy functional. By using *Lagrange multipliers* these constraints can be merged together with the energy functional, giving rise to a *Lagrangian* function that must be maximized. By taking the partial derivatives with respect to the variational parameters and the Lagrange multipliers, the solution to the optimization problem can be characterized by a set of *fixed-point equations*. These equations can then be used to straightforwardly devise an iterative solution.

Different variational methods work with different types of approximations. There are two main sources of approximation, which can be used singularly or in conjunction. One source is the energy functional, which can be substituted by a functional easy to manipulate while preserving a good degree of approximation. Another source of approximation are the constraints, i. e., the definition of the family of tractable distributions, which may not be fully consistent with the factorization represented by the graphical model (in this case, denoted as pseudo-distributions).

We do not have space here to give more details; however, it is worth to mention that while convergence proofs of several variational methods are available, it is not so common to find theoretical guarantees on the approximation error made by the specific method.

### 31.3 Latent Variable Models

Knowledge hindered in the complex relation between a large number of observable variables can be surfaced under the assumption that a simpler and unobservable process exists, which is responsible for generating the complex behavior of manifest data. Such an unobservable generative process can be modeled through the use of *latent variables*, as opposed to observable variables, that are not directly measurable, but can be inferred from observations and can explain the relation between manifest data. Intuitively, latent variables can be un-

derstood as an attempt to model the unknown physical process generating the observations or as an abstraction providing a simplified representation of the manifest data, e.g., clusters.

Probabilistic models that attempt to explain observations in terms of latent variables are called *latent variable models*. In probabilistic terms, the simplification introduced by latent variables results in conditional independence assumptions, such that (subsets of) observable variables can be considered conditionally

independent when their hidden explanation, i. e., the latent variable assignment, is given. Similarly to observed variables, latent variables can be discrete or continuous: their nature, together with that of the observations, determines different types of probabilistic models. Nevertheless, parameter estimation in the different latent variable models can be achieved through a general iterative principle, known as *expectation–maximization*.

### 31.3.1 Latent Space Representation

To understand the intuition at the basis of latent space representation, consider a joint distribution  $P(\mathcal{X}) = P(X_1, \dots, X_N)$  defined over  $N$  joint observed random variables  $X_i$ . As discussed in Sect. 31.2.1, without any simplifying assumption, the number of free parameters of this simple model grows as  $O(2^{N-1})$  for Boolean variables, which quickly becomes unmanageable for large  $N$ . One way to control the number of free parameters of a model, without taking too simplistic assumptions (e.g.,  $X_i$  being *i.i.d.*), is to introduce a collection of *latent*, or hidden, variables  $\mathcal{Z} = \{Z_1, \dots, Z_K\}$ . The latent variables are unobserved but can be used to factorize the joint distribution  $P(\mathcal{X})$  while allowing to capture (some of) the correlations between the  $\mathcal{X} = \{X_1, \dots, X_N\}$  observed variables. More formally, latent variables are such that

$$P(\mathcal{X}) = \int_{\mathbf{z}} P(\mathcal{X}|\mathcal{Z} = \mathbf{z})P(\mathcal{Z} = \mathbf{z})d\mathbf{z}, \quad (31.11)$$

that is the general formulation for the likelihood of a *latent variable model*. The details of the latent variable model, and the tractability of the integral in (31.11), are determined by the form of the conditional distribution  $P(\mathcal{X}|\mathcal{Z})$  and by the marginal probability  $P(\mathcal{Z})$ . A common approach in latent variable models is to assume that observed variables become conditionally independent given the latent variables, that is

$$P(\mathcal{X}) = \int_{\mathbf{z}} \prod_{i=1}^N P(X_i|\mathcal{Z} = \mathbf{z})P(\mathcal{Z} = \mathbf{z})d\mathbf{z}. \quad (31.12)$$

A basic assumption for this latent model to be effective, is that the conditional and marginal distributions should be more *tractable* than the joint distribution  $P(\mathcal{X})$ . For instance, in a simple scenario with discrete observations and latent variables, this entails that  $K \ll N$ . Not surprisingly, the same intuition is applied, in a deterministic context, for dimensionality reduction (cf. the number of projection directions in **PCA**) and clustering.

Different types of latent variable models are defined based on the nature of the latent and observed variables, as well as depending on the form of the conditional and marginal probabilities. In the following, we discuss two general classes of latent variable models with continuous and discrete hidden variables, which are *factor analysis* and *mixture models*, respectively.

### 31.3.2 Learning with Latent Variables: The Expectation–Maximization Algorithm

Learning, in a probabilistic setting, entails working with the model likelihood. In latent variable models, the likelihood in (31.11) might be difficult to treat due to the marginalization inside the logarithm, which can potentially couple all the model parameters. Despite the diversity of the models that can be designed, based on the general expression in (31.11), there exist a general principle to estimate their parameters.

The *expectation–maximization* (**EM**) algorithm [31.48] is a general iterative method for the maximization of the likelihood under latent variables. The key intuition of the **EM** algorithm is to define an alternative objective function where the parameter coupling introduced by the marginalization of the hidden variables is removed. The **EM** algorithm maximizes the marginal data likelihood  $P(\mathcal{X}|\theta)$ , where  $\theta$  are the model parameters, through a tractable lower bound defined by introducing a function of the latent variables, i. e.,  $Q(\mathcal{Z})$ , into the data likelihood through marginalization. For notational simplicity, consider the case of discrete latent variables. For any nonzero distribution  $Q(\mathcal{Z})$ , it holds

$$\begin{aligned} \mathcal{L}(\theta) &= \log P(\mathcal{X}|\theta) \\ &= \log \sum_{\mathbf{z}} P(\mathcal{X}, \mathcal{Z} = \mathbf{z}|\theta) \\ &= \log \sum_{\mathbf{z}} Q(\mathbf{z}) \frac{P(\mathcal{X}, \mathcal{Z} = \mathbf{z}|\theta)}{Q(\mathbf{z})} \\ &\geq \sum_{\mathbf{z}} Q(\mathbf{z}) \log P(\mathcal{X}, \mathcal{Z} = \mathbf{z}|\theta) \\ &\quad - \sum_{\mathbf{z}} Q(\mathbf{z}) \log Q(\mathbf{z}) = \tilde{\mathcal{L}}(Q, \theta), \end{aligned} \quad (31.13)$$

where the lower bound  $\tilde{\mathcal{L}}(Q, \theta) \leq \mathcal{L}(\theta)$  is obtained by the application of the Jensen inequality to the concave log function. The joint distribution  $P(\mathcal{X}, \mathcal{Z}|\theta)$  is known as the *complete data likelihood*, where the term

*complete* refers to the fact that the marginal data likelihood  $P(\mathcal{X}|\theta)$  is *completed* with the observations  $\mathbf{z}$  for the latent variables.

The *Expectation–maximization* algorithm defines an alternate optimization process where the bound  $\tilde{\mathcal{L}}(\mathcal{Q}, \theta)$  is maximized with respect to  $\mathcal{Q}(\cdot)$  and  $\theta$ . In general, this is performed by two independent maximization steps that are repeated until convergence:

- Expectation (E) Step: For  $\theta$  fixed, find the distribution  $\mathcal{Q}^{(t+1)}(\mathbf{z})$  that maximizes the bound  $\tilde{\mathcal{L}}(\mathcal{Q}, \theta^{(t)})$ ;
- Maximization (M) Step: Given the distribution  $\mathcal{Q}(\mathbf{z})^{(t+1)}$ , estimate the model parameters  $\theta^{(t+1)}$  that maximize the bound  $\tilde{\mathcal{L}}(\mathcal{Q}^{(t+1)}, \theta)$ ;

where the superscript denotes the estimate at time  $t$ . Clearly, the optimal solution for the *E-step* is attained when

$$\mathcal{Q}^{(t+1)}(\mathbf{z}) = P(\mathcal{Z} = \mathbf{z} | \mathcal{X}, \theta^{(t)}) , \quad (31.14)$$

that is when the lower bound in (31.13) becomes an equality. In practice, to explicitly evaluate the complete likelihood in  $\tilde{\mathcal{L}}(\mathcal{Q}, \theta^{(t)})$ , we would need to observe the  $\mathbf{z}$  assignments. These are unknown, since latent variables are unobservable. However, given the marginalization of  $\mathbf{z}$  in (31.13), we can substitute the unavailable  $\mathbf{z}$  observations with their expected values, by considering them as another random variable. To this end, it suffices that the E-step computes the expected value of the *complete log-likelihood*  $\log P(\mathcal{X}, \mathcal{Z}|\theta)$  with respect to  $\mathcal{Z}$ . These observations provide the final form of the *classical EM* algorithm:

- *E-step*: Given the current estimate of the model parameters  $\theta^{(t)}$ , compute

$$\mathcal{Q}^{(t+1)}(\theta | \theta^{(t)}) = E_{\mathcal{Z}|\mathcal{X}, \theta^{(t)}}[\log P(\mathcal{X}, \mathcal{Z}|\theta)] ; \quad (31.15)$$

- *M-step*: Find the new estimate of the model parameters

$$\theta^{(t+1)} = \arg \max_{\theta} \mathcal{Q}^{(t+1)}(\theta | \theta^{(t)}) . \quad (31.16)$$

In other words, the *E-step* estimates the value of the otherwise unobserved latent variables, while the *M-step* finds the parameters that maximize the current estimate of the log-likelihood. In practice, the *E-step* often reduces to estimating the expectation of  $\mathcal{Z}$  as its posterior

$P(\mathcal{Z}|\mathcal{X}, \theta^{(t)})$ , while the *M-step* uses these values as sufficient statistics to update the model parameters  $\theta^{(t+1)}$ . This alternate optimization is typically iterated until the log-likelihood does not change much between consecutive estimates, or when a number of maximum iterations is reached. Note that the two-step *EM* optimization process is prone to local optima. Hence, its convergence can be slow and, often, its solutions tend to be dependent on the initialization.

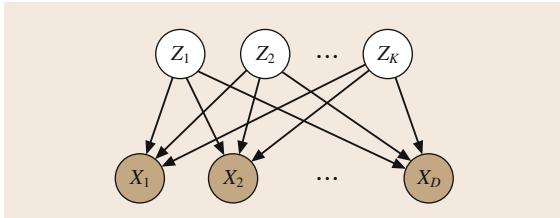

The *EM* algorithm assumes that we can calculate the expected value of the complete log-likelihood. However, there are cases in which the required summation is not computationally feasible (e.g., with infinite summations where the integral has no close-form solution): in these cases, the approximated inference methods described in Sect. 31.2.3 can be used to define nonexact *EM* algorithms. For instance, stochastic versions of the *EM* algorithm are obtained by approximating the infeasible summation using (e.g., Gibbs) sampling from the posterior distribution  $P(\mathcal{Z}|\mathcal{X}, \theta)$ . The classical *EM* algorithm is a *ML* method providing point estimates of the model parameters  $\theta$ . The *variational Bayes* (*VB*) [31.6] method has been introduced to obtain a fully Bayesian solution that returns a posterior distribution of the parameters  $P(\theta)$ , instead of their point estimate. *VB* is based on an analytical approximation of the joint posterior of the latent variables and model parameters that yields to a generalization of the *EM* alternate optimization, where the maximization at the *M-step* is taken over possible distributions  $Q(\theta)$ , instead of on  $\theta$  itself.

### 31.3.3 Linear Factor Analysis

*Factor analysis* (*FA*) is an example of a latent variable model for continuous hidden and manifest variables. In its simplest linear form, it is a classical statistical model widely used for generative dimensionality reduction. Similarly to its deterministic counterparts, e.g., *PCA*, it forms a low-dimensional embedding of a set of observations  $\mathcal{D} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$ , where each observation  $\mathbf{x}$  is a  $D$ -dimensional vector of reals. *FA* finds a lower dimensional probabilistic representation of  $\mathcal{D}$ , by assuming that the features of each  $\mathbf{x}$  are independently generated by  $K$  real-valued latent variables  $\mathcal{Z} = \{Z_1, \dots, Z_K\}$ , with  $K \ll D$  (see the associated graphical model in Fig. 31.5).

The *FA* model, assumes that observations are linked to the latent vectors through a linear model

$$\mathbf{x} = F\mathbf{z} + b + \epsilon , \quad (31.17)$$

**Fig. 31.5** Linear factor analysis: the observed  $D$ -dimensional variable  $\mathbf{X}$  is related to the  $K$  latent variables  $\mathcal{Z} = \{Z_1, \dots, Z_K\}$  through a linear mapping

where  $\epsilon \sim \mathcal{N}(\epsilon|0, \Psi)$  is the Gaussian distributed noise with zero mean and covariance  $\Psi$ ,  $b$  is a bias vector and  $F$  is the factor loading matrix. The latent variables are the *factors* and are generally assumed to be distributed as  $\mathcal{Z} \sim \mathcal{N}(\mathbf{z}|0, I_K) = P(\mathcal{Z})$ , where  $I_K$  is the  $K$ -dimensional identity matrix. Under such Gaussian assumptions, and given the linear model in (31.17), the conditional distribution of the observations is

$$P(\mathbf{X} = \mathbf{x}|\mathcal{Z} = \mathbf{z}) = \mathcal{N}(\mathbf{x}|F\mathbf{z} + b, \Psi), \quad (31.18)$$

which, inserted in (31.11), provides the distribution for the FA complete likelihood

$$P(\mathbf{X}) = \int_{\mathbf{z}} P(\mathbf{X}|\mathcal{Z})P(\mathcal{Z})d\mathbf{z} = \mathcal{N}(\mathbf{x}|b, FF^T + \Psi). \quad (31.19)$$

The form of the noise covariance  $\Psi$  determines the type of FA model: in general, this is chosen as a diagonal matrix with a vector of  $(\psi_1, \dots, \psi_D)$  values on the main diagonal. When the diagonal elements are all equal to a single value  $\sigma^2 \in \mathbb{R}$ , the FA reduces to the special case of the *Probabilistic PCA* [31.49].

Learning of the FA parameters  $\theta = (\Psi, F)$  ( $b$  is usually set a priori to the mean of the data) is obtained by maximum likelihood estimation. The most popular approach to obtain such estimates is based on solving an eigen-decomposition problem. Given the nature of FA as a latent variable model, its  $\theta$  parameters can also be estimated by applying EM to the logarithm of the complete likelihood in (31.19). The latter approach is, however, less used in general, given its slower convergence.

### 31.3.4 Mixture Models

The term *mixture models* identifies a large family of latent variable models comprising discrete hidden

variables and generic manifest variables. A mixture model assumes that each observation is generated by a weighted contribution of a number of simple distributions, selected by the hidden variables. The simplest form of mixture model assumes that an observation is independently generated by a single mixture component. Widely popular elements of this family are the *Gaussian mixture model* for continuous observations and the *mixture of unigrams* for multinomial data. In the following, we discuss an example of more articulated generative processes comprising observations with mixed component memberships.

#### Probabilistic Latent Semantic Analysis

Probabilistic latent semantic analysis (pLSA) [31.50] has been introduced to model mixed membership observations, where a manifest sample is allowed to be generated by multiple latent variables. Its primary application is on documental analysis, where latent variables are interpreted as topics to be identified in a collection of documents. Intuitively, in the mixture of unigrams, each document is assigned to a unique topic and, as a consequence, all the words in a document are constrained to belong to a single topic. The pLSA model relaxes this assumption by allowing words in a document to belong to different topics, obtaining a multitopic representation for the documents in the collection.

The typical pLSA setting includes a dataset of multinomial samples, which are the documents  $\mathcal{D} = \{d_1, \dots, d_N\}$ . Each document is an  $L$ -dimensional vector of word counts of length equal to the size of the reference dictionary. In other words, the  $i$ th observed sample is a vector  $d_i = (w_1^i, \dots, w_L^i)$ , where  $w_j^i$  is the number of occurrences of the  $j$ th word of the vocabulary in the  $i$ th document. This data is typically summarized in a rectangular  $L \times N$  integer matrix  $n$ , such that each row  $n(\cdot, d_i)$  contains the word counts for document  $d_i$ . The variables identifying words and documents, i.e.,  $W_j$  and  $D_i$ , are observed, in contrast with the set of topics  $\mathcal{Z} = \{Z_1, \dots, Z_K\}$ , which are the *latent variables*. In pLSA, every observation  $n(w_j, d_i)$  is associated with a latent topic  $z_k$  by means of the hidden variable  $Z_k$ .

The fundamental probabilities associated with this model are  $P(D = d_i)$ , that is, the document probability,  $P(W = w_j|Z = z_k)$ , that is, the probability of word  $w_j$  conditioned on topic  $z_k$ , and  $P(Z = z_k|D = d_i)$ , that is the conditional probability of topic  $z_k$  given document  $d_i$ . Given the nature of the manifest and hidden variables, all probabilities involved in pLSA are multinomials. The pLSA defines a (quasi) generative model for the word/document co-occurrences whose gener-

ative process is described by Fig. 31.6, using *plate notation*. This is a concise representation for graphical models involving replications: rectangular plates denote replication of their content for a number of times given by term on the bottom right (e.g.,  $N$  and  $L_d$  for the outer and inner plates in Fig. 31.6, respectively); each shaded circular item denotes an observed variable, while empty circles identify latent variables.

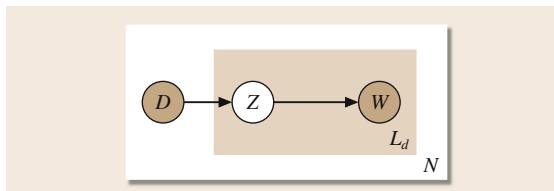

The conditional independence relationships in Fig. 31.6 allow us to factorize the joint word-topic distribution: by using the parent decomposition rule introduced in (31.8), it yields

$$\begin{aligned} P(W_j, D_i) &= P(D_i)P(W_j|D_i) \\ &= P(D_i) \sum_{k=1}^K P(Z_k|D_i)P(W_j|Z_k), \end{aligned} \quad (31.20)$$

that is the specific **pLSA** form of the general latent topic factorization in (31.12). The second equality in (31.20) is given by the marginalization of the latent topics  $Z_k$  and by the conditional independence assumption of the **pLSA** model, stating that word  $w_j$  and document  $d_i$  can be considered independent given the state of the latent variable  $Z_k$ . In other words, the word distribution of a document is modeled as a convex combination of  $K$  topic-specific distributions  $P(W_j|Z_k)$ . Such decomposition has a well-known characterization in terms of *Nonnegative matrix factorization* [31.13].

Estimation of the **pLSA** parameters  $\theta = \{P(W_j|Z_k), P(Z_k|D_i)\}$  is obtained by maximization of the log-likelihood

$$\begin{aligned} \mathcal{L}(\theta) &= \log \prod_{i=1}^D \prod_{j=1}^W P(W_j, D_i)^{n(w_j, d_i)} = \sum_{i=1}^D \sum_{j=1}^W n(w_j, d_i) \\ &\times \log \left\{ P(D_i) \sum_{k=1}^K P(Z_k|D_i)P(W_j|Z_k) \right\}, \end{aligned} \quad (31.21)$$

**Fig. 31.6** Graphical model for the probabilistic latent semantic analysis: indices for the random variables  $D$ ,  $Z$ , and  $W$  are omitted in the plate notation. The term  $L_d$  denotes replication for the  $L_d$  words present in the  $d$ th document

where  $P(W_j, D_i)$  has been expanded using the formulation in (31.20). As with other latent topic models, this maximization problem can be solved through the iterative **EM**-algorithm discussed in Sect. 31.3.2. Following (31.15), the *E-step* computes the expectation of the complete likelihood  $P(Z, W, D)$  with respect to the **pLSA** latent topics, assuming observed documents and words. It easily shows that the resulting *E-step* computes

$$P(Z_k|W_j, D_i) = \frac{P(Z_k|D_i)^{(t)} P(W_j|Z_k)^{(t)}}{\sum_{k'=1}^K P(Z_{k'}|D_i)^{(t)} P(W_j|Z_{k'})^{(t)}}, \quad (31.22)$$

that is the probability of the topic  $Z_k$  given word  $W_j$  in document  $D_i$ , estimated using the current values (at time  $t$ ) of the model parameters  $\theta^{(t)} = \{P(W_j|Z_k)^{(t)}, P(Z_k|D_i)^{(t)}\}$ . Note that the decomposition on the right-hand side of Eq. (31.22) has been obtained by factorization of the posterior  $P(Z_k|W_j, D_i)$  using the Bayes theorem.

The *M-step* equations (31.16) are obtained by differentiating the **pLSA** log-likelihood, extended with appropriate Lagrange multipliers for normalization, with respect to the  $P(Z_k|D_i)$  and  $P(W_j|Z_k)$  parameters. The resulting update equations are

$$P(Z_k|D_i)^{(t+1)} = \frac{\sum_{j=1}^W n(w_j, d_i) P(Z_k|W_j, D_i)}{\sum_{j=1}^W n(w_j, d_i)}, \quad (31.23)$$

$$P(W_j|Z_k)^{(t+1)} = \frac{\sum_{i=1}^D n(w_j, d_i) P(Z_k|W_j, D_i)}{\sum_{j=1}^W \sum_{i=1}^D n(w_j, d_i) P(Z_k|W_j, D_i)}. \quad (31.24)$$

The two-step optimization is iterated until a likelihood convergence criterion is met: often a validation set, or a *tempered* version of the **EM** are used in order to avoid model overfitting [31.50].

### Advanced Topic Models

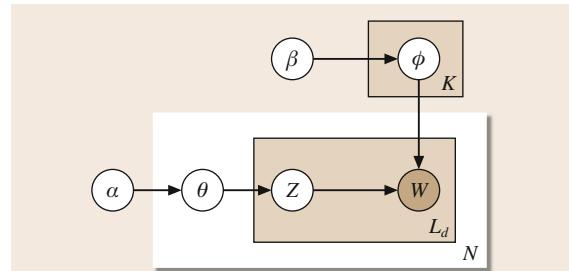

The **pLSA** was the first mixed membership model allowing a single observed sample to be generated by multiple latent topics at the same time. However, **pLSA** cannot be considered a fully generative model. In fact, the document-specific mixing weights for the topics are not sampled from a distribution, rather they are selected from  $P(z_k|d_i)$  based on the index of document  $d_i$ . Hence, **pLSA** indexes only those

documents that are in the training set  $\mathcal{D}$  and cannot directly model the generative process of unseen test documents. In other words, the **pLSA** is basically assigning null probabilities to all inputs that are not in the training set. The folding-in heuristic has been proposed to opportunistically solve this limitation, by assigning latent variables in the test-data to their **MAP** values before computing the test-set perplexity. However, the folding-in approach has been shown to lead to overly optimistic estimates of the test-set log-likelihood [31.51].

The *latent Dirichlet allocation* (**LDA**) [31.52] has been proposed as a Bayesian approach to address such modeling limitation of **pLSA**. It extends **pLSA** by treating the multinomial weights  $P(Z|D)$  as additional latent random variables, sampling them from a Dirichlet distribution, that is the conjugate prior of a multinomial distribution. Using conjugate distribution eases inference as it ensures that the posterior distribution has the same form of the prior. The latent variable decomposition of the **LDA** log-likelihood is

$$P(W = w|\phi, \alpha, \beta) = \int \sum_z P(W = w|Z = z, \phi) \times P(Z = z|\theta)P(\theta|\alpha)P(\phi|\beta)d\theta, \quad (31.25)$$

where  $P(W|Z, \phi)$  is the multinomial word-topic distribution with parameters  $\phi$  sampled from the Dirichlet distribution  $P(\phi|\beta)$ . The term  $P(Z|\theta)$  is the topic distribution having  $\theta$  as document-specific multinomial parameter being sampled from the Dirichlet  $P(\theta|\alpha)$ .

**Fig. 31.7** Graphical model for the latent Dirichlet allocation

The terms  $\alpha$  and  $\beta$  are the hyperparameters of the Dirichlet distribution, see Fig. 31.7 for the model plate notation. Direct **EM** inference is impossible for **LDA**, since the integral in (31.25) is intractable due to the couplings between the parameters within the topic marginalization. Again, approximate and stochastic Bayesian inference methods, such as those in Sect. 31.2.3, are used to fit the **LDA** parameters, including **VB** [31.52], expectation propagation [31.53], and Gibbs sampling [31.54].

The principles underlying **pLSA** and **LDA** have inspired the development of latent topic models that account for more articulated assumptions on the form of the hidden generative process. For instance, hierarchical **LDA** [31.55] proposes a generative process where observations are generated by a topic tree instead of being drawn from a flat topic collection. Further, specialized latent variable models have been developed for specific applications, such as author-topic analysis in scientific literature [31.56] and image understanding [31.57].

## 31.4 Markov Models

Time series and, more generally, sequences are a form of structured data that represents a list of observations for which a complete order can be defined, e.g., time in a temporal sequence. Let a sequence of length  $T$  be  $\mathbf{y}_n = y_1, \dots, y_T$ , where the bold notation is used to denote the fact that  $\mathbf{y}$  is a compound object (in practice, however, this is can be treated as a set of random variables). The term  $y_t$  is used to denote the  $t$ th observation with respect to the total order. Position  $t$  is often referred to as time when dealing with time-series data.

Two sequences are generally the results of independent trials, hence they can be considered **i.i.d.** samples. However, the elements composing a sequence fail to meet such **i.i.d.** property. Therefore, in principle, a prob-

abilistic model for  $\mathbf{y}$  would be required to specify the joint distribution  $P(Y_1, \dots, Y_T)$ . For discrete valued observations  $y_t$ , the joint distribution grows exponentially with the size of the observation domain. Clearly, this would make the use of the probabilistic model fairly impractical due to the exponential size of the parameter space. To reduce such parameterization, *Markov chains* make the simplifying assumption that an observation occurring at some position  $t$  of the sequence, only depends on a limited number of its predecessors with respect to the complete order. In a time series, this entails that an observation at the present time, only depends on the history of a limited number of past observations. Markov chains allow us to model such

history dependence and are the heart of the *hidden Markov model (HMM)*, which is the most popular approach to model the generative process of sequential data.

The **HMM** is a notable example of latent variable model: in the following, we provide an overview of the associated learning and inference problems. For simplicity, presentation focuses on sequences of finite length  $T$  and discrete time  $t$ . Sequence elements  $y_t$  can be either discrete valued or defined over reals, without major impact on the model. The section also discusses how the **HMM** causation assumption can be modified to give rise to alternative approaches, with interesting applications that overshoot simple sequence modeling.

### 31.4.1 Markov Chains

A Markov chain is a simple stochastic process for sequences. It assumes that an observation  $y_t$  at time (position)  $t$  only depends on a finite set of  $L \geq 1$  predecessors in the sequence. The number of predecessor  $L$  influencing the new observation is the order of the Markov chain.

#### Definition 31.4 Markov Chain

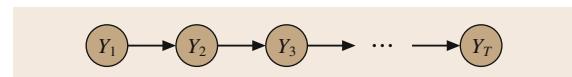

An  $L$ -order Markov chain is a sequence of random variables  $\mathbf{Y} = Y_1, \dots, Y_T$  such that for every  $t \in \{1, \dots, T\}$ , it holds

$$\begin{aligned} P(Y_t = y_t | Y_1, \dots, Y_{t-1}, Y_{t+1}, \dots, Y_T) \\ = P(Y_t = y_t | Y_{t-L}, \dots, Y_{t-1}) . \end{aligned} \quad (31.26)$$

Following from the discussions in Sect. 31.2.1, (31.26) states that the  $L$  predecessors of  $Y_t$  define the set of its Bayesian parents  $\text{pa}(Y_t) = \{Y_{t-L}, \dots, Y_{t-1}\}$ . For a first-order Markov chain, i.e.,  $L = 1$ , (31.26) reduces to  $P(Y_t = y_t | Y_{t-1} = y_{t-1})$ . Such conditional independence assumption formally encodes the intuition that the current observation can be predicted from the sole knowledge of the preceding sample. The graphical model of a first-order Markov chain is shown in Fig. 31.8, whose joint distribution decomposes as

$$\begin{aligned} P(Y_1, \dots, Y_T) &= P(Y_1)P(Y_2|Y_1), P(Y_3|Y_2) \\ &\quad \times \dots P(Y_T|Y_{T-1}) \\ &= P(Y_1) \prod_{t=2}^T P(Y_t|Y_{t-1}) . \end{aligned} \quad (31.27)$$

The first element  $Y_1$  has an empty conditioning part given that it has no predecessor. Its probability  $P(Y_1)$

**Fig. 31.8** Graphical model for a first-order Markov chain of length  $T$ , where  $\text{pa}(Y_t) = \{Y_{t-1}\}$

is referred to as *marginal* or *prior* probability, while the term  $P(Y_t|Y_{t-1})$  is the *transition* probability.

A Markov chain is *stationary* or *homogeneous*, if the transition probability does not depend on the time (position)  $t$ . In other words, the parameterization of the Markov chain is such that

$$P(Y_t = y' | Y_{t-1} = y) = f(y', y) ,$$

where the transition distribution is a function  $f(y', y)$  of the sole observations  $y, y'$ . An interesting stationary first-order Markov chain is that whose random variables take values from a finite alphabet of discrete symbols  $i, j \in \{1, \dots, M\}$ . In these chains, the transition probability

$$A_{ij} = P(Y_t = i | Y_{t-1} = j) \quad (31.28)$$

denotes the probability of occurrence of the  $i$ th symbol preceded by symbol  $j$ . For convenience, such probability is represented by the element  $A_{ij}$  of the  $M \times M$  transition matrix  $A = [A_{ij}]_{i,j=1}^M$ . Similarly, the marginal distribution defines the elements

$$\pi_i = P(Y_1 = i) \quad (31.29)$$

of the  $M \times 1$  initial state vector  $\pi = [\pi_i]_{i=1}^M$ . These Markov chains can be straightforwardly interpreted as state-transition systems, where each symbol  $i$  of the alphabet is a state and a state-transition arrow exists between states  $i$  and  $j$  having a nonzero  $A_{ij}$  entry in the transition matrix.

The Markov chains described by (31.28) and (31.29), despite their simplicity, have found wide application, e.g., in modeling of physical phenomena, economic time series, and information retrieval. Learning Markov chains requires fitting the  $M^2$  parameters of the transition matrix plus an  $M$ -dimensional prior, where  $M$  is the size of the observation alphabet. Efficient methods exist to fit stationary first-order Markov chains by maximum likelihood (ML). By using the decomposition in (31.26), substituting the definitions in (31.28) and (31.29), the Markov chain log-likelihood

for a generic sequence  $\mathbf{y}$  writes

$$\begin{aligned} \mathcal{L}(\theta) = \log P(\mathbf{Y} = \mathbf{y} | \theta) &= \log \prod_{i'=1}^M \pi_{i'}^{\delta(y_1=i')} \\ &\times \prod_{t=2}^T \prod_{i,j=1}^M A_{ij}^{\delta(y_t=i, y_{t-1}=j)}, \end{aligned} \quad (31.30)$$

where  $\theta = (A, \pi)$  are the model parameters and  $\delta(y_t = i, y_{t-1} = j)$  is the indicator function. For instance, it equals 1 if a transition from  $y_{t-1} = j$  to  $y_t = i$  can be observed in the sequence and it is 0 otherwise. Similarly,  $\delta(y_1 = i') = 1$  if and only if the first symbol of the sequence is  $i'$ . The final expression of the log-likelihood is obtained by taking the log into the products and adding appropriate Lagrange multipliers for normalization. The **ML** estimate is obtained by differentiating this final expression with respect to parameters  $A_{ij}$  and  $\pi_i$ , yielding

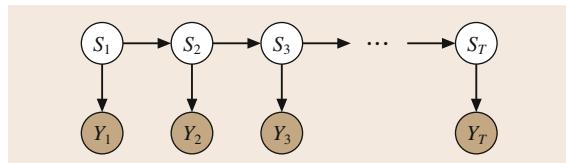

$$A_{ij} = \frac{\sum_{t=2}^T \delta(y_t = i, y_{t-1} = j)}{\sum_{t=2}^T \sum_{i=1}^M \delta(y_t = i, y_{t-1} = j)}, \quad (31.31)$$

$$\pi_i = \frac{\delta(y_1 = i)}{\sum_{i=1}^M \delta(y_1 = i)}. \quad (31.32)$$

Intuitively, the **ML** estimate corresponds to counting the number of transitions from symbol  $j$  to  $i$  across time (similarly for the initial state). Generalization to a set of  $N$  samples sequences  $\mathbf{y}^n$  is straightforward: it suffices to count transitions both in time and across samples, and similarly for the initial symbols  $y_1^n$ .

### 31.4.2 Hidden Markov Models

Markov chains model sequential data assuming that sequence elements are generated by a fully observable stochastic process. In the discrete-state Markov chain, this requires each state of the process to correspond to an observable element of the sequence, i.e., an event. On the other hand, most real-world systems generate observable events that are correlated, but not coincident, with the state of the generating process. More importantly, the only available information can be the outcome of the stochastic process at each time, i.e., event  $y_t$ , while the state of the system remains unobservable, i.e., *hidden*. The **HMM** allows modeling more general stochastic processes where the state transition dynamics is disentangled from the observable information generated by the process. The state-transition

**Fig. 31.9** A first-order HMM with hidden states  $S_t$  chosen on the discrete domain  $\{1, \dots, C\}$ , for  $t = 1 \dots T$

dynamics is assumed to be nonobservable and is modeled by a Markov chain of discrete and finite latent variables, i.e., the *hidden states*. The observable information is then generated by such hidden states similarly to how latent variables generate observations in mixture models (see Sect. 31.3.4).

The graphical model of an **HMM** is exemplified in Fig. 31.9: the hidden states are latent variables  $S_t$ , while the sequence elements  $Y_t$  are observed.

The conditional dependence expressed by the arrow  $S_t \rightarrow Y_t$  indicates that the observed element of the sequence at time  $t$  is generated by the corresponding hidden state  $S_t$  through the *emission distribution*  $b_{s_t}(y_t) = P(Y_t = y_t | S_t = s_t)$ . The unknown state-transition dynamics is modeled by the first-order Markov chain of discrete and finite hidden states  $S_t$ . By applying the Markovian decomposition in (31.27) to the hidden states chain, the joint distribution of the observed sequence  $\mathbf{y} = y_1, \dots, y_T$  and associated hidden states  $\mathbf{s} = s_1, \dots, s_T$  writes as

$$P(\mathbf{Y} = \mathbf{y}, \mathbf{S} = \mathbf{s}) = P(S_1) \prod_{t=2}^T P(S_t | S_{t-1}) P(Y_t | S_t). \quad (31.33)$$

The actual parameterization of the probabilities in (31.33) depends on the form of the observation and hidden states variables. From Sect. 31.8, a stationary hidden states chain is known to be regulated by the  $C \times C$  matrix of *state transitions*  $A_{ij} = P(S_t = i | S_{t-1} = j)$  and by the  $C$ -dimensional vector of *initial state* probabilities  $\pi_i = P(S_1 = i)$ , where  $i, j$  are drawn from  $\{1, \dots, C\}$ . For discrete sequence observations  $y_t \in \{1, \dots, M\}$ , the emission distribution is an  $M \times C$  emission matrix  $B$  such that its elements are

$$b_i(k) = B_{ki} = P(Y_t = k | S_t = i). \quad (31.34)$$

For continuous observations  $y_t$ , the state assignment  $S_t = i$  selects the  $i$ th emission distributions  $b_i(y_t) = P(Y_t | S_t = i)$  from a mixture of  $C$  candidates.

An **HMM** is a latent variable model defined by the  $\theta = (\pi, A, B)$  parameters and, implicitly, by the (unkown) number of hidden states  $C$ . In [31.58], three notable inference problems are identified for an **HMM**.

#### **Definition 31.5 Evaluation Problem**

Given a model  $\theta$  and an observed sequence  $\mathbf{y}$ , determine the likelihood  $P(\mathbf{Y} = \mathbf{y}|\theta)$  of the sequence being generated by the model.

#### **Definition 31.6 Learning Problem**

Given a dataset of  $N$  observed sequences  $\mathcal{D} = \{\mathbf{y}^1, \dots, \mathbf{y}^N\}$  and the number of hidden states  $C$ , find the parameters  $\pi, A$  and  $B$  that maximize the probability of model  $\theta = \{\pi, A, B\}$  having generated the sequences in  $\mathcal{D}$ .

#### **Definition 31.7 Optimal States Problem**

Given a model  $\theta$  and an observed sequence  $\mathbf{y}$ , find an optimal state assignment  $\mathbf{s} = s_1^*, \dots, s_T^*$  for the underlying hidden Markov chain.

These classical inference problems are addressed using efficient and numerically stable recursive algorithms that exploit message passing on the **HMM** junction tree (Sect. 31.2.3) to factorize the, otherwise hardly tractable, joint maximization problems. The underlying intuition is a recursive computation of intermediate probabilities (messages) that are passed forward and backward along the sequence (the junction tree, in practice) to accumulate evidence for solving the joint problem. A discussion of the key aspects of these solutions is provided in the following.

#### Evaluation

The evaluation problem refers to measuring how well a given **HMM** matches an observed sequences. Let the model be  $\theta = (\pi, A, B)$  and the observed sequence  $\mathbf{y} = y_1, \dots, y_T$ , the objective is to find  $P(\mathbf{Y} = \mathbf{y}|\theta)$ . To effectively compute this probability in the **HMM** assumption, it is needed to introduce the hidden states assignment corresponding to the observed sequence  $\mathbf{y}$ . Following the general approach for latent variable models in Eq. (31.11), these are introduced through marginalization on the joint assignment  $\mathbf{s} = s_1, \dots, s_T$

$$\begin{aligned} P(\mathbf{Y}|\theta) &= \sum_{\mathbf{s}} P(\mathbf{Y}, \mathbf{S} = \mathbf{s}|\theta) \\ &= \sum_{s_1, \dots, s_T} P(s_1) \prod_{t=2}^T P(s_t|s_{t-1}) P(y_t|s_t), \end{aligned} \quad (31.35)$$

where the joint probability  $P(\mathbf{Y}, \mathbf{S}|\theta)$  has been factorized according to the **HMM** assumption in (31.33).

Direct computation of (31.35) is generally infeasible, as it would require  $O(TC^T)$  operations. This probability can be efficiently computed, with  $O(TC^2)$  operations, through accumulation of a recursive term that is computed by scanning the sequence from left to right. The procedure is known as *forward algorithm*: let  $\mathbf{y}_{1:t}$  be the observed subsequence from position 1 to  $t$ , define the *forward probability* as

$$\alpha_t(i) = P(\mathbf{Y}_{1:t} = \mathbf{y}_{1:t}, S_t = i|\theta) \quad (31.36)$$

that is the probability of observing a partial sequence up to position  $t$  and the underlying hidden process being in state  $i$  at time  $t$ . A recursive formulation of the  $\alpha_t(i)$  term is obtained by introducing the hidden state  $S_{t-1}$  by marginalization, yielding

$$\begin{aligned} \alpha_t(i) &= \sum_{j=1}^C P(\mathbf{Y}_{1:t} = \mathbf{y}_{1:t}, S_t = i, S_{t-1} = j|\theta) \\ &= \sum_{j=1}^C P(Y_t = y_t|S_t = i, \theta) \\ &\quad \times P(S_t = i|S_{t-1} = j, \theta) \\ &\quad \times P(\mathbf{Y}_{1:t-1} = \mathbf{y}_{1:t-1}, S_{t-1} = j|\theta) \\ &= b_i(y_t) \sum_{j=1}^C A_{ij} \alpha_{t-1}(j), \end{aligned} \quad (31.37)$$

where the second equality follows from the conditional independence assumptions of the model. Since,  $\text{pa}(S_t) = \{S_{t-1}\}$ , the chain element  $S_t$  is completely determined by the hidden state at previous time  $S_{t-1}$ ; similarly, emission  $Y_t$  is conditional independent from the rest, given the hidden state  $S_t$ .

The forward recursion scans the observed sequence from left to right and recursively computes the  $\alpha_t(i)$  values in each position  $t = 1, \dots, T$  using (31.37). At each observed position  $t$ , the  $\alpha_t(i)$  values are computed for each  $i \in \{1, \dots, C\}$ , since the hidden states are not observed. The basis of the recursion is at  $t = 1$ , where the

(31.37) reduces to  $\alpha_1(i) = b_i(y_1)\pi_i$ , such that  $y_1$  is the first element of the observed sequence. The likelihood of the full sequence  $\mathbf{y} = \mathbf{y}_{1:T}$  is computed at the end of the forward recursion as

$$P(\mathbf{Y}|\theta) = \sum_{i=1}^C P(\mathbf{Y}_{1:T}, S_T = i|\theta) = \sum_{i=1}^C \alpha_T(i). \quad (31.38)$$

### Learning

Learning of an **HMM**  $\theta = (\pi, A, B)$  amounts to finding the values of the parameters  $\pi$ ,  $A$  and  $B$  that are most likely to have generated a dataset of observed **i.i.d.** sequences  $\mathcal{D} = \{\mathbf{y}^1, \dots, \mathbf{y}^N\}$ . From the evaluation problem, we know how to measure the quality of the matching between a sequence  $\mathbf{y}$  and a model  $\theta$  using the likelihood  $P(\mathbf{Y}|\theta)$ . The **HMM** learning problem can be solved through **ML** estimation of  $\theta$  parameters considering the hidden states as latent variables. As discussed in Sect. 31.3.2, this problem can be solved through application of the **EM** algorithm, whose **HMM** version is referred to as *Baum–Welch algorithm* [31.59], which is a form of *sum-product* inference algorithm introduced in Sect. 31.2.3. Marginalization of the hidden states as in (31.35), yields to the **HMM** log-likelihood on the dataset  $\mathcal{D}$

$$\begin{aligned} \mathcal{L}(\theta) &= \log \prod_{n=1}^N P(\mathbf{Y}^n|\theta) \\ &= \log \prod_{n=1}^N \left\{ \sum_{S_1^n, \dots, S_{T_n}^n} P(S_1^n) \right. \\ &\quad \left. \times \prod_{t=2}^{T_n} P(S_t^n|S_{t-1}^n) P(Y_t^n|S_t^n) \right\}, \end{aligned} \quad (31.39)$$

where overscript  $n$  refers to the  $n$ th sequence  $\mathbf{y}^n$  and  $T_n$  is the corresponding length. The likelihood in (31.39) is intractable due to the nonobservable state assignment that introduces the marginalization term. Following the principles of the **EM** algorithm, we assume to know the unobserved state assignment, as in (31.30). This can be achieved by introducing indicator variables  $z_{ti}^n$  for the unknown assignment, such that  $z_{ti}^n = 1$  if the chain is in state  $i$  at position  $t$  of the  $n$ th sequences, and it is 0 otherwise. Given this (assumed) knowledge about the

hidden state assignments, if is possible to write the corresponding *completed* likelihood

$$\mathcal{L}_c(\theta)$$

$$\begin{aligned} &= \log \prod_{n=1}^N \left\{ \prod_{i=1}^C P(S_1^n = i)^{z_{1i}^n} \right. \\ &\quad \times \prod_{t=2}^{T_n} \prod_{i,j=1}^C P(S_t^n = i|S_{t-1}^n = j)^{z_{ti}^n z_{(t-1)i}^n} P(Y_t^n|S_t^n = i)^{z_{ti}^n} \\ &= \sum_{n=1}^N \left\{ \sum_{i=1}^C z_{1i}^n \log \pi_i + \sum_{t=2}^{T_n} \sum_{i,j=1}^C z_{ti}^n z_{(t-1)i}^n \right. \\ &\quad \left. \times \log A_{ij} + z_{ti}^n \log b_i(y_t^n) \right\}, \end{aligned} \quad (31.40)$$

where the latter equality introduces the parameters  $\theta$  in place of the corresponding probabilities and brings the logarithms into the products.

The **EM** procedure is applied to the complete log-likelihood in (31.40). Following (31.15), the *E*-step computes the expected value of  $\mathcal{L}_c(\theta)$  with respect to the distribution of the indicator variables  $\mathcal{Z} = \{z_{ti}^n\}$ , conditional on the observed sequences  $\mathcal{D}$  and the current estimate of the parameters  $\theta^{(k)}$ . Given  $\mathcal{L}_c(\theta)$  as in (31.40), taking its conditional expectation with respect to the hidden variables  $\mathcal{Z}$ , it yields to the following posterior probability:

$$E_{\mathcal{Z}|\mathbf{Y}, \theta^{(k)}}[z_{ti}] = P(S_t = i|\mathbf{y}), \quad (31.41)$$

where superscript  $n$  is omitted for notational simplicity. The estimation of this posterior is known as the *smoothing* problem. In the Baum–Welch algorithm, this is efficiently solved by a double recursion that exploits the following decomposition of the joint probability

$$\begin{aligned} P(S_t = i, \mathbf{y}) &= P(S_t = i, \mathbf{Y}_{1:t}, \mathbf{Y}_{t+1:T}) \\ &= P(S_t = i, \mathbf{Y}_{1:t}) \\ &\quad \times P(\mathbf{Y}_{t+1:T}|S_t = i) = \alpha_t(i)\beta_t(i), \end{aligned} \quad (31.42)$$

where the observed contribution from the predecessors of  $t$  (i.e.,  $\mathbf{Y}_{1:t}$ ) is separated from that of its successors (i.e.,  $\mathbf{Y}_{t+1:T}$ ). The cancelations in (31.42) follow from the fact that  $S_t$  *d-separates* (see definition in Sect. 31.2.1) the elements of the two subsequences, i.e.,  $\mathbf{Y}_{1:t}$  and  $\mathbf{Y}_{t+1:T}$ .

The first term in (31.42) is the  $\alpha_t(i)$  probability defined in (31.36), which can be computed through the *forward algorithm*. The  $\beta_t(i)$  term can also be computed through a recursive procedure known as *backward algorithm*, due to the inverted direction with respect to the forward recursion. Consider the following recursive decomposition

$$\begin{aligned}\beta_{t-1}(j) &= P(\mathbf{Y}_{t:T} | S_{t-1} = j) \\ &= \sum_{i=1}^C P(\mathbf{Y}_{t:T}, S_t = i | S_{t-1} = j) \\ &= \sum_{i=1}^C P(Y_t | S_t = i) P(\mathbf{Y}_{(t+1):T} | S_t = i) \\ &\quad \times P(S_t = i | S_{t-1} = j) \\ &= \sum_{i=1}^C b_i(y_t) \beta_t(i) A_{ij},\end{aligned}\tag{31.43}$$

it can be computed for  $2 \leq t \leq T$  by scanning the sequence backward, assuming  $\beta_T(j) = 1$  for each  $j \in \{1, \dots, C\}$ .

The final expression of the smoothed posterior in (31.41) is given by the joint  $\alpha - \beta$  recursions, known as the *forward-backward algorithm*, that is

$$\begin{aligned}\gamma_t(i) &= P(S_t = i | \mathbf{Y}) = \frac{P(S_t = i, \mathbf{Y})}{P(\mathbf{Y})} \\ &= \frac{\alpha_t(i) \beta_t(i)}{\sum_{j=1}^C \alpha_t(j) \beta_t(j)}.\end{aligned}\tag{31.44}$$

Note that the forward and backward recursions can be ran in parallel, since the values of  $\alpha$  and  $\beta$  do not depend on each other. To complete the derivations of the sufficient statistics for the  $M$ -step, it is also necessary to estimate the joint posterior

$$E_{\mathbf{Z}|\mathbf{Y}, \theta^{(k)}}[z_{ti} z_{(t-1)j}] = P(S_t = i, S_{t-1} = j | \mathbf{Y}),\tag{31.45}$$

which can be straightforwardly factorized into known probabilities along the lines of (31.42). It turns out that such joint posterior can be estimated using the  $\alpha - \beta$  probabilities computed by the *forward-backward algorithm*, that is

$$\begin{aligned}\gamma_{t,t-1}(i,j) &= P(S_t = i, S_{t-1} = j | \mathbf{Y}) \\ &= \frac{\alpha_{t-1}(j) A_{ij} b_i(y_t) \beta_t(i)}{\sum_{m,l=1}^C \alpha_{t-1}(m) A_{lm} b_l(y_t) \beta_t(l)}.\end{aligned}\tag{31.46}$$

Parameters  $\theta = (\pi, A, B)$  are re-estimated at the  $M$ -step, with update equations that follow straightforwardly from the maximization problem in (31.16). It suffices to differentiate (31.40), extended with appropriate Lagrange multipliers to account for the sum-to-one constraints. Intuitively, the update equations can be straightforwardly written from the ML estimates for observable Markov chains in (31.31) and (31.32). It suffices to substitute the observed state counts, obtained through the indicator function  $\delta(\cdot)$ , with the virtual counts  $\gamma(\cdot)$  estimated by (31.44) and (31.46) at the  $E$ -step. For the hidden state transition and initial state distributions this yields to

$$\begin{aligned}A_{ij} &= \frac{\sum_{n=1}^N \sum_{t=2}^{T_n} \gamma_{t,t-1}^n(i,j)}{\sum_{n=1}^N \sum_{t=2}^{T_n} \gamma_{t-1}^n(j)} \\ \text{and } \pi_i &= \sum_{n=1}^N \gamma_1^n(i).\end{aligned}\tag{31.47}$$

The estimate of the parameters  $B$  depends on the form of the emission distribution: if the observed sequences take values  $k$  from a finite alphabet  $\{1, \dots, M\}$ , the corresponding multinomial emission in (31.34) is updated by

$$B_{ki} = \sum_{n=1}^N \sum_{t=1}^{T_n} \gamma_t^n(i) \delta(y_t = k),\tag{31.48}$$

where  $\delta(\cdot)$  is the indicator function counting the occurrences of the symbols  $k$  in the observed sequences. Real-valued sequences are modeled usually through Gaussian emissions, whose parameters are fit as usual through maximization of the complete log-likelihood.

Particular care must be taken to avoid numerical problems when implementing the *forward-backward algorithm*. Both recursions work with multiplications of small numbers: hence, the values of  $\alpha$  and  $\beta$  can underflow for long sequences. To this end, it is advisable to perform them in log-space or to work with scaled versions of the  $\alpha$  and  $\beta$  probabilities [31.60]. A sequential version of the smoothing algorithm exists [31.61] that directly computes the smoothed posterior  $\gamma_t(i) = P(S_t = i | \mathbf{Y})$  through a  $\gamma$ -recursion that uses the  $\alpha$  values generated by the forward algorithm.

### Optimal State

Once a model  $\theta$  has been trained, it can be interesting to determine the most likely hidden state assignment  $s^*$  that has generated an observed sequence  $\mathbf{y}$ . This inference problem, known also as decoding, has different solutions, since several optimal assignment exists,

depending on the interpretation of what an optimal assignment is. For instance, the optimal hidden sequence can be the one maximizing the expected count of correct states. On the other hand, an optimal assignment might be the sequence of hidden states  $\mathbf{s}^*$  with the maximum joint probability  $P(\mathbf{Y} = \mathbf{y}, \mathbf{S} = \mathbf{s}^*)$ .

The former optimality condition is solved by selecting, at each position  $t$ , the most likely state given by the sequence, i. e.,

$$\mathbf{s}_t^* = \arg \max_{i=1, \dots, C} P(S_t = i | \mathbf{Y}). \quad (31.49)$$

Clearly, this amounts to select the most likely state for each position independently, using the posterior computed by the Baum–Welch algorithm. Conversely, the latter optimality condition estimates the joint hidden state assignment

$$\mathbf{s}^* = \arg \max_{\mathbf{s}} P(\mathbf{Y}, \mathbf{S} = \mathbf{s}). \quad (31.50)$$

This is a complex inference problem that can be efficiently solved though a dynamic programming approach, known as the *Viterbi algorithm*. Note that the two optimality definitions generally lead to different solutions. For instance, the Viterbi solution is constrained to provide only state transitions allowed by the generating distribution, while this is not the case for the Baum, Welch solution, given that hidden states are selected independently.

The *Viterbi algorithm* is based on a backward recursion that exploits a factorization of the maximization problem in (31.50). Consider the restricted problem of determining the hidden state of the tail element  $T$

$$\begin{aligned} \max_{s_T} P(\mathbf{Y}, S_T = s_T) &= \max_{s_T} \prod_{t=1}^T P(Y_t | S_t) P(S_t | S_{t-1}) \\ &= \prod_{t=1}^{T-1} P(Y_t | S_t) P(S_t | S_{t-1}) \max_{s_T} P(Y_T | S_T) P(S_T | S_{T-1}), \end{aligned} \quad (31.51)$$

where the joint probability factorizes according to the Markov chain assumption. We can isolate the maximization problem in the rightmost term

$$\begin{aligned} \epsilon_{T-1}(s_{T-1}) &= \max_{s_T} P(Y_T | S_T = s_T) \\ &\quad \times P(S_T = s_T | S_{T-1} = s_{T-1}), \end{aligned} \quad (31.52)$$

that is a message conveying information on the maximization of the tail element to the penultimate position. Substituting the definition of  $\epsilon_{T-1}(s_{T-1})$  back

in (31.51) and adding the maximization with respect to  $s_{T-1}$ , suggests the recursive formulation of  $\epsilon(\cdot)$  for a generic position  $t - 1$ , i. e.,

$$\begin{aligned} \epsilon_{t-1}(s_{t-1}) &= \max_{s_t} P(Y_t | S_t = s_t) \\ &\quad \times P(S_t = s_t | S_{t-1} = s_{t-1}) \epsilon_t(s_t), \end{aligned} \quad (31.53)$$

for  $2 \leq t \leq T$ , where  $\epsilon_T(s_T) = 1$  is the basis of the recursion. At each step  $t$  of the backward recursion, the Viterbi algorithm computes the  $\epsilon$ -message for each possible assignment of the hidden state of  $t$  and propagates it to the predecessor  $t - 1$ . The recursion ends at the initial element of the sequence, where the initial optimal state is obtained as

$$s_1^* = \arg \max_s P(Y_1 | S_1 = s) P(S_1 = s_1) \epsilon_1(s). \quad (31.54)$$

The assignment of the remaining hidden states is obtained by backtracking through the forward recursion

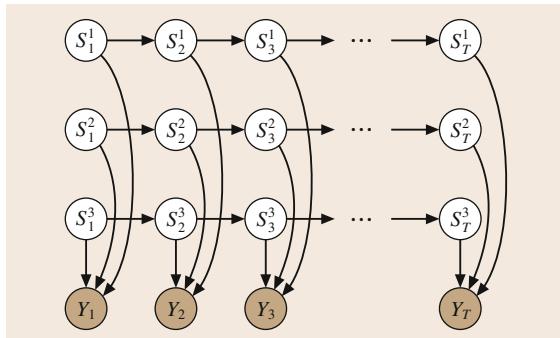

$$\begin{aligned} s_t^* &= \arg \max_s P(Y_t | S_t = s) \\ &\quad \times P(S_t = s | S_{t-1} = s_{t-1}^*) \epsilon_t(s). \end{aligned} \quad (31.55)$$

Note that the *Viterbi algorithm* is a special case of a *max-sum* inference algorithm introduced in Sect. 31.2.3.

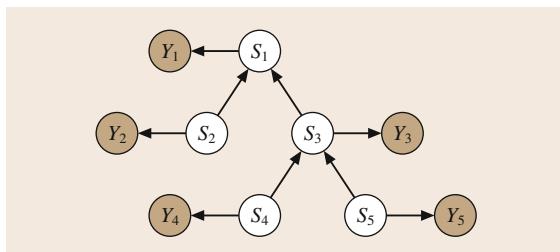

### 31.4.3 Related Models

#### Higher Order Markov Models

Hidden Markov models serve as a starting point for the design on more complex Markov generative processes, besides the obvious extension to higher order hidden chains [31.62]. *Factorial HMMs* [31.63] generalize the original model by defining super states that are collections of  $K$  discrete hidden states, each being part of an independent Markov chain (see Fig. 31.10). This factorial model results in  $K$  hidden Markov chains running in parallel: at each time step, the emission depends on the  $K$ -dimensional super state, but each state variable is decoupled from those of the other chains and evolves according to its own dynamics. By this means, it is possible to efficiently encode the state dynamics of  $K$  objects evolving independently that interact to jointly determine the observation (e.g.,  $K$  cars moving in the traffic and jointly determining traffic jams).

**Fig. 31.10** Factorial HMM with  $K = 3$  independent hidden Markov chains

**Fig. 31.11** A bottom-up hidden tree Markov model for a simple structure with five nodes: the generative process follows the direction of the arrows, i.e., from the leaves to the root ( $t = 1$ )

#### Nonhomogenous HMMs

Relaxation of the homogeneity assumption led to the *input/output hidden Markov model (IO-HMM)* [31.64] that allow modeling the causal dependence of the hidden generative process from an additional input sequence  $\mathbf{x}$ . Basically, the **IO-HMM** enables nonhomoge-

neous transition and emission distributions that are explicitly dependent (i.e., parameterized) on the currently observed label of the input sequence. An **IO-HMM** implements a mapping, referred to as *transduction*, from an observed input sequence  $\mathbf{x}$  into an output (target) sequence  $\mathbf{y}$ , realized by the input-conditional hidden process  $P(\mathbf{Y}|\mathbf{X})$ . Interesting applications of **IO-HMM** are in learning transformations between modalities in multimedia data [31.65], exploratory analysis of financial time series [31.66] and gene data analysis [31.67].

#### HMMs for Structured Data

*Hidden tree Markov models* represent the generative process of more complex, tree-structured information (see Fig. 31.11). Differently from the sequential domain, the direction of the generative process leads to different representational capabilities when dealing with trees. Top-down approaches [31.68] model all possible paths from the root to the leaves of the tree. Bottom-up models [31.69] propose a generative process from the leaves to the root, where complex structures are generated by composition of simpler substructures. Recently, an extension of the **IO-HMM** has been proposed to learn transductions between trees [31.70].

#### Bayesian and Nonparametric Extensions

**HMMs** have been extended to allow a countably infinite number of hidden states through a Bayesian approach where state distributions are modeled by Dirichlet processes [31.71]. Abstracting from the direction of the arrows in Fig. 31.9 leads to a discriminative probabilistic model known as liner-chain *conditional random fields* [31.72], whose capability to model long term dependences is widely used in natural language parsing and computer vision.

## 31.5 Conclusion and Further Reading

Graphical models have been discussed as an excellent framework for probabilistic modeling of articulated processes that can be described by a *static* set of random variables tied up by probabilistic relationships. Such relationships need not to be necessarily known, a-priori. Several approaches exists to infer them from data, i.e., to determine the presence of a corresponding edge in the graphical model. However, the same approaches tend to fix the structure of the graphical model, once this is determined from the data. In other words, these graphical models represent a *static* picture

of the process, where the set of random variables and associated relationships is held fixed from a point onward. The nature of sequence data calls for the ability to model more *dynamic* phenomena. Processing of video information requires Markov networks that can unfold their structure across the video sequence. Even *classic* text analysis needs to account for novel generative dynamics, where texts are produced as dynamic streams instead of being static collections of words, e.g., consider blog posts and associated comments, or the stream of social networks status updates. Therefore, the hori-

zon of current research is pushing graphical models to more *dynamic* formulations where, on the one hand, the structure is allowed to change over time and, on the other hand, the model is allowed to dynamically self-tune the number of parameters that is most adequate to represent the process at each time. Following the intuitions underlying the HMM approach, dynamical graphical models are being proposed that are capable of unfolding their structure across time, to better model the dynamics of complex time-varying processes. At the same time, concepts from nonparametric Bayesian statics are being used to develop models where latent variables can be dynamically adjusted to sample from

a virtually infinite set of events and where the very same structure of the latent space is adapted across time, i.e., through variable addition and pruning. Such a new class of dynamic graphical models introduces novel computational challenges associated with inference and representation of dynamic knowledge. The answers to this challenges can be partly found in the chapter, in the approximated inference methods discussed for static models and in the principles underlying the unfolding of Markov chains. Finally, it is worth to note that deep learning, described in Chap. 2, is an instance of graphical model where both nonlinearity and dynamic representations play an important role.

# Kernel Methods

Marco Signoretto, Johan A. K. Suykens

This chapter addresses the study of kernel methods, a class of techniques that play a major role in machine learning and nonparametric statistics. Among others, these methods include support vector machines (SVMs) and least squares SVMs, kernel principal component analysis, kernel Fisher discriminant analysis, and Gaussian processes. The use of kernel methods is systematic and properly motivated by statistical principles. In practical applications, kernel methods lead to flexible predictive models that often outperform competing approaches in terms of generalization performance. The core idea consists of mapping data into a high-dimensional space by means of a feature map. Since the feature map is normally chosen to be nonlinear, a linear model in the feature space corresponds to a nonlinear rule in the original domain. This fact suits many real world data analysis problems that often require nonlinear models to describe their structure.

In Sect. 32.1 we present historical notes and summarize the main ingredients of kernel methods. In Sect. 32.2 we present the core ideas of statistical learning and show how regularization can be employed to devise practical learning algorithms. In Sect. 32.3 we show a selection of techniques that are representative of a large class of kernel methods; these techniques – termed primal–dual methods – use Lagrange duality as the main mathematical tools. Section 32.4 discusses Gaussian processes, a class of kernel methods that uses a Bayesian approach to perform inference and learning. Section 32.5 recalls different approaches for the tuning of parameters. In Sect. 32.6 we review the mathematical properties of different yet equivalent notions of kernels and recall a number of specialized kernels for learning problems involving structured data. We conclude the chapter by presenting applications in Sect. 32.7.

## 32.1 Background

This chapter addresses the study of kernel methods, a class of techniques that play a major role in machine learning and nonparametric statistics.

The development of kernel-based techniques [32.1, 2] has been an important activity within machine learning in the last two decades. In this period, a number of powerful kernel-based learning algorithms were proposed. Among others, these methods include support vector machines ([SVMs](#)) and least squares [SVMs](#), kernel principal component analysis, kernel Fisher discriminant analysis, and Gaussian processes. The use of kernel methods is systematic and properly motivated by statistical principles. In practical applications, kernel methods lead to flexible predictive models that often outperform competing approaches in terms of generalization performance. The core idea consists of mapping data into a high-dimensional space by means of a feature map. Since the feature map is normally chosen to be nonlinear, a linear model in the feature space corresponds to a nonlinear rule in the original domain. This fact suits many real world data analysis problems that often require nonlinear models to describe their structure.

### 32.1.1 Summary of the Chapter

In the rest of this section we present historical notes and summarize the main ingredients of kernel methods. In Sect. 32.2 we present the core ideas of statistical learning and show how regularization can be employed to devise practical learning algorithms. In Sect. 32.3 we show a selection of techniques that are representative of a large class of kernel methods; these techniques – termed primal–dual methods – use Lagrange duality as the main mathematical tools. Section 32.4 discusses Gaussian processes, a class of kernel methods that uses a Bayesian approach to perform inference and learning. Section 32.5 recalls different approaches for the tuning of parameters. In Sect. 32.6 we review the mathematical properties of different yet equivalent notions of kernels and recall a number of specialized kernels for learning problems involving structured data. We conclude the chapter by presenting applications in Sect. 32.7. Additional information can be found in a number of existing tutorials on [SVMs](#) and kernel methods, including [32.3–7].

### 32.1.2 Historical Background

The study of the mathematical foundation of kernels can be traced back at least to the beginning of the nineteenth century in connection with a general theory of integral equations [32.8, 9]. According to [32.10] the theory of reproducing kernel Hilbert spaces ([RKHS](#)) was first applied to detection and estimation problems by Parzen [32.11]. Properties of (reproducing) kernels are thoroughly presented in [32.12]. A first systematic treatment in the domain of nonparametric statistics can be found in [32.13]. Modern mathematical reviews include [32.14, 15]. The first use of kernel in the context of machine learning is generally attributed to [32.16]. The linear support vector algorithm, which undoubtedly had a prominent role in the history of kernel methods, made its first appearance in Russia in the 1960s [32.17, 18], in the framework of the *statistical learning theory* developed by Vapnik and Chervonenkis [32.19, 20]. Later, the idea was developed in connection to kernels by Vapnik and co-workers at AT&T labs [32.21–24]. The novel approach was rooted on a solid theoretical foundation. Additionally, studies began to report state-of-the-art performances in a number of applications, which further stimulated research on kernel-based techniques.

### 32.1.3 The Main Ingredients

Before delving into the details we now present the general setting for statistical learning problems and then briefly review the main ingredients of a substantial part of kernel methods used in machine learning.

#### Setting for Statistical Learning

The setting of learning from examples comprises three components [32.25]:

1. A *generator* of input data. We shall assume that data can be represented as vectors of  $\mathbb{R}^D$ . These vectors are independently and identically distributed ([i.i.d.](#)) according to a fixed but unknown probability distribution  $p(x)$ .
2. A *supervisor* that, given input data  $x$ , returns an output value  $y$  according to a conditional distribution  $p(y|x)$  also fixed and unknown. Note that the supervisor might or might not be present.

3. A *learning machine* (or *learning algorithm*) able to choose an hypothesis

$$f(x; \theta) . \quad (32.1)$$

Note that the hypothesis  $f$  is a function of  $x$  and depends upon a parameter vector  $\theta$  belonging to a set  $\Theta$ . The corresponding *hypothesis space* is then

$$\mathcal{S} = \{f(x; \Theta) : \theta \in \Theta\} , \quad (32.2)$$

which is one-to-one with the *parameter space*  $\Theta$ .

When the supervisor is present the learning problem is called *supervised*. The goal is to find that hypothesis that best mimics the supervisor response. When the supervisor is not present, the learning problem is called *unsupervised*. In this case, the aim is to find an hypothesis that represents the best concise representation of the data produced by the generator.

In both cases we might be interested either in the whole domain or we might be concerned only with a specific subset of points.

### Feature Mapping and Kernel Trick

Kernel methods are a special class of learning algorithms. Their main idea consists of mapping input points, generally represented as elements of  $\mathbb{R}^D$ , into an high-dimensional inner product space  $\mathcal{F}$ , called the *feature space*. The mapping is performed by means of a *feature map*  $\phi$

$$\begin{aligned} \phi : \mathbb{R}^D &\rightarrow \mathcal{F} , \\ x &\mapsto \phi(x) . \end{aligned} \quad (32.3)$$

One then approaches the learning task of interest by finding a linear model in the features space according to training points  $\phi(x_1), \dots, \phi(x_N) \in \mathcal{F}$ . Since the feature map is normally chosen to be nonlinear, a linear model in the feature space corresponds to a nonlinear rule in  $\mathbb{R}^D$ . Alternative kernel methods differ in the way the linear model in the feature space is found. Nonetheless, a common feature across different techniques is the following. If the algorithm can be expressed solely in terms of inner products, one can restate the problem in terms of evaluations of a *kernel function*

$$\begin{aligned} k : \mathbb{R}^D \times \mathbb{R}^D &\rightarrow \mathbb{R} , \\ (x, y) &\mapsto k(x, y) , \end{aligned} \quad (32.4)$$

by letting

$$k(x, y) = \phi(x)^\top \phi(y) . \quad (32.5)$$

This fact, usually referred to as the *kernel trick*, is of particular interest for the cases where the feature space is infinite dimensional, which prevents direct computation in the feature space. In practice, one often starts with designing a *positive definite* kernel, which guarantees the existence of a feature map  $\phi$  satisfying (32.4).

### Primal–Dual Estimation Techniques

As we shall see, an important class of machine learning methods consists of *primal–dual* learning techniques [32.1, 2, 26]. In this case, one starts from a *primal model* representation of the type

$$\begin{aligned} f(x; w, b) &= w^\top \phi(x) + b \\ &= \sum_i w_i \phi_i(x) + b . \end{aligned} \quad (32.6)$$

With reference to (32.1) note that here we have the tuple  $\theta = (w, b)$ . The *primal problem* is then a mathematical optimization problem aimed at finding optimal  $w \in \mathcal{F}$  and  $b \in \mathbb{R}$ . Notably, the right-hand side of (32.6) is affine in  $\phi(x)$ ; however, since  $\phi$  is in general a nonlinear mapping,  $f$  is a nonlinear function of  $x$ .

A first approach consists of solving the primal problem. The information content of training data is absorbed into the primal model's parameters during the procedure to find optimal parameters; the evaluation of the model (32.6) on new patterns (*out-of-sample extension*) does no longer require the use of training data; therefore, they can be discarded after training.

A second approach relies on Lagrangian duality arguments. In this case, the solution is represented in terms of dual variables  $\alpha_1, \alpha_2, \dots, \alpha_N$  and solved in  $\alpha_i \in \mathbb{R}^N$  and  $b \in \mathbb{R}$ . The *dual model* representation is then

$$f(x; \alpha, b) = \sum_{n=1}^N \alpha_n k(x_n, x) + b \quad (32.7)$$

and depends upon the training patterns  $x_1, x_2, \dots, x_N \in \mathbb{R}^D$ . The representation in (32.6) is usually called *parametric*, while (32.7) is the *nonparametric* representation [32.26].

## 32.2 Foundations of Statistical Learning

In this section, we briefly recall the main nomenclature and give a basic introduction on statistical learning theory. Historically, statistical learning theory constituted the theoretical foundation upon which the main methods of support vector machines were grounded. The theory is similar in spirit to a number of alternative complexity criteria and bias-variance trade-off curves. Nowadays, it remains a powerful framework for the design of learning algorithms.

### 32.2.1 Supervised and Unsupervised Inductive Learning

We have already introduced the distinction between *supervised* and *unsupervised*. Three important learning tasks are found within this categorization: *regression*, *classification*, and *density estimation*. In *regression* the supervisor's response takes values in the real numbers. In *classification* the supervisor's output takes values in the discrete finite set of possible labels  $\mathcal{Y}$ . In particular, in the *binary classification* problem  $\mathcal{Y}$  consists of two elements, e.g.,  $\mathcal{Y} = \{-1, 1\}$ . *Density estimation* is an instance of unsupervised learning: there is no supervisor. The functional relation to be learned from examples is the probability density  $p(x)$  (the generator). Supervised and unsupervised learning are concerned with estimating a function (an optimal hypothesis) over the whole input domain  $\mathbb{R}^D$  based upon a finite set of training points. Therefore, they are *inductive* approaches aiming at the general picture.

### 32.2.2 Semi-Supervised and Transductive Learning

#### Semi-Supervised Inductive Learning

In supervised learning the  $N$  training data are *i.i.d.* pairs

$$\{(x_1, y_1), (x_2, y_2), \dots, (x_N, y_N)\} \subset \mathbb{R}^D \times \mathcal{Y}, \quad (32.8)$$

each of which is assumed to be drawn according to

$$p(x, y) = p(y|x)p(x). \quad (32.9)$$

There is yet another inductive approach, namely *semi-supervised learning*. In semi-supervised learning one has a set of labeled pairs (32.8), as in supervised learning, as well as a set of unlabeled data

$$\{x_{N+1}, x_{N+2}, \dots, x_{N+T}\} \subset \mathbb{R}^D \quad (32.10)$$

*i.i.d.* from the generator  $p(x)$ , as in unsupervised learning. The purpose is the same as in supervised learning: to find an approximation of the supervisor response. However this goal is achieved by a learning algorithm that takes into account the additional information coming from the unlabeled data. According to [32.27], semi-supervised learning was popularized for the first time in the mid-1970s although similar ideas appeared earlier. Alternative semi-supervised learning algorithms differ in the way they exploit the information from the unlabeled set. One popular idea is to assume that the (possibly high-dimensional) input data lie (roughly) on a low-dimensional manifold [32.28–31].

#### Transductive Learning

In induction one seeks for the general picture with the purpose of making an out-of-sample prediction. This is an ambitious goal that might be unmotivated in certain settings. What if all the (unlabeled) data are given in advance? Suppose that one is only interested in prediction at given (finitely many) points. It is expected that this less ambitious task results in simple inference problems. These ideas are reflected in the approach found in *transductive learning* formulations. As in semi-supervised learning in transductive learning one has training pairs (32.65) as well as test (unlabeled) data (32.10). However, differently from semi-supervised learning one is only interested in making predictions for the test data (32.10).

### 32.2.3 Bounds on Generalization Error

Transductive and inductive inference share the common goal of achieving the lowest possible error on test data. In contrast with induction, transduction assumes that input test data are given in advance and consist of a finite discrete set of patterns drawn from the same distribution as the training set. From this perspective, it is clear that both transductive and inductive learning are concerned with *generalization*. In turn, a powerful framework to study the problem of generalization is the *structural risk minimization (SRM)* principle.

#### Expected and Empirical Risk

The starting point is the definition of a *loss*  $L(y, f(x; \theta))$ , or discrepancy, between the response  $y$  of the supervisor to a given input  $x$  and the response  $f(x; \theta)$  of the learning algorithm (that can be transductive or inductive). Formally, the generalization error can be defined

as the *expected risk*

$$R(\theta) = \int L(y, f(x; \theta)) p(x, y) dx dy. \quad (32.11)$$

From a mathematical perspective the goal of learning is the minimization of this quantity. However,  $p(x, y)$  is unknown and one can rely only on the sample version of (32.11), namely the *empirical risk*

$$R_{\text{emp}}^N(\theta) = \sum_{n=1}^N L(y_n, f(x_n, \theta)). \quad (32.12)$$

A possible learning approach is based on *empirical risk minimization* (**ERM**) and encompasses maximum likelihood (**ML**) inference [32.25]. It consists of finding

$$\hat{\theta}_N := \arg \min_{\theta \in \Theta} R_{\text{emp}}^N(\theta). \quad (32.13)$$

### Consistency

#### Definition 32.1

The **ERM** approach is said to be *consistent* if

$$\begin{aligned} R_{\text{emp}}^N(\hat{\theta}_N) &\xrightarrow{N} \inf_{\theta \in \Theta} R(\theta), \\ R(\hat{\theta}_N) &\xrightarrow{N} \inf_{\theta \in \Theta} R(\theta), \end{aligned}$$

where  $\xrightarrow{N}$  denotes convergence in probability for  $N \rightarrow \infty$ .

In words: the **ERM** is consistent if, as the number of training patterns  $N$  increases, *both* the expected risk  $R(\hat{\theta}_N)$  and the empirical risk  $R_{\text{emp}}^N(\hat{\theta}_N)$  converge to the minimal possible risk  $\min_{\theta \in \Theta} R(\theta)$ , see Fig. 32.1 for an illustration.

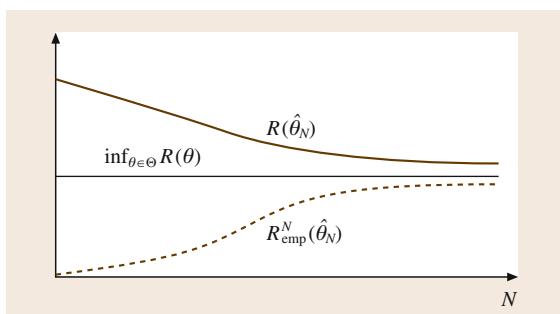

Fig. 32.1 Consistency of **ERM**

It was shown in [32.32] that the necessary and sufficient condition for consistency is that

$$P \left\{ \sup_{\theta \in \Theta} |R(\theta) - R_{\text{emp}}^N(\theta)| \geq \epsilon \right\} \xrightarrow{N} 0, \quad \forall \epsilon > 0. \quad (32.14)$$

In turn, the necessary and sufficient conditions for (32.14) to hold true were established in 1968 by *Vapnik* [32.33, 34] and are based on *capacity factors*.

### Capacity Factors

Consistency is one of the main theoretical questions in statistics. From a learning perspective, however, it does not address the most important aspect. The aspect that one should be mostly concerned with is how to control the generalization of a certain learning algorithm. Whereas consistency is an asymptotic result, we want to minimize the expected risk given that we have available only finitely many observations to train the learning algorithm. It turns out, however, that consistency is central to address also this aspect [32.25]. Additionally, a crucial role for answering this question is played by capacity factors that, roughly speaking, are all measures of how well the set of functions  $\{f(x; \theta) : \theta \in \Theta\}$  can separate data. A more detailed description is given in the following (precise definitions and formulas can be found in [32.25, Chap. 2]). In general, the theory states that without restricting the set of admissible functions, the **ERM** is not consistent. The interested reader is referred to [32.25, 35].

**VC Entropy.** The first capacity factor (here and below **VC** is used as an abbreviation for Vapnik–Chervonenkis.) relates to the expected number of *equivalence classes* according to which the training patterns divide the set of functions  $\{f(x; \theta) : \theta \in \Theta\}$  (an equivalence class is a subset of  $\{f(x; \theta) : \theta \in \Theta\}$  consisting of functions that attribute the same labels to the input pattern in the training set). We denote the **VC** entropy by  $\text{En}(p, N)$ , where the symbols emphasize the dependence of the **VC** Entropy on the underlying joint probability  $p$  and the number of training patterns  $N$ . The condition

$$\lim_{N \rightarrow \infty} \frac{\text{En}(p, N)}{N} = 0$$

forms the necessary and sufficient condition for (32.14) to hold true *with respect to the fixed probability density p*.

**Growth Function.** It corresponds to the maximal number of *equivalence classes* with respect to all the

possible training samples of cardinality  $N$ . As such, it is a distribution-independent version of the VC entropy obtained via a worst-case approach. We denote it by  $\text{Gr}(N)$ . The condition

$$\lim_{N \rightarrow \infty} \frac{\ln \text{Gr}(N)}{N} = 0$$

forms the necessary and sufficient condition for (32.14) to hold true *for all the probability densities p*.

**VC Dimension.** This is the cardinality of the largest set of points that the algorithm can shatter; we denote it by  $\dim_{\text{VC}}$ . Note that  $\dim_{\text{VC}}$  is a property of  $\{f(x; \theta) : \theta \in \Theta\}$ , which neither depends on  $N$  nor on  $p$ . Roughly speaking it tells how flexible the set of functions is. A finite value of  $\dim_{\text{VC}}$  forms the necessary and sufficient condition for (32.14) to hold true *for all the probability densities p*.

The three capacities are related by the chain of inequalities [32.33, 34]

$$\text{En}(p, N) \leq \ln \text{Gr}(N) \leq \dim_{\text{VC}} \left( \ln \frac{N}{\dim_{\text{VC}}} + 1 \right). \quad (32.15)$$

### Finite-Sample Bounds

One of the key results of the theory developed by Vapnik and Chervonenkis is the following probabilistic bound. With probability  $1 - \eta$  simultaneously for all  $\theta \in \Theta$  it holds that [32.25]

$$R(\theta) \leq R_{\text{emp}}^N(\theta) + \sqrt{\frac{\text{En}(p, 2N) - \ln \eta}{N}}. \quad (32.16)$$

Note that the latter depends on  $p$ . The result says that, for a fixed set of functions  $\{f(x; \theta) : \theta \in \Theta\}$ , one can pick that  $\theta \in \Theta$  that minimizes  $R_{\text{emp}}^N(\theta)$  and in this way obtain the best guarantee on  $R(\theta)$ . Now, taking into account (32.15) one can formulate the following bound based on the growth function

$$R(\theta) \leq R_{\text{emp}}^N(\theta) + \sqrt{\frac{\ln \text{Gr}(2N) - \ln \eta}{N}}. \quad (32.17)$$

In the same way one has

$$R(\theta) \leq R_{\text{emp}}^N(\theta) + \sqrt{\frac{\dim_{\text{VC}} \left( \ln \frac{2N}{\dim_{\text{VC}}} + 1 \right) - \ln \eta}{N}}. \quad (32.18)$$

Figure 32.2 illustrates the main idea.

Note that both (32.17) and (32.18) are distribution-independent. Additionally (32.18) only depends upon the VC dimension (which, contrary to Gr, is independent from  $N$ ). Unfortunately there is no free lunch: (32.17) is less tight than (32.16) and (32.18) is less tight than (32.17).

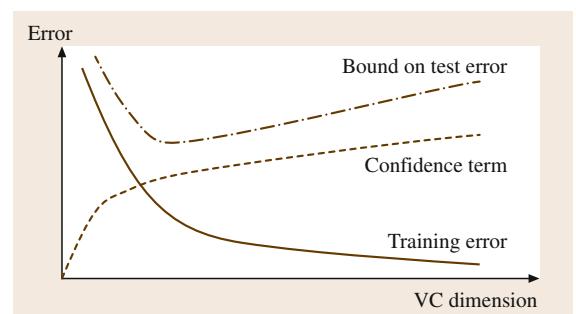

So far we gave a flavor of the theoretical framework in which the support vector algorithms were originally conceived. Recent research reinterpreted and significantly improved the error bounds using mathematical tools from approximation and learning theory, functional analysis, and statistics. The interested reader is referred to [32.36] and [32.37]. Although tighter bounds exist, the study of sharper bounds remains a challenge for future research. In fact, existing bounds are normally too loose to lead to practical model selection techniques, i.e., strategies for tuning the parameters that control the capacity of the model's class. Nonetheless, the theory provides important guidelines for the derivation of algorithms.

### The Role of Transduction

It turns out that a key step in obtaining the bound (32.16) is based upon the *symmetrization lemma*

$$\begin{aligned} & P \left\{ \sup_{\theta} |R(\theta) - R_{\text{emp}}^N(\theta)| \geq \epsilon \right\} \\ & \leq 2P \left\{ \sup_{\theta} |R_{\text{emp}_1}^{N_1}(\theta) - R_{\text{emp}_2}^{N_2}(\theta)| \geq \frac{\epsilon}{2} \right\}, \end{aligned} \quad (32.19)$$

where  $R_{\text{emp}_1}^{N_1}$  and  $R_{\text{emp}_2}^{N_2}$  are constructed upon two different i.i.d. samples, precisely as in transduction. More specifically, (32.16) comes from upper-bounding the right-hand side of (32.19) [32.38]. More generally it is apparent that to obtain all bounds of this type the key element remains the symmetrization lemma [32.25].

**Fig. 32.2** Illustration of the generalization bound depending on capacity factors

Notably starting from the latter one can derive bounds explicitly designed for the transductive case where one of the two samples plays the role of the training set and the other of the test set. In light of this, Vapnik argues that transductive inference is a fundamental step in machine learning. Additionally, since the bounds for transduction are tighter than those for induction, the theory suggests that, whenever possible, transductive inference should be preferred over inductive inference. Practical algorithms can take advantage of this fact by implementing the *adaptive* version of the structural risk minimization (**SRM**) principle that we discuss next.

### 32.2.4 Structural Risk Minimization and Regularization

#### The Structural Risk Minimization Principle

The structure of the bounds above suggests that one should minimize the empirical risk while controlling some measure of complexity. The idea behind the **SRM**, introduced in the 1970s, is to construct nested subsets of functions

$$\mathcal{S}_1 \subset \mathcal{S}_2 \subset \dots \subset \mathcal{S}_L = \mathcal{S} = \{f(x, \theta) : \theta \in \Theta\}, \quad (32.20)$$

where each subset  $\mathcal{S}_l$  has capacity  $h_l$  (**VC** entropy, growth function, or **VC** dimension) with  $h_1 < h_2 < \dots < h_l$  and  $\mathcal{S}$  is the entire hypothesis space. Then one chooses an element of the nested subsets so that the second term in the right-hand side of the bounds is kept under control; within that subset one then picks that specific function that minimizes the empirical risk. As Vapnik points out in [32.38]:

[...] to find a good solution using a finite (limited) number of training examples one has to construct a (smart) structure which reflects prior knowledge about the problem of interest.

In practice one can use the information coming from the unlabeled data to define a smart structure to improve the learning. In other words, the side information coming from unlabeled data can serve the purpose of devising a *data-dependent* set of functions. On top of this, one should use additional side information over the structure of the problem, whenever available. Indeed, using *informative representations* for the input data is also a way to construct a smart set of functions. In fact, representing the data in a suitable form implies a mapping from the input space to a more convenient set of fea-

tures. We will discuss this aspect more extensively in Sect. 32.6.

#### Learning Through Regularization

So far we have addressed the theory but we have not talked about how to practically implement it. It is understood that the essential idea of **SRM** is to find the best trade-off between the empirical risk and some measure of complexity (the capacity) of the hypothesis space. This ensures that the left-hand side of **VC** bounds – the expected risk that we are interested in to achieve generalization – is minimized. In practice there are different ways to define the sets in the sequence (32.20). The generic set  $\mathcal{S}_l$  could be the set of polynomials of degree  $l$  or a set of splines with  $l$  nodes. However, it is in connection to *regularization theory* that practical implementations of the **SRM** principle find their natural domain.

#### Tikhonov Theory

Regularization theory was introduced by Andrey Tikhonov [32.39–41] as a way to solve ill-posed problems. Ill-posed problems are problems that are not well posed in the sense of Hadamard [32.42]. Consider solving in  $f$  a linear operatorial equation of the type

$$Af = b. \quad (32.21)$$

In the general case,  $f$  is an element of a Hilbert space,  $A$  is a compact operator, and  $b$  is an element of its range. Even if a solution exists, it is often observed that a slight perturbation of the right-hand side  $b$  causes large deviations in the solution  $f$ . Tikhonov proposed to solve this problem by minimizing a functional of the type

$$\|Af - b\|^2 + \lambda \Gamma(f),$$

where  $\|\cdot\|$  is a suitable norm on the range of  $A$ ,  $\lambda$  is some hyperparameter, and  $\Gamma$  is a regularization functional (sometimes called *stabilizer*). The theory of such an approach was developed by Tikhonov and Ivanov; in particular it was shown that there exists a strategy to choose  $\lambda$  depending on the accuracy of  $b$  that asymptotically leads to the desired solution  $f^*$ . This was shown under the assumption that there exists  $c^*$  such that  $f^* \in \{f : \Gamma(f) \leq c^*\}$ .

According to Vapnik [32.20], the theory of Tikhonov regularization differs from statistical learning theory in a number of ways. To begin with Tikhonov regularization considers specific structures in the nested sequence (32.20) (depending on the way  $\Gamma$  is defined);

secondly it requires the solution to be in the hypothesis space; finally the theory developed by Tikhonov and Ivanov was not concerned with guarantees for a finite number of observations.

When  $f$  is an element of a reproducing kernel Hilbert space (**RKHS**) (Sect. 32.6), the theory is best known through the work of Wahba [32.13, 43].

### SRM and Regularization in RKHSs

**SVMs**, and more generally, primal–dual learning algorithms, represent an important class of kernel methods. The primal–dual approach emphasizes the geometrical aspects of the problem and it is particularly insightful when (32.7) is used to define a discriminative rule arising in a classification problem. We will consider this class of learning algorithms in later sections. Alternatively, the setting of **RKHSs** provides a convenient way to define the sequence (32.20). When the hypothesis space  $\mathcal{S}$  coincides with a **RKHS** of functions  $\mathcal{H}$ , a nested sequence can be constructed by bounding the norm in  $\mathcal{H}$ , used as a proxy for the complexity of models

$$\mathcal{S}_l = \{f \in \mathcal{H} : \|f\| \leq a_l\}. \quad (32.22)$$

It turns out that there is a measure of capacity of  $\mathcal{S}_l$ , which is an increasing function of  $a_l$  [32.44]. This capacity measure can be used to derive probabilistic bounds in line with (32.16), (32.17), and (32.18). In practice, instead of solving the *constrained problem*

$$\begin{aligned} & \min_{f \in \mathcal{H}} R_{\text{emp}}^N(f) \\ & \text{subject to } \|f\| \leq a_l \end{aligned} \quad (32.23)$$

for any  $l$ , one normally solves the provably equivalent *penalized problem*

$$\min_{f \in \mathcal{H}} R_{\text{emp}}^N(f) + \lambda_l \|f\|^2 \quad (32.24)$$

and pick the optimal  $\lambda_l$  appropriately. Note that in (32.23) and (32.24) we wrote  $R_{\text{emp}}^N(f)$  instead of  $R_{\text{emp}}^N(\theta)$ , as before. In fact, in this case, the solution of the learning problem is found by formulating a *convex variational problem* where the function  $f$  itself plays the role of the optimization variable  $\theta$ . In practice, however, the *representer theorem* [32.13, 43, 45, 46] shows that a representation of the optimal  $f$  only depends upon an expansion of kernel functions centered at the training patterns. This result leads to a representation for  $f$  in line with (32.7). More specifically it holds that  $f(x) =$

$\sum_{n=1}^N \alpha_n k(x_n, x)$  where  $\alpha \in \mathbb{R}^N$  is found solving a finite dimensional optimization problem. The latter is *convex* [32.47] provided that  $L$  in the empirical risk (32.12) is a convex loss function.

### Abstract Penalized Empirical Risk Minimization Problems

The penalized empirical risk minimization problem was introduced in (32.24) in the setting of **RKHS** of functions. However, it shall be noted that it is a very general idea. Ultimately this can be related to the generality of (32.21). The latter can either refer to infinite dimensional problems or to a finite system of linear equations involving objects living in some finite dimensional space. Therefore, for the sake of generality, one can consider in place of (32.24) the problem

$$\min_{\theta \in \Theta} R_{\text{emp}}^N(\theta) + \lambda \Gamma(\theta), \quad (32.25)$$

where  $\Theta$  — which is one-to-one with the hypothesis space — either coincides with some abstract vector space, or it is a subset of it;  $R_{\text{emp}}^N$  is the empirical risk and  $\Gamma : \Theta \rightarrow \mathbb{R}$  is a suitable penalty function. This, in particular, includes the situations where  $\theta$  is a vector, a matrix, or a higher-order tensor (i. e., a higher-order array generalizing the notion of matrices).

### 32.2.5 Types of Regularization

A penalty frequently used in practice is  $\Gamma(\theta) = \|\theta\|^2$ , where  $\|\theta\|$  is the *Hilbertian norm* defined upon the space's inner product

$$\|\theta\|^2 = \langle \theta, \theta \rangle. \quad (32.26)$$

This choice leads to *ridge regression* [32.48, 49]. Note that, in this case,  $\|\theta\| = 0$  if and only if  $\theta$  is the zero vector of the space. A more general class of quadratic penalties is represented by *seminorms*. A seminorm is allowed to assign zero length to some nonzero vectors (in addition to the zero vector). They are commonly used in smoothing splines [32.13, 50], where the unknown is decomposed into an unpenalized parametric component and a penalized nonparametric part.

#### LASSO and Non-Hilbertian Norms

The methods that we present in the next sections are all instances of the problem class in (32.25); although this is not necessarily emphasized in the presentation, they all employ a simple quadratic penalty. This is

central to relying on Lagrange duality theory [32.47, 51], which, in turn, constitutes the main technical tool for the derivation of a large class of kernel methods. However, it is important to mention that in the last decade much research effort has been expended on the design of alternative penalties (correspondingly, there has been increased interest in other notions of duality, such as *Fenchel duality*). This arises from the realization that using a certain penalty is also a way to convey prior knowledge. This fact is best understood within a Bayesian setting, in light of a *maximum a posteriori* (MAP) interpretation of (32.25), see, e.g., [32.44]. A penalty term based on the space's inner product has been replaced with various type of *non-Hilbertian norms*. These are norms that, contrary to (32.26), do not arise from inner products. **LASSO** (least absolute shrinkage and selection operator, [32.52]) is perhaps the most prominent example of such cases. In **LASSO** one considers linear functions

$$f(x; \theta) = \langle \theta, x \rangle = \sum_{d=1}^D \theta_d x_d$$

and uses the  $l_1$  norm

$$\|\theta\|_1 = \sum_{d=1}^D |\theta_d| \quad (32.27)$$

to promote the sparsity of the parameter vector  $\theta$ . Note that this corresponds to defining the structure (32.20) according to

$$\mathcal{S}_l = \{f(x; \theta) : \|\theta\|_1 \leq a_l\}. \quad (32.28)$$

Like ridge regression, **LASSO** is a continuous shrinkage method that achieves good prediction performance via a bias-variance trade-off. Since usually the estimated coefficient vector has many entries equal to zero, the approach has the further advantage over ridge regression of giving rise to interpretable models.

More recently, different structure-inducing penalties have been proposed as a promising alternative [32.53–55]. The general idea is to convey structural assumption on the problem, such as grouping or hierarchies over the set of input variables, by suitably crafting the penalty. In this way, the users are permitted to customize the regularization approach according to their subjective knowledge on the task. Correspondingly, as in (32.28), one (implicitly) forms a smart structure of

nested subsets of functions, in agreement with the **SRM** principle.

These ideas have been generalized to the case where  $\Theta$  is infinite dimensional, in particular in the framework of the multiple kernel learning (**MKL**) problem. This was investigated both from a functional viewpoint [32.56, 57], and from the more pragmatic point of view of optimization [32.58–60].

### Spectral Regularization

Yet another generalization of (32.25) arises in the context of *multitask learning* [32.61–63]. In this setting one approaches simultaneously different learning tasks under some common constraint(s). The general idea, sometimes also known as *collaborative filtering*, is that one can take advantage of shared features across tasks. In practical applications it was shown that one can significantly gain in terms of generalization performance from exploiting such prior knowledge. From the point of view of learning through regularization, a sensible approach is given in [32.64, 65]. Suppose one has  $T$  datasets, one for each task; the  $t$ -th dataset has  $N_t$  observations. Note that, in general,  $N_1 \neq N_2 \neq \dots \neq N_T$ . In this setting one has to learn vectors  $\theta_t$ ,  $t = 1, 2, \dots, T$ , one per task; the parameter space is, therefore, a space of matrices,  $\Theta = \mathbb{R}^{F \times T}$  where  $F$  is, possibly, infinity. The idea translates into penalized empirical risk minimization problems of the type

$$\min_{\theta = [\theta_1, \theta_2, \dots, \theta_T] \in \mathbb{R}^{F \times T}} \sum_{t=1}^T R_{\text{emp}}^{N_t}(\theta_t) + \lambda \|\theta\|_* , \quad (32.29)$$

where  $\|\theta\|_*$  is the *nuclear norm*

$$\|\theta\|_* = \sum_{r=1}^R \sigma_r(\theta) \quad (32.30)$$

and  $\sigma_1(\theta), \sigma_2(\theta), \dots, \sigma_R(\theta)$  are the  $R \leq \min(T, F)$  nonzero singular values of the  $F \times T$  matrix  $\theta$ . Note that (32.30) corresponds to the  $l_1$  norm of the vector of singular values. The definition also remains valid in the infinite dimensional case under some regularity assumptions [32.66]. The nuclear norm is the convex envelope of the rank function on the spectral-norm unit ball [32.67]; roughly speaking, it represents the best convex relaxation of the rank function.

The use of the nuclear norm in (32.29) is motivated by the assumption that the parameter vectors of

related tasks should be approximately linearly dependent. This assumption is meaningful for a number of cases of interest. Other uses of the nuclear norm exist; ultimately, this is due to the fact that notions of rank are ubiquitous in the mathematical formulations stemming from real-life problems. As a consequence, the nuclear norm is a very versatile mathematical tool to

impose structure on (seemingly) very diverse settings. This includes the identification of linear time-invariant systems [32.68, 69] and the analysis of nonstationary cointegrated systems [32.70]. Finally we mention that, in place of (32.30), one can consider *spectral penalties* [32.71, 72] that include the nuclear norm as a special case.

## 32.3 Primal-Dual Methods

The purpose of this section is to introduce the methods that have served as the archetypal approaches for a large class of kernel methods. In the process, we detail the Lagrange duality argument underlying general primal-dual techniques. We begin by giving a short overview of the formulations of **SVMs** introduced by Vapnik; successively, we discuss a number of modifications and extensions.

### 32.3.1 SVMs for Classification

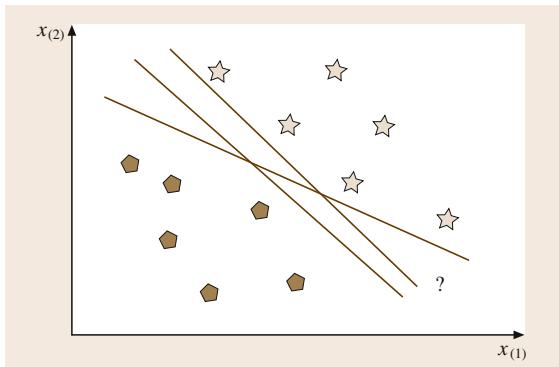

#### Margin

The problem of pattern recognition amounts to finding the label  $y \in \{-1, 1\}$  that corresponds to a generic input point  $x \in \mathbb{R}^D$ . This task can be approached by assigning a label  $\hat{y}$  according to the model

$$\hat{y} = \text{sign} [w^\top \phi(x) + b], \quad (32.31)$$

where  $w^\top \phi(x) + b$  is a hyperplane, found by a learning algorithm based on training data

$$\{(x_1, y_1), (x_2, y_2), \dots, (x_N, y_N)\} \subset \mathbb{R}^D \times \{-1, 1\}. \quad (32.32)$$

**Fig. 32.3** Several possible separating hyperplanes exist

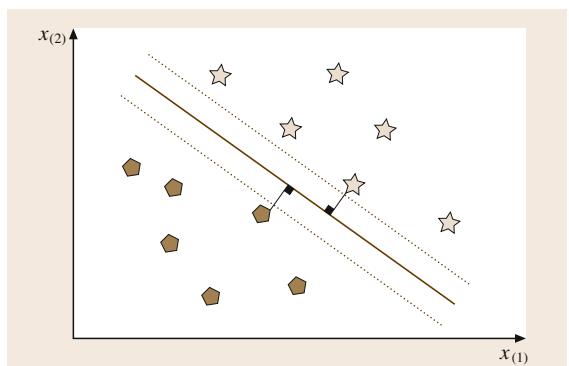

The concept of feature map  $\phi$  was presented in short in Sect. 32.1.3. Later we will discuss the role of  $\phi$  in more detail. For now, it suffices to say that  $\phi$  is expected to capture features that are important for the discrimination of points. In the simplest case,  $\phi$  is the identity map, i.e.,  $\phi : x \mapsto x$ . Note that  $w^\top \phi(x) + b$  is a primal model of the type (32.6), with  $w \in \mathcal{F}$  and  $b \in \mathbb{R}$ .

In general, one can see that there are several possible separating hyperplanes, see Fig. 32.3.

The solution picked by the support vector classification (**SVC**) algorithm is the one that separates the data with the maximal margin. More precisely, Vapnik considered a rescaling of the problem so that points closest to the separating hyperplane satisfy the normalizing condition

$$|w^\top \phi(x) + b| = 1. \quad (32.33)$$

The two hyperplanes  $w^\top \phi(x) + b = 1$  and  $w^\top \phi(x) + b = -1$  are called *canonical hyperplanes*, and the distance between them is called the *margin*, see Fig. 32.4.

**Fig. 32.4** SVC finds the solution that maximizes the margin

Assuming that the classification problem is *separable*, i.e., that there exists at least a hyperplane separating the training data (32.65), one obtains a canonical representation  $(w, b)$  satisfying

$$y_n (w^\top \phi(x_n) + b) \geq 1, \quad n = 1, \dots, N. \quad (32.34)$$

Let us assume, without loss of generality, that  $y_1 = 1$  and  $y_2 = -1$ . If the corresponding patterns  $x_1$  and  $x_2$  are among the closest points to the separating hyperplane, the scaling imposed by *Vapnik* implies

$$\begin{aligned} w^\top \phi(x_1) + b &= 1, \\ w^\top \phi(x_2) + b &= -1, \end{aligned} \quad (32.35)$$

which, in turn, leads to

$$w^\top (\phi(x_1) - \phi(x_2)) = 2. \quad (32.36)$$

Now the normal vector to the separating hyperplane  $w^\top \phi(x) + b$  is  $(1/\|w\|)w$ . The margin is equal to the component of the vector  $\phi(x_1) - \phi(x_2)$  along  $(1/\|w\|)w$ , i.e., the projection

$$(1/\|w\|)w^\top (\phi(x_1) - \phi(x_2)).$$

Using (32.36) one obtains that the margin is equal to  $2/\|w\|$ ; correspondingly, the distance between the points satisfying (32.33) and the separating hyperplane is  $1/\|w\|$ . By minimizing  $\|w\|$ , subject to the set of constraints (32.34), one obtains a *maximal margin classifier* that maximizes the margin between the two classes. This hyperplane, in turn, can be naturally envisioned as the simplest solution given the observed data.

### Primal Problem

In practice, for computational reasons it is more convenient to minimize  $\frac{1}{2}\|w\|^2 = \frac{1}{2}w^\top w$  rather than  $\|w\|$ . Additionally, it is in general unrealistic to assume that the classification problem is separable. In practical applications, one should try to find a set of features (in fact, a feature mapping from the input domain to a more convenient representation) that allow to separate the two classes as much as possible. Nonetheless, there might be no boundary that can perfectly separate the data; therefore one should tolerate misclassifications. Taking this requirement into account leads to the primal problem for the **SVC** algorithm [32.24]. This is the

quadratic programming (**QP**) problem

$$\min_{w, b, \xi} J_P(w, \xi) = \frac{1}{2}w^\top w + c \sum_{n=1}^N \xi_n$$

$$\text{subject to } \begin{aligned} y_n (w^\top \phi(x_n) + b) &\geq 1 - \xi_n, \quad n = 1, \dots, N \\ \xi_n &\geq 0, \quad n = 1, \dots, N, \end{aligned} \quad (32.37)$$

where  $c > 0$  is a user-defined parameter. In this problem, one accounts for misclassifications by replacing the set of constraints (32.34), with the set of constraints

$$y_n (w^\top \phi(x_n) + b) \geq 1 - \xi_n, \quad n = 1, \dots, N, \quad (32.38)$$

where  $\xi_1, \xi_2, \dots, \xi_N$  are positive slack variables. It is clear that for higher values of  $c$  one penalizes more the violations of the conditions in (32.34).

### Dual Problem

The Lagrangian corresponding to (32.37) is

$$\begin{aligned} \mathcal{L}(w, b, \xi; \alpha, \nu) &= J_P(w, \xi) \\ &- \sum_{n=1}^N \alpha_n (y_n (w^\top \phi(x_n) + b) - 1 + \xi_n) - \sum_{n=1}^N \nu_n \xi_n, \end{aligned} \quad (32.39)$$

with Lagrangian multipliers  $\alpha_n \geq 0$ ,  $\nu_n \geq 0$  for  $n = 1, \dots, N$ . The solution is given by the saddle point of the Lagrangian

$$\max_{\alpha, \nu} \min_{w, b, \xi} \mathcal{L}(w, b, \xi; \alpha, \nu). \quad (32.40)$$

One obtains

$$\begin{cases} \frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{n=1}^N \alpha_n y_n \phi(x_n), \\ \frac{\partial \mathcal{L}}{\partial b} = 0 \rightarrow \sum_{n=1}^N \alpha_n y_n = 0, \\ \frac{\partial \mathcal{L}}{\partial \xi_n} = 0 \rightarrow 0 \leq \alpha_n \leq c, \quad n = 1, \dots, N. \end{cases} \quad (32.41)$$

The dual problem is then the **QP** problem

$$\begin{aligned} \max_{\alpha} J_D(\alpha) \\ \text{subject to } \sum_{n=1}^N \alpha_n y_n = 0 \\ 0 \leq \alpha_n \leq c, \quad n = 1, \dots, N, \end{aligned} \quad (32.42)$$

where

$$J_D(\alpha) = -\frac{1}{2} \sum_{m,n=1}^N y_m y_n k(x_m, x_n) \alpha_m \alpha_n + \sum_{n=1}^N \alpha_n , \quad (32.43)$$

and we used the kernel trick

$$k(x_m, x_n) = \phi(x_m)^\top \phi(x_n) , \quad m, n = 1, \dots, N . \quad (32.44)$$

The classifier based on the dual model representation is

$$\text{sign} \left[ \sum_{n=1}^N \alpha_n y_n k(x, x_n) + b \right] , \quad (32.45)$$

where  $\alpha_n$  are positive real numbers obtained solving (32.42) and  $b$  is obtained based upon Karush–Kuhn–Tucker (KKT) optimality conditions, i.e., the set of conditions that must be satisfied at the optimum of a constrained optimization problem. These are

$$\begin{cases} \frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{n=1}^N \alpha_n y_n \phi(x_n) , \\ \frac{\partial \mathcal{L}}{\partial b} = 0 \rightarrow \sum_{n=1}^N \alpha_n y_n = 0 , \\ \frac{\partial \mathcal{L}}{\partial \xi_n} = 0 \rightarrow c - \alpha_n - \nu_n = 0 , \quad n = 1, \dots, N \\ \alpha_n (y_n (w^\top \phi(x_n) + b) - 1 + \xi_n) = 0 , \quad n = 1, \dots, N , \\ \nu_n \xi_n = 0 , \quad n = 1, \dots, N , \\ \alpha_n \geq 0 , \quad n = 1, \dots, N , \\ \nu_n \geq 0 , \quad n = 1, \dots, N . \end{cases} \quad (32.46)$$

From these equations it can be seen that, at optimum, we have

$$y_n (w^\top \phi(x_n) + b) - 1 = 0 \text{ if } 0 < \alpha_n < c , \quad (32.47)$$

from which one can compute  $b$ .

### SVC as a Penalized Empirical Risk Minimization Problem

The derivation so far followed the classical approach due to Vapnik; the main argument comes from geometrical insights on the pattern recognition problem.

Whenever the feature space is finite dimensional, one can approach learning either by solving the primal problem or by solving the dual one; when this is not the case, one can still use the dual problem and rely on the dual representation obtained.

Before proceeding, we highlight a different, yet equivalent problem formulation. For the primal problem this reads

$$\min_{w,b} \sum_{n=1}^N \left[ 1 - y_n (w^\top \phi(x_n) + b) \right]_+ + \lambda w^\top w , \quad (32.48)$$

where we let  $\lambda = 1/(2c)$  and we define  $[ \cdot ]_+$  by

$$[a]_+ = \begin{cases} a, & \text{if } a \geq 0 \\ 0, & \text{otherwise} . \end{cases} \quad (32.49)$$

Problem (32.37) is an instance of (32.25) obtained by letting (note that  $\mathcal{F} \times \mathbb{R}$  is naturally equipped with the inner product  $(w_1, b_1), (w_2, b_2) = w_1^\top w_2 + b_1 b_2$  and it is a (finite-dimensional) Hilbert space (HS).)  $\Theta = \mathcal{F} \times \mathbb{R}$  and taking as penalty the seminorm

$$\Gamma : (w, b) \mapsto w^\top w . \quad (32.50)$$

This shows that (32.37) is essentially a regularized empirical risk minimization problem that can be analyzed in the framework of the SRM principle presented in Sect. 32.2.

### VC Bounds for Classification

In Sect. 32.2.3 we already discussed bounds on the generalization error in terms of capacity factors. In particular, (32.18) states a bound for the case of VC dimension. The larger this VC dimension the smaller the training error (empirical risk) can become but the confidence term (second term on the right-hand side of (32.18)) will grow. The minimum of the sum of these two terms is then a good compromise solution. For SVM classifiers, Vapnik has shown that hyperplanes satisfying  $\|w\| \leq a$  have a VC dimension  $h$  that is upper-bounded by

$$h \leq \min([r^2 a^2], N) + 1 , \quad (32.51)$$

where  $[ \cdot ]$  represents the integer part and  $r$  is the radius of the smallest ball containing the points  $\phi(x_1), \phi(x_2), \dots, \phi(x_N)$  in the feature space  $\mathcal{F}$ .

Note that for each value of  $a$  there exists a corresponding value of  $\lambda$  in (32.48), correspondingly, a value of  $c$  in (32.37) or (32.42). Additionally, the radius  $r$  can

also be computed by solving a QP problem, see, e.g., [32.26]. It follows that one could compute solutions corresponding to multiple values of the hyperparameters, find the corresponding empirical risk and radius and then pick the model corresponding to the least value of the right-hand side of the bound (32.18). As we have already remarked, however, the bound (32.18) is often too conservative. Sharper bounds and frameworks alternative to VC theory have been derived, see, e.g. [32.73]. In practice, however, the choice of parameters is often guided by data-driven model selection criteria, see Sect. 32.5.

### Relative Margin and Data-Dependent Regularization

Although maximum margin classifiers have proved to be very effective, alternative notions of data separation have been proposed.

The authors of [32.74, 75], for instance, argue that maximum margin classifiers might be misled by direction of large variations. They propose a way to correct this drawback by measuring the margin not in an absolute sense but rather relative to the spread of data in any projection direction. Note that this can be seen as a way to conveniently craft the hypothesis space, an important aspect that we discussed in Sect. 32.2.

### 32.3.2 SVMs for Function Estimation

In addition to classification, the support vector methodology has also been introduced for linear and nonlinear function estimation problems [32.25]. For the general nonlinear case, output values are assigned according to the primal model

$$\hat{y} = w^\top \phi(x) + b. \quad (32.52)$$

In order to estimate the model's parameter  $w$  and  $b$ , from training data consisting of  $N$  input–output pairs, Vapnik proposed to evaluate the empirical risk according to

$$R_{\text{emp}} = \frac{1}{N} \sum_{n=1}^N \left| y_n - w^\top \phi(x_n) - b \right|_\epsilon \quad (32.53)$$

with the so called Vapnik's  $\epsilon$ -insensitive loss function defined as

$$|y - f(x)|_\epsilon = \begin{cases} 0, & \text{if } |y - f(x)| \leq \epsilon \\ |y - f(x)| - \epsilon, & \text{otherwise.} \end{cases} \quad (32.54)$$

The idea is illustrated in Fig. 32.5.

The corresponding primal optimization problem is the QP problem

$$\begin{aligned} \min_{w, b, \xi} \quad & J_P(w, \xi, \xi^*) = \frac{1}{2} w^\top w + c \sum_{n=1}^N (\xi_n + \xi_n^*) \\ \text{subject to} \quad & y_n - w^\top \phi(x_n) - b \leq \epsilon + \xi_n, \\ & n = 1, \dots, N, \\ & w^\top \phi(x_n) + b - y_n \leq \epsilon + \xi_n^*, \\ & n = 1, \dots, N, \\ & \xi_n, \quad \xi_n^* \geq 0, \quad n = 1, \dots, N, \end{aligned} \quad (32.55)$$

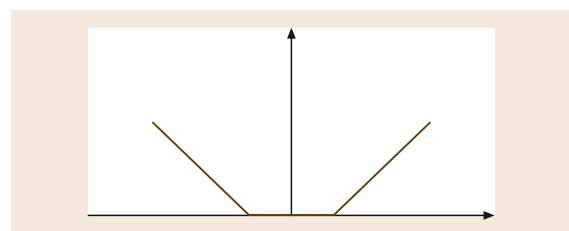

where  $c > 0$  is a user-defined parameter that determines the amount up to which deviations from the desired accuracy  $\epsilon$  are tolerated. Following the same approach considered above for (32.37), one obtains the dual QP problem

$$\begin{aligned} \max_{\alpha, \alpha^*} \quad & J_D(\alpha_m, \alpha_m^*) \\ \text{subject to} \quad & \sum_{n=1}^N (\alpha_m - \alpha_m^*) = 0, \\ & 0 \leq \alpha_n \leq c, \quad n = 1, \dots, N, \\ & 0 \leq \alpha_n^* \leq c, \quad n = 1, \dots, N, \end{aligned} \quad (32.56)$$

where

$$\begin{aligned} J_D(\alpha_m, \alpha_m^*) = & - \frac{1}{2} \sum_{m,n=1}^N (\alpha_m - \alpha_m^*)(\alpha_n - \alpha_n^*) k(x_m, x_n) \\ & - \epsilon \sum_{n=1}^N (\alpha_n - \alpha_n^*) + \sum_{n=1}^N y_n (\alpha_n - \alpha_n^*). \end{aligned} \quad (32.57)$$

Note that, whereas (32.37) and (32.42) have tuning parameter  $c$ , in (32.55) and (32.56) one has the additional parameter  $\epsilon$ .

**Fig. 32.5**  $\epsilon$ -insensitive loss

Before continuing, we note that a number of interesting modifications of the original SVR primal–dual formulations exist. In particular, [32.76] proposed the  $\nu$ -tube support vector regression. In this method, the objective  $J_P(w, \xi, \xi^*)$  in (32.55) is replaced by

$$\begin{aligned} J_P(w, \xi, \xi^*, \epsilon) \\ = \frac{1}{2} w^\top w + c \left( \nu \epsilon + \frac{1}{N} \sum_{n=1}^N (\xi_n + \xi_n^*) \right). \end{aligned} \quad (32.58)$$

In the latter,  $\epsilon$  is an optimization variable rather than a hyperparameter, as in (32.37);  $\nu$ , on the other hand, is fixed by the user and controls the fraction of support vectors that is allowed outside the tube.

### 32.3.3 Main Features of SVMs

Here we briefly highlight the main features of support vector algorithms, making a direct comparison with classical neural networks.

#### Choice of Kernel

A number of possible kernels, such as the Gaussian radial basis function (RBF) kernel, can be chosen in (32.44). Some examples are included in Table 32.1.

In general, it is clear from (32.44) that a valid kernel function must preserve the fundamental properties of the inner-product. That is, for the equality to hold, the bivariate function  $k : \mathbb{R}^D \times \mathbb{R}^D \rightarrow \mathbb{R}$  is required to be symmetric and positive definite. Note that this, in particular, imposes restriction on  $\tau$  in the polynomial kernel. A more in depth discussion on kernels is postponed to Sect. 32.6.

#### Global Solution

(32.37) and its dual (32.42) are convex problems. This means that any local minimum must also be global. Therefore, even though SVCs share similarities with neural network schemes (see below), they do not suffer from the well-known issue of local minima.

#### Sparseness

The dual model is parsimonious: typically, many  $\alpha$ 's are zero at the solution with the nonzero ones located in the proximity of the decision boundary. This is also

**Table 32.1** Some examples of kernel functions

| kernel name                  | $k(x, y)$                                 |
|------------------------------|-------------------------------------------|
| Linear                       | $x^\top y$                                |
| Polynomial of degree $d > 0$ | $(\tau + x^\top y)^d$ , for $\tau \geq 0$ |
| Gaussian RBF                 | $\exp(-\ x - y\ ^2/\sigma^2)$             |

desirable in all those setting were one requires fast online out-of-sample evaluations of models.

#### Neural Network Interpretation

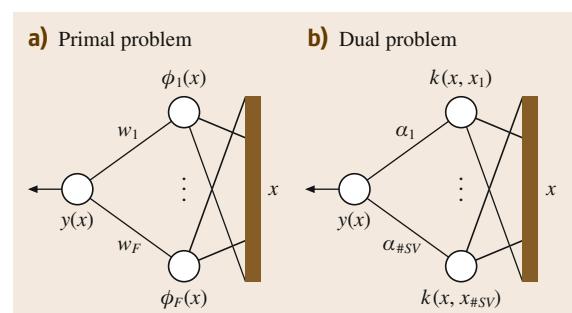

Both primal (parametric) and dual (nonparametric) problems admit neural network representations [32.26], see Fig. 32.6. Note that in the dual problem the size of the QP problem is not influenced by the dimension  $D$  of the input space, nor it is influenced by the dimension of the feature space. Notably, in classical multilayer perceptrons one has to fix the number of hidden units in advance; in contrast, in SVMs the number of hidden units follows from the QP problem and corresponds to the number of support vectors.

#### SVM Solvers

The primal and dual formulations presented above are all QP problems. This means that one can rely on general purpose QP solvers for the training of models. Additionally, a number of specialized decomposition methods have been developed, including the sequential minimum optimization (SMO) algorithm [32.77]. Publicly available software packages such as libSVM [32.78, 79] and SVMlight [32.80] include implementations of efficient solvers.

### 32.3.4 The Class of Least-Squares SVMs

We discuss here the class of least-squares SVMs (LS-SVMs) obtained by simple modifications to the SVMs formulations. The arising problems relate to a number of existing methods and entail certain advantages with respect to the original SVM formulations.

**Fig. 32.6a,b** Primal–dual network interpretations of SVMs [32.26]. (a) The number  $F$  of hidden units in the primal weight space corresponds to the dimensionality of the feature space. (b) The number  $\# \text{SV}$  of hidden units in the dual weight space corresponds to the number of nonzero  $\alpha$ 's

### LS-SVMs for Classification

We illustrate the idea with respect to the formulation for classification (**LS-SVC**). The approach, originally proposed in [32.81], considers the primal problem

$$\begin{aligned} \min_{w, b, \epsilon} J_P(w, \epsilon) &= \frac{1}{2} w^\top w + \frac{\gamma}{2} \sum_{n=1}^N \epsilon_n^2 \\ \text{subject to } y_n(w^\top \phi(x_n) + b) &= 1 - \epsilon_n, \\ n &= 1, \dots, N. \end{aligned} \quad (32.59)$$

This formulation simplifies the primal problem (32.37) in two ways. First, the inequality constraints are replaced by equality constraints; the 1's on the right-hand side in the constraints are regarded as target values rather than being treated as a threshold. An error  $\epsilon_n$  is allowed so that misclassifications are tolerated in the case of overlapping distributions. Secondly, a squared loss function is taken for these error variables. The Lagrangian for (32.59) is

$$\begin{aligned} \mathcal{L}(w, b, \epsilon; \alpha, v) \\ = J_P(w, \epsilon) - \sum_{n=1}^N \alpha_n (y_n(w^\top \phi(x_n) + b) - 1 + \epsilon_n), \end{aligned} \quad (32.60)$$

where  $\alpha$ 's are Lagrange multipliers that can be positive or negative since the problem now only entails equality constraints. The **KKT** conditions for optimality yield

$$\begin{cases} \frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{n=1}^N \alpha_n y_n \phi(x_n), \\ \frac{\partial \mathcal{L}}{\partial b} = 0 \rightarrow \sum_{n=1}^N \alpha_n y_n = 0, \\ \frac{\partial \mathcal{L}}{\partial \epsilon_n} = 0 \rightarrow \gamma \epsilon_n = \alpha_n, \quad n = 1, \dots, N, \\ \frac{\partial \mathcal{L}}{\partial \alpha_n} = 0 \rightarrow y_n(w^\top \phi(x_n) + b) - 1 + \epsilon_n = 0, \\ n = 1, \dots, N \end{cases} \quad (32.61)$$

By eliminating the primal variables  $w$  and  $b$ , one obtains the **KKT** system [32.82]

$$\begin{bmatrix} 0 & y^\top \\ y & \Omega + I/\gamma \end{bmatrix} \begin{bmatrix} b \\ \alpha \end{bmatrix} = \begin{bmatrix} 0 \\ 1_N \end{bmatrix}, \quad (32.62)$$

where

$$y = [y_1, y_2, \dots, y_N]^\top$$

and

$$1_N = [1, 1, \dots, 1]^\top$$

are  $N$ -dimensional vectors and  $\Omega$  is defined entry-wise by

$$(\Omega)_{mn} = y_m y_n \phi(x_m)^\top \phi(x_n) = y_m y_n k(x_m, x_n). \quad (32.63)$$

In the latter, we used the kernel trick introduced before. The dual model obtained corresponds to (32.45) where  $\alpha$  and  $b$  are now obtained solving the linear system (32.62), rather than a more complex **QP** problem, as in (32.42). Notably, for **LS-SVMs** (and related methods) one can exploit a number of computational shortcuts related to spectral properties of the kernel matrix; for instance, one can compute solutions for different values of  $\gamma$  at the price of computing the solution of a single problem, which cannot be done for **QPs** [32.83–85].

The **LS-SVC** is easily extended to handle multiclass problems [32.26]. Extensive comparisons with alternative techniques (including **SVC**) for binary and multiclass classification are considered in [32.26, 86]. The results show that, in general, **LS-SVC** either outperforms or perform comparably to the alternative techniques. Interestingly, it is clear from the primal problem (32.61) that **LS-SVC** maximizes the margin while minimizing the within-class scattering from targets  $\{+1, -1\}$ . As such, **LS-SVC** is naturally related to Fisher discriminant analysis in the feature space [32.26]; see also [32.2, 87, 88].

### Alternative Formulations

Besides classification, a primal–dual approach similar to the one introduced above has been considered for function estimation [32.26]; in this case too the dual model representation is obtained by solving a linear system of equations rather than a **QP** problem, as in **SVR**. This approach to function estimation is similar to a number of techniques, including smoothing splines [32.13], regularization networks [32.44, 89], kernel ridge regression [32.90], and Kriging [32.91]. **LS-SVM** solutions also share similarities with Gaussian processes [32.92, 93], which we discuss in more detail in the next section.

Other formulations have been considered within a primal–dual framework. These include principal component analysis [32.94], which we discuss next, spectral clustering [32.95], canonical correlation analysis [32.96], dimensionality reduction and data visualization [32.97], recurrent networks [32.98], and optimal

control [32.99]; see also [32.100]. In all these cases the estimation problem of interest is conceived at the primal level as an optimization problem with equality constraints, rather than inequality constraints as in **SVMs**. The constraints relate to the model which is expressed in terms of the feature map. From the **KKT** optimality conditions one jointly finds the optimal model representation and the model estimate. As for the case of classification the dual model representation is expressed in terms of kernel functions.

### Sparsity and Robustness

An important difference with **SVMs**, is that the dual model found via **LS-SVMs** depends upon all the training data. Reduction and pruning techniques have been used to achieve the sparse representation in a second stage [32.26, 101]. A different approach, which makes use of the primal-dual setting, leads to *fixed-size* techniques [32.26], which relate to the *Nyström method* proposed in [32.102] but lead to estimation in the primal setting. Optimized versions of fixed-size **LS-SVMs** are currently applicable to large data sets with millions of data points for training and tuning on a personal computer [32.103].

In **LS-SVM** the estimation of the support values is only optimal in the case of a Gaussian distribution of the error variables [32.26]; [32.101] shows how to obtain robust estimates for regression by applying a weighted version of **LS-SVM**. The approach is suitable in the case of outliers or non-Gaussian error distributions with heavy tails.

### 32.3.5 Kernel Principal Component Analysis

Principal component analysis (**PCA**) is one of the most important techniques in the class of unsupervised learning algorithms. **PCA** linearly transforms a number of possibly correlated variables into uncorrelated features called principal components. The transformation is performed to find directions of maximal variation. Often, few principal components can account for most of the structure in the original dataset. **PCA** is not suitable for discovering nonlinear relationships among the original variables. To overcome this limitation [32.104] originally proposed the idea of performing **PCA** in a feature space rather than in the input space.

Regardless of the space where the transformation is performed, there is a number of different ways to characterize the derivation of the **PCA** problem [32.105]. Ultimately, **PCA** analysis is readily performed by solv-

ing an eigenvalue problem. Here we consider a primal-dual formulation similar to the one introduced above for **LS-SVC** [32.106]. In this way the eigenvalue problem is seen to arise from optimality conditions. Notably the approach emphasizes the underlying model, which is important for finding the projection of out-of-sample points along the direction of maximal variation. The analysis assumes the knowledge of  $N$  training data pairs

$$\{x_1, x_2, \dots, x_N\} \subset \mathbb{R}^D \quad (32.64)$$

i.i.d. according to the generator  $p(x)$ . The starting point is to define the generic *score variable*  $z$  as

$$z(x) = w^\top (\phi(x) - \hat{\mu}_\phi). \quad (32.65)$$

The latter represents one projection of  $\phi(x) - \mu_\phi$  into the target space. Note that we considered data centered in the feature space with

$$\hat{\mu}_\phi = \frac{1}{N} \sum_{n=1}^N \phi(x_n) \quad (32.66)$$

corresponding to the center of the empirical distribution. The primal problem consists of the following constrained formulation [32.94]

$$\begin{aligned} \max_{w,z} \quad & -\frac{1}{2} w^\top w + \frac{\gamma}{2} \sum_{n=1}^N z_n^2 \\ \text{subject to } \quad & z_n = w^\top (\phi(x_n) - \hat{\mu}_\phi), \quad n = 1, \dots, N. \end{aligned} \quad (32.67)$$

where  $\gamma > 0$ . The latter maximizes the empirical variance of  $z$  while keeping the norm of the corresponding parameter vector  $w$  small by the regularization term. One can also include a bias term, see [32.26] for a derivation.

The Lagrangian corresponding to (32.67) is

$$\begin{aligned} \mathcal{L}(w, z; \alpha) = & -\frac{1}{2} w^\top w + \frac{\gamma}{2} \sum_{n=1}^N z_n^2 \\ & - \sum_{n=1}^N \alpha_n (z_n - w^\top (\phi(x_n) - \hat{\mu}_\phi)), \end{aligned} \quad (32.68)$$

with conditions for optimality given by

$$\begin{cases} \frac{\partial \mathcal{L}}{\partial w} = 0 \rightarrow w = \sum_{n=1}^N \alpha_n (\phi(x_n) - \mu_\phi), \\ \frac{\partial \mathcal{L}}{\partial z_n} = 0 \rightarrow \alpha_n = \gamma z_n, \quad n = 1, \dots, N, \\ \frac{\partial \mathcal{L}}{\partial \alpha_n} = 0 \rightarrow z_n = w^\top (\phi(x_n) - \hat{\mu}_\phi), \\ \quad n = 1, \dots, N. \end{cases} \quad (32.69)$$

By eliminating the primal variables  $w$  and  $z$ , one obtains for  $n = 1, \dots, N$

$$\frac{1}{\gamma} \alpha_n - \sum_{m=1}^N \alpha_m (\phi(x_n) - \hat{\mu}_\phi) (\phi(x_m) - \hat{\mu}_\phi) = 0. \quad (32.70)$$

The latter is an eigenvalue decomposition that can be stated in matrix notation as

$$\Omega_c \alpha = \lambda \alpha, \quad (32.71)$$

where  $\lambda = 1/\gamma$  and  $\Omega_c$  is the centered Gram matrix defined entry-wise by

$$[\Omega_c]_{nm} = k(x_n, x_m) - \frac{1}{N} \sum_{l=1}^N k(x_m, x_l) - \frac{1}{N} \sum_{l=1}^N k(x_n, x_l) + \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N k(x_j, x_i). \quad (32.72)$$

As before, one may choose any positive definite kernel; a typical choice corresponds to the Gaussian RBF

kernel. By solving the eigenvalue problem (32.71) one finds  $N$  pairs of eigenvalues and eigenvectors

$$(\lambda_m, \alpha^m), \quad m = 1, 2, \dots, N.$$

Correspondingly, one finds  $N$  score variables with dual representation

$$z_m(x) = \sum_{n=1}^N \alpha_n^m \left( k(x_n, x) - \frac{1}{N} \sum_{l=1}^N k(x, x_l) - \frac{1}{N} \sum_{l=1}^N k(x_n, x_l) + \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N k(x_j, x_i) \right), \quad (32.73)$$

in which  $\alpha^m$  is the eigenvector associated to the eigenvalue  $\lambda_m$ . Note that all eigenvalues are positive and real because  $\Omega_c$  is symmetric and positive semidefinite; the eigenvectors are mutually orthogonal, i.e.,  $(\alpha^l)^\top \alpha^m = 0$ , for  $l \neq m$ . Note that when the feature map is nonlinear, the number of score variables associated to nonzero eigenvalues might exceed the dimensionality  $D$  of the input space. Typically, one selects then the minimal number of score variables that preserve a certain reconstruction accuracy, see [32.26, 104, 105].

Finally, observe that by the second optimality condition in (32.61), one has  $z_l = \lambda_l \alpha^l$  for  $l = 1, 2, \dots, N$ . From this, we obtain that the score variables are empirically uncorrelated. Indeed, we have for  $l \neq m$

$$\begin{aligned} & \sum_{n=1}^N z_l(x_n) z_m(x_n) \\ &= \sum_{n=1}^N \lambda_l \lambda_m (\alpha^l)^\top \alpha^m = 0. \end{aligned} \quad (32.74)$$

## 32.4 Gaussian Processes

So far we have dealt with primal-dual kernel methods; regularization was motivated by the **SRM** principle, which achieves generalization by trading off empirical risk with the complexity of the model class. This is representative of a large number of procedures. However, it leaves out an important class of kernel-based probabilistic techniques that goes under the name of *Gaussian processes*. In Gaussian processes one uses

a Bayesian approach to perform inference and learning. The main idea goes back at least to the work of Wiener [32.107] and Kolmogorov [32.108] on time-series analysis.

As a first step, one poses a probabilistic model which serves as a prior. This prior is updated in the light of training data so as to obtain a predictive distribution. The latter represents a spectrum of possible answers. In

contrast, in the standard **SVM/LS-SVM** framework one obtains only point-wise estimates. The approach, however, is analytically tractable only for a limited number of cases of interests. In the following, we summarize the main ideas in the context of regression where tractability is ensured by Gaussian posteriors; the interested reader is referred to [32.109] for an in-depth review.

### 32.4.1 Definition

A real-valued stochastic process  $f$  is a Gaussian process (**GP**) if for every finite set of indices  $x_1, x_2, \dots, x_N$  in an index set  $\mathcal{X}$ , the tuple

$$f_x = (f(x_1), f(x_2), \dots, f(x_N)) \quad (32.75)$$

is a multivariate Gaussian random variable taking values in  $\mathbb{R}^N$ . Note that the index set  $\mathcal{X}$  represents the set of all possible inputs. This might be a countable set, such as  $\mathbb{N}$  (e.g. a discrete time index) or, more commonly in machine learning, the Euclidean space  $\mathbb{R}^D$ . A **GP**  $f$  is fully specified by a *mean function*  $m : \mathcal{X} \rightarrow \mathbb{R}$  and a *covariance function*  $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  defined by

$$m(x) = \mathbb{E}[f(x)], \quad (32.76)$$

$$k(x, x') = \mathbb{E}[(f(x) - m(x))(f(x') - m(x'))]. \quad (32.77)$$

In light of this, one writes

$$f \sim \mathcal{GP}(m, k). \quad (32.78)$$

Usually, for notational simplicity one takes the mean function to be zero, which we consider here; however, this need not to be the case.

Note that the specification of the covariance function implies a distribution over any finite collection of random variables obtained sampling the process  $f$  at given locations. Specifically, we can write for (32.75)

$$f_x \sim \mathcal{N}(0, K), \quad (32.79)$$

which means that  $f_x$  follows a multivariate zero-mean Gaussian distribution with  $N \times N$  covariance matrix  $K$  defined entry-wise by

$$[K]_{nm} = k(x_n, x_m).$$

The typical use of a **GP** is in a regression context, which we consider next.

### 32.4.2 GPs for Regression

In regression one observes a dataset of input–output pairs  $(x_n, y_n)$ ,  $n = 1, 2, \dots, N$  and wants to make a prediction at one or more test points. In the following, we call  $y$  the vector obtained stacking the target observations and denote by  $X$  the collection of input training patterns (32.64). In order to carry on the Bayesian inference, one needs a model for the generating process. It is generally assumed that function values are observed in noise, that is,

$$y_n = f(x_n) + \epsilon_n, \quad n = 1, 2, \dots, N. \quad (32.80)$$

One further assumes that  $\epsilon_n$  are i.i.d. zero-mean Gaussian random variables independent of the process  $f$  and with variance  $\sigma^2$ . Under these circumstances, the noisy observations are Gaussian with mean zero and covariance function

$$c(x_m, x_n) = \mathbb{E}[y_m y_n] = k(x_m, x_n) + \sigma^2 \delta_{nm}, \quad (32.81)$$

where the Kronecker delta function  $\delta_{nm}$  is 1 if  $n = m$  and 0 otherwise.

Suppose now that we are interested in the value  $f_*$  of the process at a single test point  $x_*$  (the approach that we discuss below extends to multiple test points in a straightforward manner). By relying on properties of Gaussian probabilities, we can readily write the joint distribution of the test function value and the noisy training observations. This reads

$$\begin{bmatrix} y \\ f_* \end{bmatrix} \sim \mathcal{N}\left(0, \begin{bmatrix} K + \sigma^2 I_N & k_* \\ k_*^\top & k_* \end{bmatrix}\right), \quad (32.82)$$

where  $I_N$  is the  $N \times N$  identity matrix,  $k_* = k(x_*, x_*)$ , and finally

$$k_x = [k(x_1, x_*), k(x_2, x_*), \dots, k(x_N, x_*)]^\top. \quad (32.83)$$

#### Prediction with Noisy Observations

Using the conditioning rule for multivariate Gaussian distributions, namely:

$$\begin{aligned} \begin{bmatrix} x \\ y \end{bmatrix} &\sim \mathcal{N}\left(\begin{bmatrix} a \\ b \end{bmatrix}, \begin{bmatrix} A & C \\ C^\top & B \end{bmatrix}\right) \Rightarrow \\ y|x &\sim \mathcal{N}\left(b + C^\top A^{-1}(x - a), B - C^\top A^{-1}C\right), \end{aligned}$$

one arrives at the key predictive equation for GP regression

$$f_*|y, X, x_* \sim \mathcal{N}(m_*, \sigma_*^2), \quad (32.84)$$

where

$$m_* = k_x^\top (K + \sigma^2 I)^{-1} y, \quad (32.85)$$

$$\sigma_*^2 = k_* - k_x^\top (K + \sigma^2 I)^{-1} k_x. \quad (32.86)$$

Note that, by letting  $\alpha = (K + \sigma^2 I)^{-1} y$ , one obtains for the mean value

$$m_* = \sum_{n=1}^N \alpha_n k(x_n, x_*). \quad (32.87)$$

Up to the bias term  $b$ , the latter coincides with the typical dual model representation (32.7), in which  $x$  plays the role of a test point. Therefore, one can see that, in the framework of GPs, the covariance function plays the same role of the kernel function. The variance  $\sigma_*^2$ , on the other hand, is seen to be obtained from the prior covariance, by subtracting a positive term which accounts for the information about the process conveyed by training data.

### Weight-Space View

We have presented GPs through the so-called *function space view* [32.109], which ultimately captures the distinctive nature of this class of methodologies. Here we illustrate a different view, which allows one to achieve three objectives: 1) it is seen that Bayesian linear models are a special instance of GPs; 2) the role of Bayes' rule is highlighted; 3) one obtains additional insight on the relationship with the feature map and kernel function used before within primal-dual techniques.

**Bayesian Regression.** The starting point is to characterize  $f$  as a parametric model involving a set of basis functions  $\psi_1, \psi_2, \dots, \psi_F$

$$f(x) = \sum_i w_i \psi_i(x) = w^\top \psi(x). \quad (32.88)$$

Note that  $F$  might be infinity. For the special case where  $\psi$  is the identity mapping, one recognizes in (32.80) the standard modeling assumptions for Bayesian linear regression analysis. Inference is based on the posterior

distribution over the weights, computed by Bayes' rule

$$\text{posterior} = \frac{\text{likelihood} \times \text{prior}}{\text{marginal likelihood}},$$

$$p(w|y, X) = \frac{p(y|X, w)p(w)}{p(y|X)}, \quad (32.89)$$

where the marginal likelihood (a.k.a. normalizing constant) is independent of the weights

$$p(y|X) = \int p(y|X, w)p(w)dw. \quad (32.90)$$

**Explicit Feature Space Formulation.** To make a prediction for a test pattern  $x_*$  we average over all possible parameter values with weights corresponding to the posterior probability

$$p(f_*|y, X, x_*) = \int p(f_*|w, x_*)p(w|y, X)dw. \quad (32.91)$$

One can see that computing the posterior  $p(w|y, X)$  based upon the prior

$$p(w) = \mathcal{N}(0, \Sigma_p) \quad (32.92)$$

gives the predictive model

$$f_*|y, X, x_* \sim \mathcal{N}\left(\psi(x_*)^\top \Sigma_p \Psi A y, \psi(x_*)^\top \Sigma_p \psi(x_*) - \psi(x_*)^\top \Sigma_p \Psi A \Psi^\top \Sigma_p \psi(x_*)\right), \quad (32.93)$$

where  $A = (\Psi^\top \Sigma_p \Psi + \sigma^2 I_N)^{-1}$  and we denoted by

$$\Psi = [\psi(x_1), \psi(x_2), \dots, \psi(x_N)]$$

the feature representation of the training patterns. It is not difficult to see that (32.93) is (32.84) in disguise. In particular, one has

$$k(x, y) = \psi(x)^\top \Sigma_p \psi(y). \quad (32.94)$$

The positive definiteness of  $\Sigma_p$  ensures the existence and uniqueness of the square root  $\Sigma_p^{1/2}$ . If we now define

$$\phi(x) = \Sigma_p^{1/2} \psi(x), \quad (32.95)$$

we retrieve the relationship in (32.44). We conclude that the kernel function considered in the previous sections can be interpreted as the covariance function of a GP.

### 32.4.3 Bayesian Decision Theory

Bayesian inference is particularly appealing when prediction is intended for supporting decisions. In this case, one requires a loss function  $L(f_{\text{true}}, f_{\text{guess}})$  which specifies the penalty obtained by guessing  $f_{\text{guess}}$  when the true value is  $f_{\text{true}}$ . Note that the predictive distribution (32.84) or – equivalently – (32.93) was derived without reference to the loss function. This is a major difference with respect to the techniques developed within the framework of statistical learning. Indeed, in the non-Bayesian framework of penalized empirical risk minimization, prediction and loss are entangled; one tackles learning in a somewhat more direct way. In contrast, in the Bayesian setting there is a clear distinction between 1) the model that generated the data and 2) capturing the consequences of making guesses. In light of this, [32.109] advises one to beware of arguments like *a Gaussian likelihood implies a squared error loss*. In order to find the point prediction that incurs the minimal *expected loss*, one can define the merit

function

$$R(f_{\text{guess}}|y, X, x_*) = \int L(f_*, f_{\text{guess}}) p(f_*|y, X, x_*) df_* . \quad (32.96)$$

Note that, since the true value  $f_{\text{true}}$  is unknown, the latter averages with respect to the model's opinion  $p(f_*|y, X, x_*)$  on what the truth might be. The corresponding best guess is

$$f_{\text{opt}} = \arg \min_{f_{\text{guess}}} R(f_{\text{guess}}|y, X, x_*) . \quad (32.97)$$

Since  $p(f_*|y, X, x_*)$  is Gaussian and hence symmetric,  $f_{\text{opt}}$  always coincides with the mean  $m_*$  whenever the loss is also symmetric. However, in many practical problems such as in critical safety applications, the loss can be asymmetrical. In these cases, one must solve the optimization problem in (32.97). Similar considerations hold for classification, see [32.109]. For an account on decision theory see [32.110].

## 32.5 Model Selection

Kernel-based models depend upon a number of parameters which are determined during training by numerical procedures. Still, one or more hyperparameters usually need to be tuned by the user. In **SVC**, for instance, one has to fix the value of  $c$ . The choice of the kernel function, and of the corresponding parameters, also needs to be properly addressed.

In general, performance measures used for model selection include k-fold cross-validation, leave-one-out (**LOO**) cross-validation, generalized approximate cross-validation (**GACV**), approximate span bounds, **VC** bounds, and radius-margin bounds. For discussions and comparisons see [32.111, 112]. Another approach found in the literature is kernel-target alignment [32.113].

### 32.5.1 Cross-Validation

In practice, model selection based on cross-validation is usually preferred over generalization error bounds. Criticism for cross-validation approaches is related to the high computational load involved; [32.114] presents an efficient methodology for hyperparameter tuning and model building using **LS-SVMs**. The

approach is based on the closed form **LOO** cross-validation computation for **LS-SVMs**, only requiring the same computational cost of one single **LS-SVM** training. Leave-one-out cross-validation-based estimates of performance, however, generally exhibit a relatively high variance and are, therefore, prone to over-fitting. To amend this, [32.115] proposed the use of Bayesian regularization at the second level of inference.

### 32.5.2 Bayesian Inference of Hyperparameters

Many authors have proposed a full Bayesian framework for kernel-based algorithms in the spirit of the methods developed by *MacKay* for classical **MLPs** [32.116–118]. In particular, [32.26] discusses the case of **LS-SVMs**. It is shown that, besides leading to tuning strategies, the approach allows us to take probabilistic interpretations of the outputs; [32.109] discusses the Bayesian model selection for **GPs**. In general, the Bayesian framework consists of multiple levels of inference. The parameters (i. e., with reference to the primal model,  $w$  and  $b$ ) are inferred at level 1. Contrary to **MLPs**, this usually entails the solution of a convex op-

timization problem or even solving a linear system, as in **LS-SVMs** and **GPs**. The regularization parameter(s) and the kernel parameter(s) are inferred at higher levels.

The method progressively integrates out the parameters by using the evidence at a certain level of inference as the likelihood at the successive level.

## 32.6 More on Kernels

We have already seen that a kernel arising from an inner product can be interpreted as the covariance function of a Gaussian process. In this section we further study the mathematical properties of different yet equivalent notions of kernels. In particular, we will discuss that positive definite kernels are *reproducing*, in a sense that we are about to clarify. We will then review a number of specialized kernels for learning problems involving structured data.

### 32.6.1 Positive Definite Kernels

Denote by  $\mathcal{X}$  a nonempty index set. A symmetric function  $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  is a *positive definite kernel* if for any  $N \in \mathbb{N}$  and for any tuple  $(x_1, x_2, \dots, x_N) \in \mathcal{X}^N$ , the Gram matrix  $K$  defined entry-wise by  $K_{nm} = k(x_n, x_m)$ , satisfies (note that, by definition, a positive definite kernel satisfies  $k(x, x) \geq 0$  for any  $x \in \mathcal{X}$ )

$$\alpha^\top K \alpha = \sum_{n=1}^N \sum_{m=1}^N K_{nm} \alpha_n \alpha_m \geq 0 \quad \forall \alpha \in \mathbb{R}^N.$$

In particular, suppose  $\mathcal{F}$  is some Hilbert space (**HS**) (for an elementary introduction see [32.66]) with inner product  $\langle \cdot, \cdot \rangle$ . Then for any function  $\phi : \mathcal{X} \rightarrow \mathcal{F}$  one has

$$\begin{aligned} & \sum_{n=1}^N \sum_{m=1}^N \langle \phi(x_n), \phi(x_m) \rangle \alpha_n \alpha_m \\ &= \sum_{n=1}^N \sum_{m=1}^N \langle \alpha_n \phi(x_n), \alpha_m \phi(x_m) \rangle \\ &= \left\| \sum_{n=1}^N \alpha_n \phi(x_n) \right\|^2 \geq 0. \end{aligned} \tag{32.98}$$

From the first line one can then see that

$$k : (x, y) \mapsto \langle \phi(x), \phi(y) \rangle \tag{32.99}$$

is a positive definite kernel in the sense specified above. A continuous positive definite kernel  $k$  is often called a *Mercer kernel* [32.36].

Note that in Sect. 32.1.3 we denoted  $\langle \phi(x), \phi(y) \rangle$  by  $\phi(x)^\top \phi(y)$ , implicitly making the assumption that the feature space  $\mathcal{F}$  is a finite dimensional Euclidean space. However, one can show that the feature space associated to certain positive definite kernels (such as the Gaussian **RBF** [32.119]) is an infinite dimensional **HS**; in turn, the inner product in such a space is commonly denoted as  $\langle \cdot, \cdot \rangle$ .

### 32.6.2 Reproducing Kernels

#### Evaluation Functional

Let  $(\mathcal{H}, \langle \cdot, \cdot \rangle)$  be a **HS** of real-valued functions (the theory of **RKHSs** generally deals with complex-valued functions [32.12, 14]; here we stick to the real setting for simplicity) on  $\mathcal{X}$  equipped with the norm  $\|f\| = \sqrt{\langle f, f \rangle}$ . For  $x \in \mathcal{X}$  we denote by  $L_x$  the evaluation functional

$$\begin{aligned} L_x : \mathcal{H} &\rightarrow \mathbb{R}, \\ f &\mapsto f(x). \end{aligned} \tag{32.100}$$

$L_x$  is said to be bounded if there exists  $c > 0$  such that  $|L_x f| = |f(x)| \leq c \|f\|$  for all  $f \in \mathcal{H}$ . By the Riesz representation theorem [32.120] if  $L_x$  is bounded then there exists a unique  $\eta_x \in \mathcal{H}$  such that for any  $f \in \mathcal{H}$

$$L_x f = \langle f, \eta_x \rangle. \tag{32.101}$$

#### Reproducing Kernel

A function

$$\begin{aligned} k : \mathcal{X} \times \mathcal{X} &\rightarrow \mathbb{R}, \\ (x, y) &\mapsto k(x, y) \end{aligned} \tag{32.102}$$

is said to be a *reproducing kernel* of  $\mathcal{H}$  if and only if

$$\forall x \in \mathcal{X}, k(\cdot, x) \in \mathcal{H}, \tag{32.103}$$

$$\forall x \in \mathcal{X}, \forall f \in \mathcal{H} \langle f, k(\cdot, x) \rangle = f(x). \tag{32.104}$$

Note that by  $k(\cdot, x)$  we mean the function  $k(\cdot, x) : t \mapsto k(t, x)$ .

The definition of reproducing kernel (r.k.) implies that  $k(\cdot, x) = \eta_x$ , i.e.,  $k(\cdot, x)$  is the representer of the evaluation functional  $L_x$ ; (32.104) goes under the name of *reproducing property*. From (32.103) and (32.104) it is clear that

$$k(x, y) = \langle k(\cdot, x), k(\cdot, y) \rangle, \quad \forall x, y \in \mathcal{X}; \quad (32.105)$$

since  $\langle \cdot, \cdot \rangle$  is symmetric, it follows that  $k(x, y) = k(y, x)$ . A HS of functions that possesses a reproducing kernel is called a *reproducing kernel Hilbert space (RKHS)*.

Finally, notice that the reproducing kernel (r.k.) of a space of a HS of functions corresponds in a one-to-one manner with the definition of the inner product  $\langle \cdot, \cdot \rangle$ ; changing the inner product implies a change in the reproducing kernel.

### Basic Properties of RKHSs

Let  $(\mathcal{G}, \langle \cdot, \cdot \rangle)$  be a HS of functions. If, for any  $x$ , the evaluation functional  $L_x$  is bounded, then it is clear that  $\mathcal{G}$  is a RKHS with reproducing kernel

$$k(x, y) = \langle \eta_x, \eta_y \rangle. \quad (32.106)$$

Vice versa, if  $\mathcal{G}$  admits a reproducing kernel  $k$ , then all evaluation functionals are bounded. Indeed, we have

$$\begin{aligned} |f(x)| &= \langle f, k(\cdot, x) \rangle \leq \|f\| \|k(\cdot, x)\| \\ &= \sqrt{k(x, x)} \|f\|, \end{aligned} \quad (32.107)$$

where we simply relied on the Cauchy–Schwarz inequality. Boundedness of evaluation functionals means that all the functions in the space are well defined for all  $x$ . Note that this is not the case, for instance, of the space of *square-integrable functions*.

It is not difficult to prove that, in a RKHS  $\mathcal{H}$ , the representation of a bounded linear functional  $A$  is simply  $Ak(\cdot, x)$ , i.e., it is obtained by applying  $A$  to the representer of  $L_x$ . As an example, take the functional evaluating the derivative of  $f$  at  $x$

$$D_x : f \mapsto f'(x).$$

If  $D_x$  is bounded on  $\mathcal{H}$ , then the property implies that

$$f'(x) = \langle f, k'(\cdot, x) \rangle, \quad \forall f \in \mathcal{H},$$

where  $k'(\cdot, x)$  is the derivative of the function  $k(\cdot, x)$ .

### 32.6.3 Equivalence Between the Two Notions

#### Moore–Aronszajn Theorem

If we let

$$\begin{aligned} \phi : \mathcal{X} &\rightarrow \mathcal{H}, \\ x &\mapsto k(x, \cdot), \end{aligned} \quad (32.108)$$

one can see that, in light of (32.98), the reproducing kernel  $k$  is also a positive definite kernel. The converse result, stating that a positive definite kernel is the reproducing kernel of a HS of functions  $(\mathcal{H}, \langle \cdot, \cdot \rangle)$ , is found in the Moore–Aronszajn theorem [32.12]. This completes the equivalence between positive definite kernels and reproducing kernels.

#### Feature Maps and the Mercer Theorem

Note that (32.108) is a first feature map associated to the kernel function  $k$ . Correspondingly, this shows that the RKHS  $\mathcal{H}$  is a possible instance of the feature space. A different feature map can be given in view of the Mercer theorem [32.8, 121], which historically played a major role in the development of kernel methods. The theorem states that every positive definite kernel can be written as

$$k(x, y) = \sum_{i=1}^{\infty} \mu_i e_i(x) e_i(y), \quad (32.109)$$

where the series in the right-hand side of (32.109) converges absolutely and uniformly,  $(e_i)_i$  is an orthonormal sequence of eigenfunctions, and  $(\mu_i)_i$  is the corresponding sequence of nonnegative eigenvalues such that for some measure  $\nu$

$$\int k(x, y) e_i(y) d\nu(y) = \mu_i e_i(x) \quad \forall x \in \mathcal{X}, \quad (32.110)$$

$$\int e_j(y) e_i(y) d\nu(y) = \delta_{ij}. \quad (32.111)$$

The eigenfunctions  $(e_i)_i$  belong to the RKHS  $(\mathcal{H}, \langle \cdot, \cdot \rangle)$  associated to  $k$ . In fact, by (32.110) one has

$$e_i(x) = \frac{1}{\mu_i} \int k(x, y) e_i(y) d\nu(y), \quad (32.112)$$

and therefore  $e_i$  can be approximated by elements in the span of  $(k_x)_{x \in \mathcal{X}}$  [32.36]. One can further see that  $(\sqrt{\mu_i} e_i)_i$  is an orthonormal basis for  $\mathcal{H}$ ; indeed one

has

$$\begin{aligned}
 & \langle \sqrt{\mu_i} e_i, \sqrt{\mu_j} e_j \rangle \\
 & \stackrel{\text{by (32.10)}}{=} \left\langle \frac{1}{\sqrt{\mu_i}} \int k(\cdot, y) e_i(y) d\nu(y), \sqrt{\mu_j} e_j \right\rangle \\
 & = \int \frac{\sqrt{\mu_j}}{\sqrt{\mu_i}} \langle k(\cdot, y), e_j \rangle e_i(y) d\nu(y) \\
 & \stackrel{\text{by (32.10)}}{=} \int \frac{\sqrt{\mu_j}}{\sqrt{\mu_i}} e_j(y) e_i(y) d\nu(y) \stackrel{\text{by (32.111)}}{=} \frac{\sqrt{\mu_j}}{\sqrt{\mu_i}} \delta_{ij}. \tag{32.113}
 \end{aligned}$$

Note that we considered the general case in which the expansion (32.109) involves infinitely many terms. However, there are positive definite kernels (e.g., the polynomial kernel) for which only finitely many eigenvalues are nonzero.

In light of the Mercer theorem one can see that a different feature map is given by

$$\begin{aligned}
 \phi : \mathcal{X} & \rightarrow \mathcal{F}, \\
 x & \mapsto (\sqrt{\mu_i} e_i(x))_i. \tag{32.114}
 \end{aligned}$$

Note that  $\phi$  maps  $x$  into an infinite dimensional vector with  $i$ -th entry  $\phi_i(x) = \sqrt{\mu_i} e_i(x)$ .

#### Connecting Functional and Parametric View

One can see now that  $\sum_i w_i \phi_i(x)$  in the primal model (32.6) corresponds to the evaluation in  $x$  of a function  $f$  in a RKHS. To see this, we start from decomposing  $f$  according to the orthonormal basis  $(\sqrt{\mu_i} e_i)_i$

$$\begin{aligned}
 f &= \sum_i \langle f, \sqrt{\mu_i} e_i \rangle \sqrt{\mu_i} e_i \\
 &= \sum_i w_i \sqrt{\mu_i} e_i, \tag{32.115}
 \end{aligned}$$

where we let  $w_i = \langle f, \sqrt{\mu_i} e_i \rangle / \sqrt{\mu_i}$ . Now one has

$$\begin{aligned}
 L_x f &= \langle f, k(\cdot, x) \rangle = \left\langle \sum_i w_i \sqrt{\mu_i} e_i, k(\cdot, x) \right\rangle \\
 &= \sum_i w_i \sqrt{\mu_i} \langle e_i, k(\cdot, x) \rangle = \sum_i w_i \sqrt{\mu_i} e_i(x) \\
 &= \sum_i w_i \phi_i(x), \tag{32.116}
 \end{aligned}$$

where we applied the reproducing property on  $e_i$  and used the definition of feature map (32.114). Addition-

ally, notice that one has

$$\begin{aligned}
 \|f\|^2 &= \langle f, f \rangle = \left\langle \sum_i w_i \sqrt{\mu_i} e_i, \sum_j w_j \sqrt{\mu_j} e_j \right\rangle \\
 &= \sum_i \sum_j w_i w_j \langle \sqrt{\mu_i} e_i, \sqrt{\mu_j} e_j \rangle \\
 &\stackrel{\text{by (32.113)}}{=} \sum_i \sum_j w_i w_j \frac{\sqrt{\mu_j}}{\sqrt{\mu_i}} \delta_{ij} \\
 &= \sum_i w_i^2. \tag{32.117}
 \end{aligned}$$

This shows that the penalty  $w^\top w$ , used within the primal problems of Sect. 32.3, can be connected to the squared norm of a function. The interested reader is referred to [32.14, 36] for additional properties of kernels.

#### 32.6.4 Kernels for Structured Data

In applications where data are well represented by vectors in a Euclidean space one usually uses the Gaussian RBF kernel, which is *universal* [32.122]. Nonetheless, there exists an entire set of rules according to which one can design new kernels from elementary positive definite functions [32.1]. Although the idea of kernels has been around for a long time, it was only in the 1990s that the machine learning community started to realize that the index set  $\mathcal{X}$  does not need to be (a subset of) some Euclidean space. This significantly improved the applicability of kernel-based algorithms to a broad range of data types, including sequence data, graphs and trees, and XML and HTML documents [32.123].

#### Probabilistic Kernels

One powerful approach consists of applying a kernel that brings generative models into a (possibly discriminative) kernel-based method [32.124, 125]. Generative models can deal naturally with missing data and in the case of hidden Markov models can handle sequences of varying length. A popular probabilistic similarity measure is the *Fisher kernel* [32.126, 127]. The key intuition behind this approach is that similarly structured objects should induce similar log-likelihood gradients in the parameters of a predefined class of generative models [32.126]. Different instances exist, depending on the generative model of interest, see also [32.1].

### Graph Kernels and Dynamical Systems

Graphs can very naturally represent entities, their attributes, and their relationships to other entities; this makes them one of the most widely used tools for modeling structured data. Various type of kernels for graphs have been proposed, see [32.128, 129] and references therein. The approach can be extended to carry on recognitions and decisions for tasks involving dynamical systems; in fact, kernels on dynamical systems are related to graph kernels through the dynamics of random walks [32.128, 130].

### Tensors and Kernels

Tensors are multidimensional arrays that represent higher-order generalizations of vectors and matrices. Tensor-based methods are often particularly effective in low signal-to-noise ratios and when the number of observations is small in comparison with the di-

mensionality of the data. They are used in domains ranging from neuroscience to vision and chemometrics, where tensors best capture the multiway nature of the data [32.131]. The authors of [32.132] proposed a family of kernels that exploit the algebraic structure of data tensors. The approach is related to a generalization of the singular value decomposition (**SVD**) to higher-order tensors [32.133]. The essential idea is to measure similarity based upon a Grassmannian distance of the subspaces spanned by matrix unfolding of data tensors. It can be shown that the approach leads to perfect separation of tensors generated by different sets of rank-1 atoms [32.132]. Within this framework, [32.134] proposed a kernel function for multichannel signals; the idea exploits the spectral information of tensors of fourth order cross-cumulants associated to each multichannel signal.

## 32.7 Applications

Kernel methods have been shown to be successful in many different applications. In this section we mention only a few examples.

### 32.7.1 Text Categorization

Recognition of objects and handwritten digits is studied in [32.135–137]; natural language text categorization is discussed in [32.138, 139]. The task consists of classifying documents based on their content. Attribute value representation of text is used to adequately represent the document text; typically, each distinct word in a document represents a feature with values corresponding to the number of occurrences.

### 32.7.2 Time-Series Analysis

The use of kernel methods for time-series prediction has been discussed in a number of papers [32.140–144], with applications ranging from electric load forecasting [32.145] to financial time series prediction [32.146]. Nonlinear system identification by **LS-SVMs** is discussed in [32.26] and references therein; [32.134] stud-

ies the problem of training a discriminative classifier given a set of labeled multivariate time series. Applications include brain decoding tasks based on magnetoencephalography (**MEG**) recordings.

### 32.7.3 Bioinformatics and Biomedical Applications

Gene expression analysis performed by **SVMs** is discussed in [32.147]. Applications in metabolomics, genetics, and proteomics are presented in the tutorial paper [32.148]; [32.149] discussed different techniques for the integration of side information in models based on gene expression data to improve the accuracy of diagnosis and prognosis in cancer; [32.150] provides an introduction to general data fusion problems using **SVMs** with application to computational biology problems. Detection of remote protein homologies by **SVMs** is discussed in [32.151], which combines discriminative methods with generative models. Bioengineering and bioinformatics applications can also be found in [32.152–154]. Survival analysis based on primal-dual techniques is discussed in [32.155, 156].

# Neurodynamics

Robert Kozma, Jun Wang, Zhigang Zeng

This chapter introduces basic concepts, phenomena, and properties of neurodynamic systems. It consists of four sections with the first two on various neurodynamic behaviors of general neurodynamics and the last two on two types of specific neurodynamic systems. The neurodynamic behaviors discussed in the first two sections include attractivity, oscillation, synchronization, and chaos. The two specific neurodynamics systems are memristive neurodynamic systems and neurodynamic optimization systems.

## 33.1 Dynamics of Attractor and Analog Networks

An attractor, as a well-known mathematical object, is central to the field of nonlinear dynamical systems (**NDS**) theory, which is one of the indispensable conceptual underpinnings of complexity science. An attractor is a set towards which a variable moves according to the dictates of a nonlinear dynamical system, evolves over time, such that points get close enough to the attractor, and remain close even if they are slightly disturbed. To well appreciate what an attractor is, some corresponding **NDS** notions, such as phase or state space, phase portraits, basins of attractions, initial conditions, transients, bifurcations, chaos, and strange attractors are needed to tame some of the unruliness of complex systems.

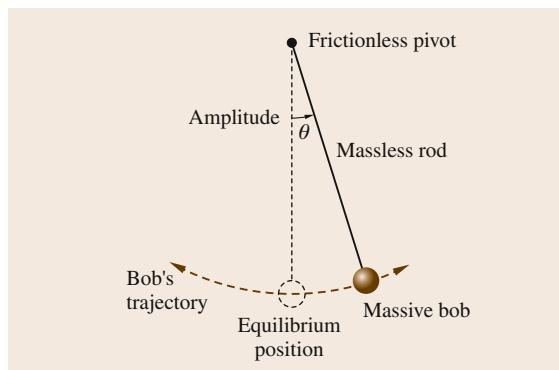

Most of us have at least some inkling of what *nonlinear* means, which can be illustrated by the most well-known and vivid example of the *butterfly effect* of a chaotic system that is nonlinear. It has prompted

the use of the image of tiny air currents produced by a butterfly flapping its wing in Brazil, which are then amplified to the extent that they may influence the building up of a thunderhead in Kansas. Although no one can actually claim that there is such a linkage between Brazilian lepidopterological dynamics and climatology in the Midwest of the USA, it does serve to vividly portray nonlinearity in the extreme.

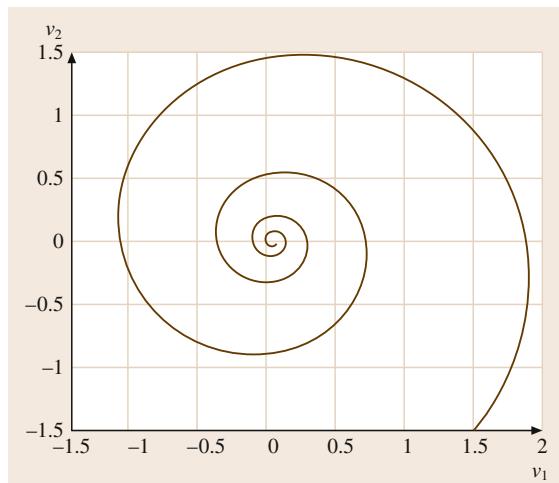

As the existence of both the nonlinearity and the capacity in passing through different regimes of stability and instability, the outcomes of the nonlinear dynamical system are unpredictable. These different regimes of a dynamical system are understood as different phases governed by different attractors, which means that the dynamics of each phase of a dynamical system are constrained within the circumscribed range allowable by that phase's attractors.

### 33.1.1 Phase Space and Attractors

To better grasp the idea of phase space, a time series and phase portrait have been used to represent the data points. Time series display changes in the values of variables on the  $y$ -axis (or the  $z$ -axis), and time on the  $x$ -axis as in a time series chart, however, the phase portrait plots the variables against each other and leaves time as an implicit dimension not explicitly plotted. Attractors can be displayed by phase portraits as the long-term stable sets of points of the dynamical system. This means that the locations in the phase portrait towards which the system's dynamics are attracted after transient phenomena have died down. To illustrate phase space and attractors, two examples are employed.

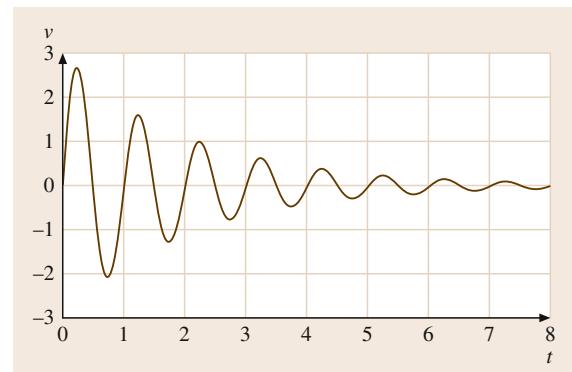

**Fig. 33.1** Schematics of an unpushed swing

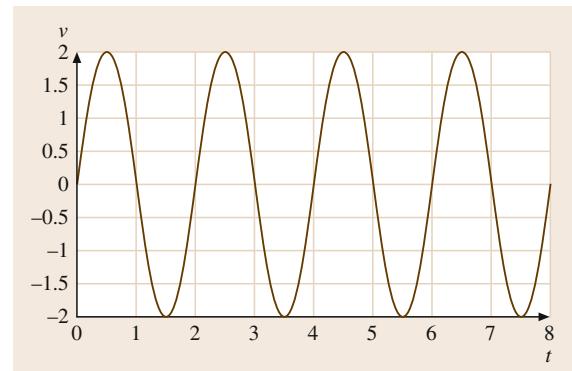

**Fig. 33.2** Phase portrait and fixed point attractor of an unpushed swing

Imagine a child on a swing and a parent pulling the swing back. This gives a good push to make the child move forward. When the child is not moving forward, he will move backward on the swing as shown in Fig. 33.1. The unpushed swing will come to rest as shown in the times series chart and phase space. The time series show an oscillation of the speed of the swing, which slows down and eventually stops, that is its flat lines. In phase space, the swing's speed is plotted against the distance of the swing from the central point called a fixed point attractor since it attracts the system's dynamics in the long run. The fixed point attractor in the center of Fig. 33.2 is equivalent to the flat line in Fig. 33.3. The fixed point attractor is another way to see and say that an unpushed swing will come to a state of rest in the long term. The curved lines with arrows spiraling down to the center point in Fig. 33.2 display what is called the basin of attraction for the unpushed swing. These basins of attraction represent various initial conditions for the unpushed swing, such as starting heights and initial velocities.

**Fig. 33.3** Time series of the unpushed swing

**Fig. 33.4** Time series chart of the pushed swing

Now consider another type of a similar dynamical system, this time the swing is pushed each time it comes back to where the parent is standing. The time series chart of the pushed swing is shown in Fig. 33.4 as a continuing oscillation. This oscillation is around a zero value for  $y$  and is positive when the swing is going in one direction and negative when the swing is going in the other direction. As a phase space diagram, the states of variables against each other are shown in Fig. 33.5. The unbroken oval in Fig. 33.5 is a different kind of attractor from the fixed point one in Fig. 33.2. This attractor is well known as a limit cycle or periodic attractor of a pushed swing. It is called a limit cycle because it represents the cyclical behavior of the oscillations of the pushed swing as a limit to which the dynamical systems adheres under the sway of this attractor. It is periodic because the attractor oscillates around the same values, as the swing keeps going up and down until it has a same heights from the lowest point. Such dynamical system can be called periodic for it has a repeating cycle or pattern.

By now, what we have learned about attractors can be summarized as follows: they are spatially displayed phase portraits of a dynamical system as it changes over the course of time, thus they represent the long-term dynamics of the system so that whatever the initial conditions represented as data points are, their trajectories in phase space fall within its basins of attraction, they are attracted to the attractor. In spite of wide usage in mathematics and science, as *Robinson* points out there is still no precise definition of an attractor, although many

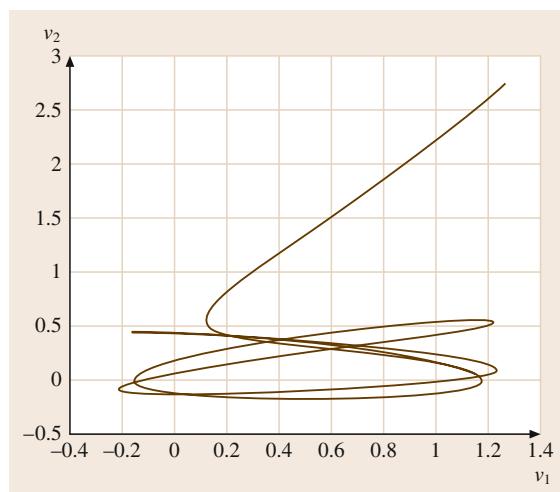

have been offered [33.2]. So he suggests thinking about an attractor as a phase portrait that attracts a large set of initial conditions and has some sort of minimality property, which is the smallest portrait in the phase space of the system. The attractor has the property of attracting the initial conditions after any initial transient behavior has died down. The minimality requirement implies the invariance or stability of the attractor. As a minimal object, the attractor cannot be split up into smaller subsets and retains its role as what dominates a dynamical system during a particular phase of its evolution.

### 33.1.2 Single Attractors of Dynamical Systems

Standard methods for the study of stability of dynamical systems with a unique attractor include the Lyapunov method, the Lasalles invariance principle, and the combination of thereof. Usually, given the properties of a (unique) attractor, we can realize a dynamical system with such an attractor.

Since the creation of the fundamental theorems of Lyapunov stability, many researchers have gone further and proved that most of the fundamental Lyapunov theories are reversible. Thus, from theory, this demonstrates that these theories are efficacious; i.e., there necessarily exists the corresponding Lyapunov function if the solution has some kind of stability. However, as for the construction of an appropriate  $V$  function for the determinant of stability, researchers are still interested. The difference between the existence and its construction is large. However, there is no general rule for the construction of the Lyapunov function. In some cases, different researchers have different methods for the construction of the Lyapunov function based on their experience and technique. Those, who can construct a good quality Lyapunov function, can get more useful information to demonstrate the effectiveness of their theories. Certainly, many successful Lyapunov functions have a practical background. For example, some equations inferred from the physical model have a clear physical meaning such as the mechanics guard system, in which the total sum of the kinetic energy and potential energy is the appropriate  $V$  function. The linear approximate method can be used; i.e., for the nonlinear differential equation, firstly find its corresponding linear differential equation's quadric form positive defined  $V$  function, then consider the nonlinear quality for the construction of a similar  $V$  function.

*Grossberg* proposed and studied additive neural networks because they add nonlinear contributions to the

**Fig. 33.5** Phase portrait and limit cycle attractor of a pushed swing (after [33.1])

neuron activity. The additive neural network has been used for many applications since the 1960s [33.3, 4], including the introduction of self-organizing maps. In the past decades, neural networks as a special kind of nonlinear systems have received considerable attention. The study of recurrent neural networks with their various generalizations has been an active research area [33.5–17]. The stability of recurrent neural networks is a prerequisite for almost all neural network applications. Stability analysis is primarily concerned with the existence and uniqueness of equilibrium points and global asymptotic stability, global exponential stability, and global robust stability of neural networks at equilibria. In recent years, the stability analysis of recurrent neural networks with time delays has received much attention [33.18, 19]. Single attractors of dynamical systems are shown in Fig. 33.6.

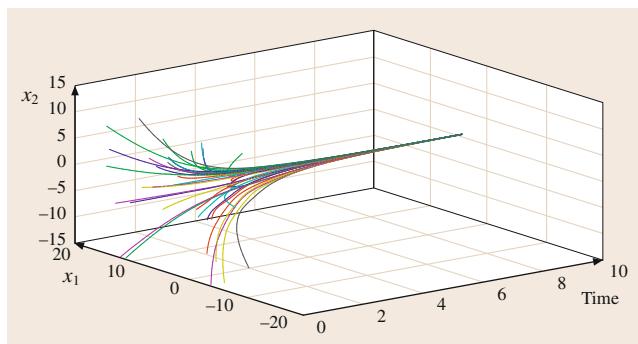

### 33.1.3 Multiple Attractors of Dynamical Systems

Multistable systems have attracted extensive interest in both modeling studies and neurobiological research in

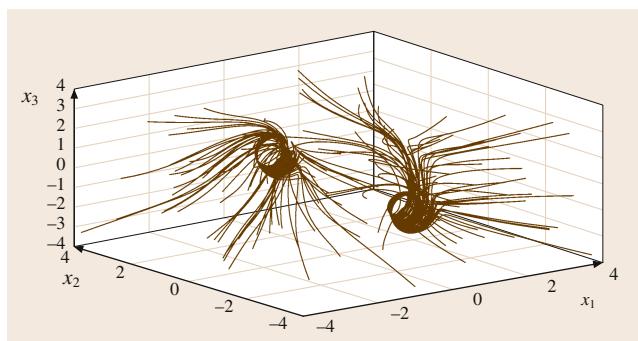

recent years due to their feasibility to emulate and explain biological behavior [33.20–34]. Mathematically, multistability allows the system to have multiple fixed points and periodic orbits. As noted in [33.35], more than 25 years of experimental and theoretical work has indicated that the onset of oscillations in neurons and in neuron populations is characterized by multistability.

Multistability analysis is different from monostability analysis. In monostability analysis, the objective is to derive conditions that guarantee that each nonlinear system contains only one equilibrium point, and all the trajectories of the neural network converge to it. Whereas in multistability analysis, nonlinear systems are allowed to have multiple equilibrium points. Stable and unstable equilibrium points, and even periodic trajectories may co-exist in a multistable system.

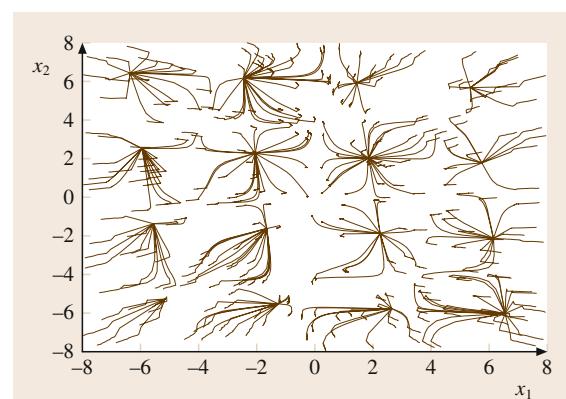

The methods to study the stability of dynamical systems with a unique attractor include the Lyapunov method, the Lasalles invariance principle, and the combination of the two methods. One unique attractor can be realized by one dynamical system, but it is much more complicated for multiple attractors to be realized by one dynamical system or dynamical multisystems because of the compatibility, agreement, and behavior optimization among the systems. Generally, the usual global stability conditions are not adequately applicable to multistable systems. The latest results on multistability of neural networks can be found in [33.36–52]. It is shown in [33.45, 46] that the  $n$ -neuron recurrent neural networks with one step piecewise linear activation function can have  $2^n$  locally exponentially stable equilibrium points located in saturation regions by partitioning the state space into  $2^n$  subspaces. In [33.47], mul-

**Fig. 33.6** Single attractors of dynamical systems

**Fig. 33.7** Two limit cycle attractors of dynamical systems

**Fig. 33.8**  $2^4$  equilibrium point attractors of dynamical systems

tistability of almost periodic solutions of recurrently connected neural networks with delays is investigated. In [33.48], by constructing a Lyapunov functional and using matrix inequality techniques, a delay-dependent multistability criterion on recurrent neural networks is derived. In [33.49], the neural networks with a class of nondecreasing piecewise linear activation functions with  $2r$  corner points are considered. It is proved that the  $n$ -neuron dynamical systems can have and only have  $(2r+1)^n$  equilibria under some conditions, of which  $(r+1)^n$  are locally exponentially stable and others are unstable. In [33.50], some multistability properties for a class of bidirectional associative memory recurrent neural networks with unsaturation piecewise linear transfer functions are studied based on local inhibition. In [33.51], for two classes of general activation functions, multistability of competitive neural networks

with time-varying and distributed delays is investigated by formulating parameter conditions and using inequality techniques. In [33.52], the existence of  $2^n$  stable stationary solutions for general  $n$ -dimensional delayed neural networks with several classes of activation functions is presented through formulating parameter conditions motivated by a geometrical observation. Two limit cycle attractors and  $2^4$  equilibrium point attractors of dynamical systems are shown in Figs. 33.7 and 33.8, respectively.

### 33.1.4 Conclusion

In this section, we briefly introduced what attractors can be summarized as, and phase space and attractors. Furthermore, single-attractor and multiattractors of dynamical systems were also discussed.

## 33.2 Synchrony, Oscillations, and Chaos in Neural Networks

### 33.2.1 Synchronization

#### Biological Significance of Synchronization

Neurodynamics deals with dynamic changes of neural properties and behaviors in time and space at different levels of hierarchy in neural systems. The characteristic spiking dynamics of individual neurons is of fundamental importance. In large-scale systems, such as biological neural networks and brains with billions of neurons, the interaction among the connected neural components is crucial in determining collective properties. In particular, synchronization plays a critical role in higher cognition and consciousness experience [33.53–57]. Large-scale synchronization of neuronal activity arising from intrinsic asynchronous oscillations in local electrical circuitries of neurons are at the root of cognition. Synchronization at the level of neural populations is characterized next.

There are various dynamic behaviors of potential interest for neural systems. In the simplest case, the system behavior converges to a fixed point, when all major variables remain unchanged. A more interesting dynamic behavior emerges when the system behavior periodically repeats itself at period  $T$ , which will be described first. Such periodic oscillations are common in neural networks and are often caused by the presence of inhibitory neurons and inhibitory neural populations. Another behavior emerges when the system

neither converges to a fixed point nor exhibits periodic oscillations, rather it maintains highly complex, chaotic dynamics. Chaos can be microscopic effect at the cellular level, or mesoscopic dynamics of neural populations or cortical regions. At the highest level of hierarchy, chaos can emerge as the result of large-scale, macroscopic effect across cortical areas in the brain.

Considering the temporal dynamics of a system of interacting neural units, limit cycle oscillations and chaotic dynamics are of importance. Synchronization in limit cycle oscillations is considered first, which illustrates the basic principles of synchronization. The extension to more complex (chaotic) dynamics is described in Sect. 33.2.3. Limit cycle dynamics is described as a cyclic repetition of the system's behavior at a given time period  $T$ . The cyclic repetition covers all characteristics of the system, e.g., microscopic currents, potentials, and dynamic variables; see, e.g., the Hodgkin–Huxley model of neurons [33.58]. Limit cycle oscillations can be described as a cyclic loop of the system trajectory in the space of all variables. The state of the system is given as a point on this trajectory at any given time instant. As time evolves, the point belonging to the system traverses along the trajectory. Due to the periodic nature of the movement, the points describing the system at time  $t$  and  $t + T$  coincide fully. We can define a convenient reference system by selecting a center point of the trajectory and describe the mo-

tion as the vector pointing from the center to the actual state on the trajectory. This vector has an amplitude and phase in a suitable coordinate system, denoted as  $\xi(t)$  and  $\phi(t)$ , respectively. The evolution of the phase in an isolated oscillator with frequency  $\omega_0$  can be given as follows

$$\frac{d\phi(t)}{dt} = \omega_0. \quad (33.1)$$

Several types of synchronization can be defined. The strongest synchronization takes place when two (or multiple) units have identical behaviors. Considering limit cycle dynamics, strong synchronization means that the oscillation amplitude and phase are the same for all units. This means complete synchrony. An example of two periodic oscillators is given by the clocks shown in Fig. 33.9a–c [33.59]. Strong synchronization means that the two pendulums are connected with a rigid object forcing them move together. The lack of connection between the two pendulums means the absence of synchronization, i.e., they move completely independently. An intermediate level of synchrony may arise with weak coupling between the pendulums, such as a spring or a flexible band. Phase synchrony takes place when the amplitudes are not the same, but the

phases of the oscillations could still coincide. Figure 33.9b–d depicts the case of out-of-phase synchrony, when the phases of the two oscillators are exactly the opposite.

### Amplitude Measures of Synchrony

Denote by  $a_j(t)$  the time signal produced by the individual units (neurons);  $j = 1, \dots, N$ , and the overall signal of interacting units ( $A$ ) is determined as

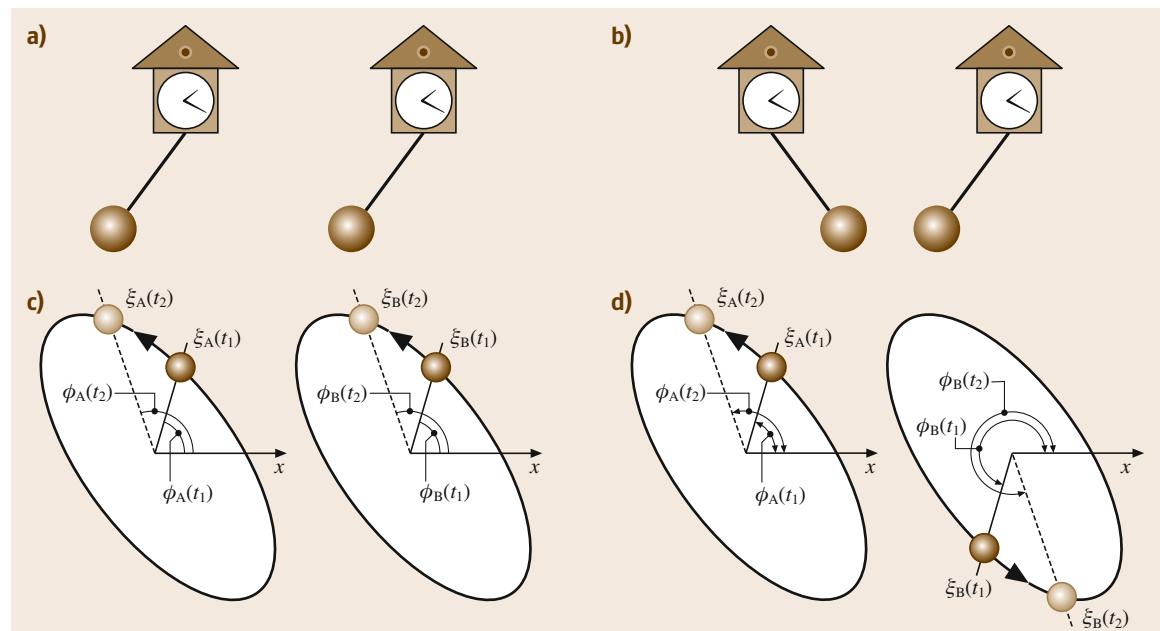

$$A(t) = 1/N \sum_{j=1}^N a_j(t). \quad (33.2)$$

The variance of time series  $A(t)$  is given as follows

$$\sigma_A^2 = \langle A^2(t) \rangle - \langle A(t) \rangle^2. \quad (33.3)$$

Here  $\langle f(t) \rangle$  denotes time averaging over a give time window. After determining the variance of the individual channels  $\sigma_{A_j}^2$  based on (33.3), the synchrony  $\chi_N$  in the system with  $N$  components is defined as follows

$$\chi_N^2 = \frac{\sigma_A^2}{1/N \sum_{i=1}^N \sigma_{A_i}^2}. \quad (33.4)$$

**Fig. 33.9a–d** Synchronization in pendulums, in phase and out of phase (after [33.59]). Bottom plots: Illustration of periodic trajectories, case of in-phase (a–c) and out-of-phase oscillations (b–d)

This synchrony measure has a nonzero value in synchronized and partially synchronized systems  $0 < \chi_N < 1$ , while  $\chi_N = 0$  means the complete absence of synchrony in neural networks [33.60].

Fourier transform-based signal processing methods are very useful for the characterization of synchrony in time series, and they are widely used in neural network analysis. The Fourier transform makes important assumptions on the analyzed time series, including stationary or slowly changing statistical characteristics and ergodicity. In many applications these approximations are appropriate. In analyzing large-scale synchrony on brain signals, however, alternative methods are also justified. Relevant approaches include the Hilbert transform for rapidly changing brain signals [33.61, 62]. Here both Fourier and Hilbert-based methods are outlined and avenues for their applications in neural networks are indicated. Define the cross correlation function (CCF) between discretely sampled time series  $x_i(t)$  and  $x_i(t)$ ,  $t = 1, \dots, N$  as follows

$$\text{CCF}_{ij}(\tau) = \frac{1}{T} \sum_{t=1}^{T-\tau} [x_i(t + \tau) - \langle x_i \rangle][x_j(t) - \langle x_j \rangle]. \quad (33.5)$$

Here  $\langle x_i \rangle$  is the mean of the signal over period  $T$ , and it is assumed that  $x_i(t)$  is normalized to unit variance. For completely correlated pairs of signals, the maximum of the cross correlation is 1, for uncorrelated signals it equals 0. The cross power spectral density  $\text{CPSD}_{ij}(\omega)$ , cross spectrum for short, is defined as the Fourier transform of the cross correlation as follows:  $\text{CPSD}_{ij}(\omega) = \mathcal{F}(\text{CCF}_{ij}(\tau))$ . If  $i = j$ , i.e., the two channels coincide, then we talk about autocorrelation and auto power spectral density  $\text{APSD}_{ii}(\omega)$ ; for details of Fourier analysis, see [33.63]. Coherence  $\gamma^2$  is defined by normalizing the cross spectrum by the autospectra

$$\gamma_{ij}^2(\omega) = \frac{|\text{CPSD}_{ij}(\omega)|^2}{|\text{APSD}_{ii}(\omega)||\text{APSD}_{jj}(\omega)|}. \quad (33.6)$$

The coherence satisfies  $0 \leq \gamma^2(\omega) \leq 1$  and it contains useful information on the frequency content of the synchronization between signals. If coherence is close to unity at some frequencies, it means that the two signals are closely related or synchronized; a coherence near zero means the absence of synchrony at those frequencies. Coherence functions provide useful information on synchrony in brain signals at various frequency bands [33.64]. For other information-theoretical characterizations, including mutual information and entropy measures.

### Phase Synchronization

If the components of the neural network are weakly interacting, the synchrony evaluated using the amplitude measure  $\chi$  in (33.4) may be low. There can still be a meaningful synchronization effect in the system, based on phase measures. Phase synchronization is defined as the global entrainment of the phases [33.65], which means a collective adjustment of their rhythms due to their weak interaction. At the same time, in systems with phase synchronization the amplitudes need not be synchronized. Phase synchronization is often observed in complex chaotic systems and it has been identified in biological neural networks [33.61, 65].

In complex systems, the trajectory of the system in the phase space is often very convoluted. The approach described in (33.1), i.e., choosing a center point for the oscillating cycle in the phase space with natural frequency  $\omega_0$ , can be nontrivial in chaotic systems. In such cases, the Hilbert transform-based approach can provide a useful tool for the characterization of phase synchrony. Hilbert analysis determines the analytic signal and its instantaneous frequency, which can be used to describe phase synchronization effects. Considering time series  $s(t)$ , its analytic signal  $z(t)$  is defined as follows [33.62]

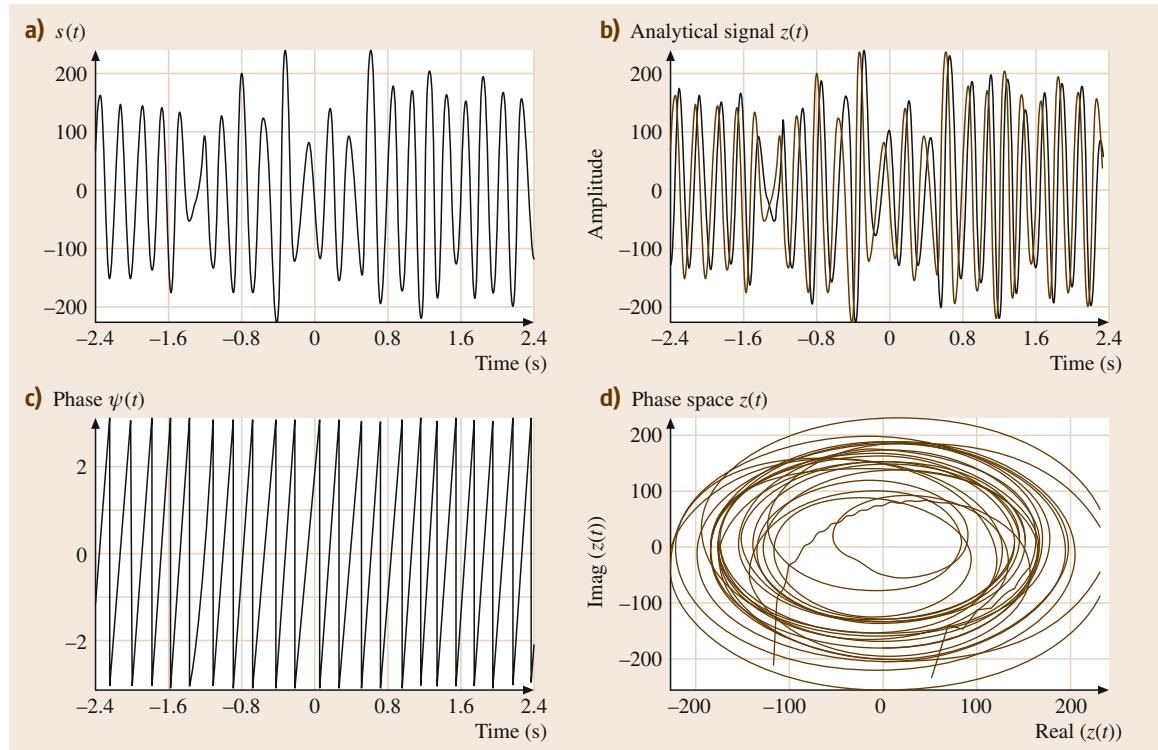

$$z(t) = s(t) + i\hat{s}(t) = A(t)e^{i\Phi(t)}. \quad (33.7)$$

Here  $A(t)$  is the analytic amplitude,  $\Phi(t)$  is the analytic phase, while  $\hat{s}(t)$  is the Hilbert transform of  $s(t)$ , given by

$$\hat{s}(t) = \frac{1}{\pi} \text{PV} \int_{-\infty}^{+\infty} \frac{s(\tau)}{t - \tau} d\tau, \quad (33.8)$$

where **PV** stands for the principal value of the integral computed over the complex plane. The analytic signal and its instantaneous phase can be determined for an arbitrary broadband signal. However, the analytic signal has clear meaning only at a narrow frequency band, therefore, the bandpass filter should precede the evaluation of analytic signal in data with broad frequency content.

The Hilbert method of analytic signals is illustrated using actual local field potentials measured over rabbits with an array of chronically implanted intracranial electrodes [33.67]. The signals have been filtered in the theta band (3–7 Hz). An example of time series  $s(t)$  is shown in Fig. 33.10a. The Hilbert transform  $\hat{s}(t)$  is depicted in Fig. 33.10b in red, while blue color shows  $s(t)$ . Figure 33.10c shows the analytic

**Fig. 33.10a-d** Demonstration of the Hilbert analytic signal approach on electroencephalogram (EEG) signals (after [33.66]); (a) signal  $s(t)$ ; (b) Hilbert transform  $\hat{s}(t)$  (red) of signal  $s(t)$  (blue); (c) instantaneous phase  $\Phi(t)$ ; and analytic signal in complex plane  $z(t)$

phase  $\Phi(t)$ , and Fig. 33.10d depicts the analytic  $z(t)$  signal in the complex plane. Figure 33.11 shows the unwrapped instantaneous phase with bifurcating phase curves indicating desynchronization at specific time instances  $-1.3$  s,  $-0.4$  s, and  $1$  s. The plot on the right-hand side of Fig. 33.11 depicts the evolution of the instantaneous frequency in time. The frequency is around  $5$  Hz most of the time, indicating phase synchronization. However, it has very large dispersion at a few specific instances (desynchronization).

Synchronization between channels  $x$  and  $y$  can be measured using the phase lock value (**PLV**) defined as follows [33.61]

$$\text{PLV}_{xy}(t) = \left| \frac{1}{T} \int_{t-T/2}^{t+T/2} e^{i[\Phi_x(\tau) - \Phi_y(\tau)]} d\tau \right|. \quad (33.9)$$

**PLV** ranges from  $1$  to  $0$ , where  $1$  indicates complete phase locking. **PLV** defined in (33.9) determines an average value over a time window of length  $T$ . Note that

**PLV** is a function of  $t$  by applying the given sliding window. **PLV** is also the function of the frequency, which is being selected by the bandpass filter during the pre-processing phase. By changing the frequency band and time, the synchronization can be monitored at various conditions. This method has been applied productively in cognitive experiments [33.68].

### Synchronization–Desynchronization Transitions

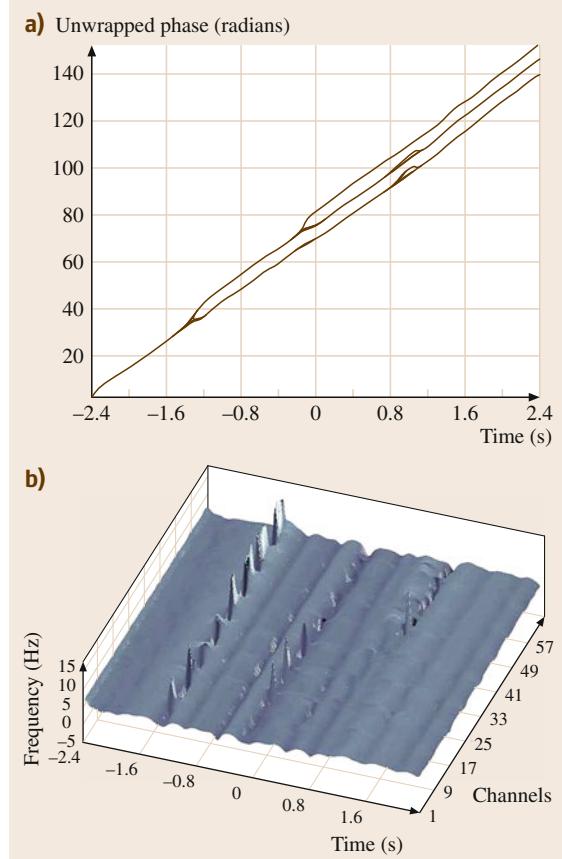

Transitions between neurodynamic regimes with and without synchronization have been observed and exploited for cognitive monitoring. The Haken–Kelso–Bunz (HKB) model is one of the prominent and elegant approaches providing a theoretical framework for synchrony switching, based on the observations related to bimanual coordination [33.69]. The HKB model invokes the concepts of metastability and multistability as fundamental properties of cognition. In the experiment, the subjects were instructed to follow the rhythm of a metronome with their index fingers in an

anti-phase manner. It was observed that by increasing the metronome frequency, the subject spontaneously switched their anti-phase movement to in-phase at a certain oscillation frequency and maintained it thereon even if the metronome frequency was decreased again below the given threshold.

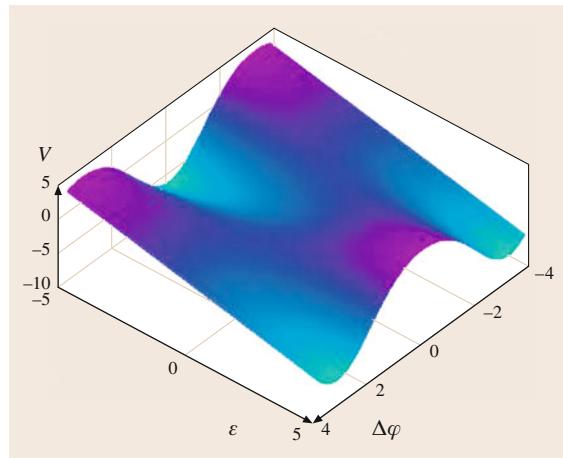

The following simple equation is introduced to describe the dynamics observed:  $d\Delta\Phi/dt = -\sin(\Phi) - 2\varepsilon \sin(2\Phi)$ . Here  $\Delta\Phi = \phi_1 - \phi_2$  is the phase difference between the two finger movements, control parameter  $\varepsilon$  is related to the inverse of the introduced oscillatory frequency. The system dynamics is illustrated in Fig. 33.12 by the potential surface  $V$ , where stable fixed points correspond to local minima. For low oscillatory frequencies (high  $\varepsilon$ ), there are stable equilibria at anti-phase conditions. As the oscillatory frequency increases

(low  $\varepsilon$ ) the dynamics transits to a state where only the in-phase equilibrium is stable.

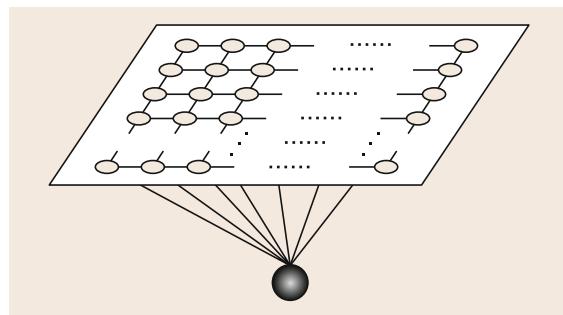

Another practical example of synchrony-desynchrony transition in neural networks is given by image processing. An important basic task of neural networks is image segmentation, which is difficult to accomplish with excitatory nodes only. There is evidence that biological neural networks use inhibitory connections for completing basic pattern separation and integration tasks [33.70]. Synchrony between interacting neurons may indicate the recognition of an input. A typical neural network architecture implementing such a switch between synchronous and nonsynchronous states using local excitation and global inhibition is shown in Fig. 33.13. This system uses amplitude difference to

**Fig. 33.11a,b** Illustration of instantaneous phases; **(a)** unwrapped phase with bifurcating phase curves indicating desynchronization at specific time instances  $-1.3\text{ s}$ ,  $-0.4\text{ s}$ , and  $1\text{ s}$ ; **(b)** evolution of instantaneous frequency in time

**Fig. 33.12** Illustration of the potential surface ( $V$ ) of the HKB system as a function of the phase difference in radians  $\Delta\Phi$  and inverse frequency  $\varepsilon$ . The transition from anti-phase to in-phase behavior is seen as the oscillation frequency increases ( $\varepsilon$  decreases)

**Fig. 33.13** Neural network with local excitation and a global inhibition node (black; after [33.70])

measure synchronization between neighboring neurons. Phase synchronization measures have been proposed as well to accomplish the segmentation and recognition tasks [33.71]. Phase synchronization provides a very useful tool for learning and control of the oscillations in weakly interacting neighborhoods.

### 33.2.2 Oscillations in Neural Networks

#### Oscillations in Brains

The interaction between opposing tendencies in physical and biological systems can lead to the onset of oscillations. Negative feedback between the system's components plays an important role in generating oscillations in electrical systems. Brains as large-scale bioelectrical networks consist of components oscillating at various frequencies. The competition between inhibitory and excitatory neurons is a basic ingredient of cortical oscillations. The intricate interaction between oscillators produces the amazingly rich oscillations that we experimentally observe as brain rhythms at multiple time scales [33.72, 73].

Oscillations occur in the brain at different time scales, starting from several milliseconds (high frequencies) to several seconds (low frequencies). One can distinguish between oscillatory components based on their frequency contents, including delta (1–4 Hz), theta (4–7 Hz), alpha (7–12 Hz), beta (12–30 Hz), and gamma (30–80 Hz) bands. The above separation of brain wave frequencies is somewhat arbitrary, however, they can be used as a guideline to focus on various activities. For example, higher cognitive functions are broadly assumed to be manifested in oscillations in the higher beta and gamma bands.

Brain oscillations take place in time and space. A large part of cognitive activity happens in the cortex, which is a convoluted surface of the six-layer cortical sheet of gyri and sulci. The spatial activity is organized on multiple scales as well, starting from the neuronal level ( $\mu\text{m}$ ), to granules (mm), cortical activities (several cm), and hemisphere-wide level (20 cm). The temporal and spatial scales are not independent, rather they delicately interact and modulate each other during cognition. Modern brain monitoring tools provide insight to these complex space–time processes [33.74].

#### Characterization of Oscillatory Networks

Oscillations in neural networks are synchronized activities of populations of neurons at certain well-defined frequencies. Neural systems are often modeled as the interaction of components which oscillate at specific,

well-defined frequencies. Oscillatory dynamics can correspond to either microscopic neurons, to mesoscopic populations of tens of thousands neurons, or to macroscopic neural populations including billions of neurons. Oscillations at the microscopic level have been thoroughly studied using spiking neuron models, such as the Hodgkin–Huxley equation (HH). Here we focus on populations of neurons, which have some natural oscillation frequencies. It is meaningful to assume that the natural frequencies are not identical due to the diverse properties of populations in the cortex. Interestingly, the diversity of oscillations at the microscopic and mesoscopic levels can give rise to large-scale synchronous dynamics at higher levels. Such emergent oscillatory dynamics is the primary subject of this section.

Consider  $N$  coupled oscillators with natural frequencies  $\omega_j$ ;  $j = 1, \dots, N$ . A measure of the synchronization in such systems is given by parameter  $R$ , which is often called the *order parameter*. This terminology was introduced by Haken [33.75] to describe the emergence of macroscopic order from disorder. The time-varying order parameter  $R(t)$  is defined as [33.76]

$$R(t) = \left| 1/N \times \sum_{j=1}^N e^{i\theta_j(t)} \right|. \quad (33.10)$$

Order parameter  $R$  provides a useful synchronization measure for coupled oscillatory systems. A common approach is to consider a globally coupled system, in which all the components interact with each other. This is the broadest possible level of interaction. The local coupling model represents just the other extreme limit, i.e., each node interacts with just a few others, which are called its direct neighbors. In a one-dimensional array, a node has two neighbors on its left and right, respectively (assuming periodic boundary conditions). In a two-dimensional lattice, a node has four direct neighbors, and so on. The size of the neighborhood can be expanded, so the connectivity in the network becomes more dense. There is of special interest in networks that have a mostly regular neighborhood with some further neighbors added by a selection rule from the whole network. The addition of remote or non-local connections is called rewiring, and the networks with rewiring are small world networks. They have been extensively studied in network theory [33.76–78]. Figure 33.14 illustrates local (top left) and global coupling (bottom right), as well as intermediate coupling, with the bottom left plot giving an example of network with random rewiring.

### The Kuramoto Model

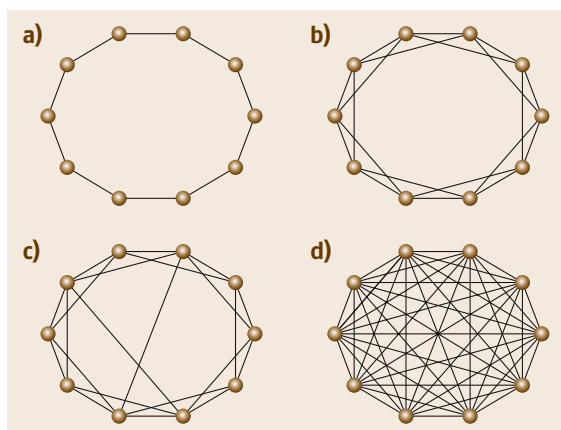

The Kuramoto model [33.79] is a popular approach to describe oscillatory neural systems. It implements mean-field (global) coupling. The synchronization in this model allows an analytical solution, which helps to interpret the underlying dynamics in clear mathematical terms [33.76]. Let  $\theta_j$  and  $\omega_j$  denote the phase and the inherent frequency of the  $i$ -th oscillator. The oscillators are coupled by a nonlinear interaction term depending on their pair-wise phase differences. In the Kuramoto model, the following sinusoidal coupling term has been used to model neural systems

$$\frac{d\theta_j}{dt} = \omega_j + \frac{K}{N} \sum_{j=1}^N \sin(\theta_i - \theta_j), \quad j = 1, \dots, N. \quad (33.11)$$

Here  $K$  denotes the coupling strength and  $K = 0$  means no coupling. The system in (33.11) and its generalizations have been studied extensively since its first introduction by Kuramoto [33.79]. Kuramoto used Lorenztian initial distribution of phases  $\theta$  defined as:  $L(\theta) = \gamma / \{\pi(\gamma^2 + (\omega - \omega_0)^2)\}$ . This leads to the asymptotic solution  $N \rightarrow \infty$  and  $t \rightarrow \infty$  for order parameter  $R$  in simple analytic terms

$$R = \sqrt{1 - (K_c/K)} \quad \text{if } K > K_c, R = 0 \text{ otherwise}. \quad (33.12)$$

Here  $K_c$  denotes the critical coupling strength given by  $K_c = 2\gamma$ . There is no synchronization between the

**Fig. 33.14a–d** Network architectures with various connectivity structures: (a) local, (b) and (c) are intermediate, and (d) global (mean-field) connectivity

oscillators if  $K \leq K_c$ , and the synchronization becomes stronger as  $K$  increases at supercritical conditions  $K > K_c$ , see Fig. 33.15. Inputs can be used to control synchronization, i. e., a highly synchronized system can be (partially) desynchronized by input stimuli [33.80, 81]. Alternatively, input stimuli can induce large-scale synchrony in a system with low level of synchrony, as evidenced by cortical observations [33.82].

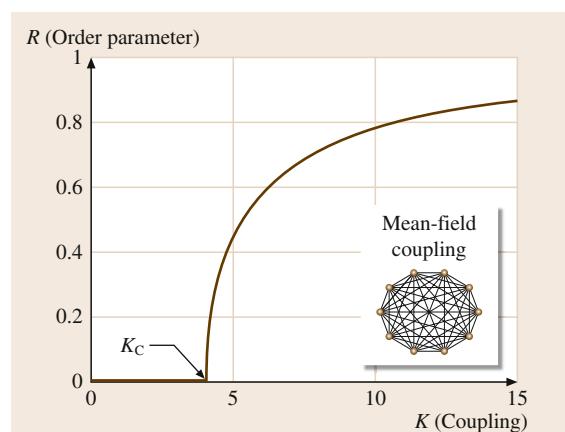

### Neural Networks as Dynamical Systems

A dynamical system is defined by its equation of motion, which describes the location of the system as a function of time  $t$

$$\frac{dX(t, \lambda)}{dt} = F(X), \quad X \in \mathbb{R}^n. \quad (33.13)$$

Here  $X$  is the state vector describing the state of the system in the  $n$ -dimensional Euclidean space  $X = X(x_1, \dots, x_n) \in \mathbb{R}^n$  and  $\lambda$  is the vector of system parameters. Proper initial conditions must be specified and it is assumed that  $F(X)$  is a sufficiently smooth nonlinear function. In neural dynamics it is often assumed that the state space is a smooth manifold, and the goal is to study the evolution of the trajectory of  $X(t)$  in the state space as time varies along the interval  $[t_0, T]$ .

The Cohen–Grossberg (CG) equation is a general formulation of the motion of a neural network as a dynamical system with distributed time delays in the presence of inputs. The CG model has been studied

**Fig. 33.15** Kuramoto model in the mean-field case. Dependence of order parameter  $R$  on the coupling strength  $K$ . Below a critical value  $K_c$ , the order parameter is 0, indicating the absence of synchrony; synchrony emerges for  $K$  above the critical value

thoroughly in the past decades and it served as a starting point for various other approaches. The general form of the CG model is [33.83]

$$\frac{dz_i(t)}{dt} = -a_i(x_i(t)) \left[ b_i(x_i(t)) - \sum_{j=1}^N a_{ij}f_j(x_j(t)) - \sum_{j=1}^N b_{ij}f_j(x_j(t - \tau_{ij})) + u_j \right], \quad i = 1, \dots, N. \quad (33.14)$$

Here  $X(t) = [x_1(t), x_2(t), \dots, x_N(t)]^\top$  is the state vector describing a neural network with  $N$  neurons. Function  $a_i(t)$  describes the amplification,  $b_i(t)$  denotes a properly behaved function to guarantee that the solution remains bounded,  $f_i(x)$  is the activation function,  $u_i$  denotes external input,  $a_{ij}$  and  $b_{ij}$  are components of the connection weight matrix and the delayed connection weight matrix, respectively, and  $\tau_{ij}$  describes the time delays between neurons,  $i, j = 1, \dots, n$ . The solution of (33.14) can be determined after specifying suitable initial conditions.

There are various approaches to guarantee the stability of the CG equation as it approaches its equilibria under specific constraints. Global convergence assuming symmetry of the connectivity matrix has been shown [33.83]. The symmetric version of a simplified CG model has become popular as the Hopfield or Hopfield–Tank model [33.84]. Dynamical properties of CG equation have been studied extensively, including asymptotic stability, exponential stability, robust stability, and stability of periodic bifurcations and chaos. Symmetry requirements for the connectivity matrix have been relaxed, still guaranteeing asymptotic stability [33.85]. CG equations can be employed to find the optimum solutions of a nonlinear optimization problem when global asymptotic stability guarantees the stability of the solution [33.86]. Global asymptotic stability of the CG neural network with time delay is studied using linear matrix inequalities (LMI). LMI is a fruitful approach for global exponential stability by constructing Lyapunov functions for broad classes of neural networks.

### Bifurcations in Neural Network Dynamics

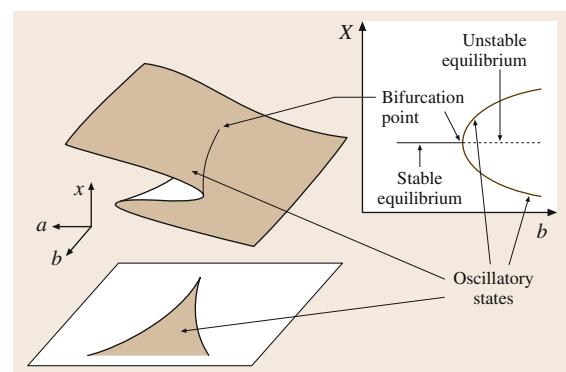

Bifurcation theory studies the behavior of dynamical systems in the neighborhood of bifurcation points, i.e., at points when the topology of the state space abruptly changes with continuous variation of a system parameter. An example of the state space is given by the folded

surface in Fig. 33.16, which illustrates a cusp bifurcation point. Here  $\lambda = [a, b]$  is a two-dimensional parameter vector,  $X \in \mathbb{R}^1$  [33.87]. As parameter  $b$  increases, the initially unfolded manifold undergoes a bifurcation through a cusp folding with three possible values of state vector  $X$ . This is an example of pitchfork bifurcation, when a stable equilibrium point bifurcates into one unstable and two stable equilibria. The projection to the  $a - b$  plane shows the cusp bifurcation folding with multiple equilibria. The presence of multiple equilibria provides the conditions for the onset of oscillatory states in neural networks. The transition from fixed point to limit cycle dynamics can be described by bifurcation theory.

### Neural Networks with Inhibitory Feedback

Oscillations in neural networks are typically due to delayed, negative feedback between neural population. Mean-field models are described first, starting with Wilson–Cowan (WC) oscillators, which are capable of producing limit cycle oscillations. Next, a class of more general networks with excitatory–inhibitory feedback are described, which can generate unstable limit cycle oscillations.

The Wilson–Cowan model is based on statistical analysis of neural populations in the mean-field limit, i.e., assuming that all components of the system fully interact [33.88, 89]. In the brain it may describe a single cortical column in one of the sensory cortices, which in turn interacts with other columns to generate synchronous or asynchronous oscillations, depending on the cognitive state. In its simplest manifestation, the WC model has one excitatory and one inhibitory com-

**Fig. 33.16** Folded surface in the state space illustrating cusp bifurcation following (after [33.87]). By increasing parameter  $b$ , the stable equilibrium bifurcates to two stable and one unstable equilibria

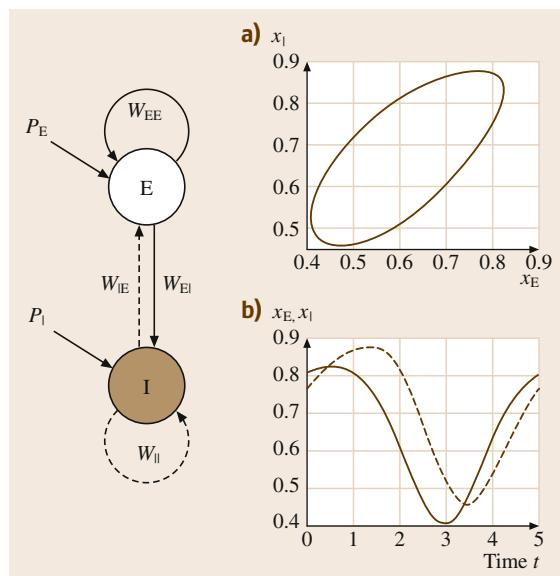

ponent, with interaction weights denoted as  $w_{EE}$ ,  $w_{EI}$ , and  $w_{II}$ . Nonlinear function  $f$  stands for the standard sigmoid with rate constant  $a$

$$\frac{dX_E}{dt} = -X_E + f(w_{EE}X_E + w_{IE}X_I + P_E), \quad (33.15)$$

$$\frac{dX_I}{dt} = -X_I + f(w_{EI}X_E + w_{II}X_I + P_I), \quad (33.16)$$

$$f(x) = 1/[1 + e^{-ax}]. \quad (33.17)$$

$P_E$  and  $P_I$  describe the effect of input stimuli through the excitatory and inhibitory nodes, respectively. The inhibitory weights are negative, while the excitatory ones are positive. The WC system has been extensively studied with dynamical behaviors including fixed point and oscillatory regimes. In particular, for fixed weight values, it has been shown that the WC system undergoes a pitchfork bifurcation by changing  $P_E$  or  $P_I$  input levels. Figure 33.17 shows the schematics of the two-node system, as well as the illustration of the oscillatory states following the bifurcation with parameters  $w_{EE} = 11.5$ ,  $w_{II} = -2$ ,  $w_{EI} = -w_{IE} = -10$ , and input values  $P_E = 0$  and  $P_I = -4$ , with rate constant  $a = 1$ . Stochastic versions of the Wilson–

**Fig. 33.17** Schematic diagram of the Wilson–Cowan oscillator with excitatory (E) and inhibitory (I) populations; solid lines show excitatory, dashed show inhibitory connections. The right panels show the trajectory in the phase space of  $X_E - X_I$  and the time series of the oscillatory signals (after [33.90]).

Cowan oscillators have been extensively developed as well [33.90]. Coupled Wilson–Cowan oscillators have been used in learning models and have demonstrated applicability in a number of fields, including visual processing and pattern classification [33.91–93].

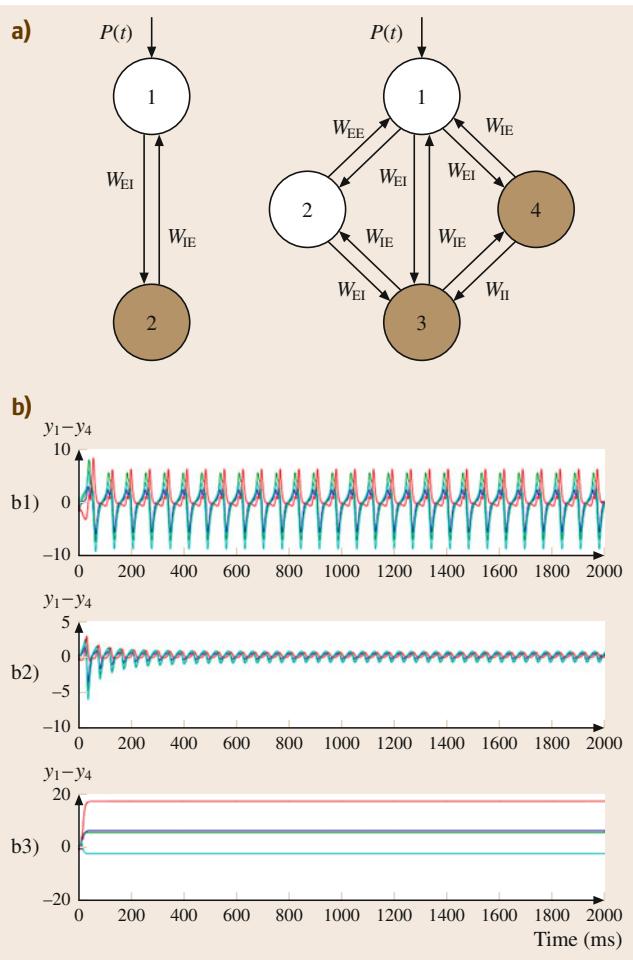

Oscillatory neural networks with interacting excitatory–inhibitory units have been developed in Freeman K sets [33.94]. That model uses an asymmetric sigmoid function  $f(x)$  modeled based on neurophysiological activations and given as follows

$$f(x) = q\{1 - \exp(-[1/(q(e^x - 1))])\}. \quad (33.18)$$

Here  $q$  is a parameter specifying the slope and maximal asymptote of the sigmoid curve. The sigmoid has unit gain at zero, and has maximum gain at positive  $x$  values due to its asymmetry, see (33.18). This property provides the opportunity for self-sustained oscillations without input at a wide range of parameters. Two versions of the basic oscillatory units have been studied, either one excitatory and one inhibitory unit, or two excitatory and two inhibitory units. This is illustrated in Fig. 33.18. Stability conditions of the fixed point and limit cycle oscillations have been identified [33.95, 96]. The system with two E and two I units has the advantage that it avoids self-feedback, which is uncharacteristic in biological neural populations. Interestingly, the extended system has an operating regime with an unstable equilibrium without stable equilibria. This condition leads to an inherent instability in a dynamical regime when the system oscillates without input. Oscillations in the unstable region have been characterized and conditions for sustained unstable oscillations derived [33.96]. Simulations in the region confirmed the existence of limit cycles in the unstable regime with highly irregular oscillatory shapes of the cycle, see Fig. 33.18, upper plot. Regions with regular limit cycle oscillations and fixed point oscillations have been identified as well, see Fig. 33.18, middle and bottom [33.97].

### Spatiotemporal Oscillations in Heterogeneous NNs

Neural networks describe the collective behavior of populations of neurons. It is of special interest to study populations with a large-number of components having complex, nonlinear interactions. Homogeneous populations of neurons allow mathematical modeling in mean-field approximation, leading to oscillatory models such as the Wilson–Cowan oscillators and Freeman KII sets. Field models with heterogeneous structure and dynamic

**Fig. 33.18a,b** Illustration of excitatory–inhibitory models. **(a) Left:** simplified model with one excitatory (E) and one inhibitory (I) node. **Right:** extended model with two E and two I nodes. **(b)** Simulations with the extended model with two E and two I nodes;  $y_1 - y_4$  show the activations of the nodes; b1: limit cycle oscillations in the unstable regime; b2: oscillations in the stable limit cycle regime; b3: fixed point regime (after [33.97])

variables are of great interest as well, as they are the prerequisite of associative memory functions of neural networks.

A general mathematical formulation views the neuropil, the interconnected neural tissue of the cortex, as a dynamical system evolving in the phase space, see (33.13). Consider a population of spiking neurons each of which is modeled by a Hodgkin–Huxley equation. The state of a neuron at any time instant is determined by its depolarization potential, microscopic

current, and spike timing. Each neuron is represented by a point in the state space given by the above coordinates comprising vector  $X(t) \in \mathbb{R}^n$ , and the evolution of a neuron is given with its trajectory the state space. Neuropils can include millions and billions of neurons; thus the phase space of the neurons contains a myriads of trajectories. Using the ensemble density approach of population modeling, the distribution of neurons in the state space at a given time  $t$  is described by a probability density function  $p(X, t)$ . The ensemble density approach models the evolution of the probability density in the state space [33.98]. One popular approach uses the Langevin formalism given next.

### Field Theories of Neural Networks

Consider the stochastic process  $X(t)$ , which is described by the Langevin equation [33.99]

$$dX(t) = \mu(X(t))dt + \sigma(X(t))dW(t). \quad (33.19)$$

Here  $\mu$  and  $\sigma$  denote the drift and variance, respectively, and  $dW(t)$  is a Wiener process (Brown noise) with normally distributed increments. The probability density  $p(X, t)$  of Langevin equation (33.19) satisfies the following form of the Fokker–Planck equation, after omitting higher-order terms

$$\begin{aligned} \frac{\partial p(X, t)}{\partial t} = & - \sum_{i=1}^n \frac{\partial}{\partial x_i} [\mu_i(X)p(X, t)] \\ & + \sum_{i=1}^n \sum_{j=1}^n \frac{\partial^2}{\partial x_i \partial x_j} [D_{ij}(X)p(X, t)]. \end{aligned} \quad (33.20)$$

The Fokker–Planck equation has two components. The first one is a flow term containing drift vector  $\mu_i(X)$ , while the other term describes diffusion with diffusion coefficient matrix  $D_{ij}(X, t)$ . The Fokker–Planck equation is a partial differential equation (PDE) that provides a deterministic description of macroscopic events resulting from random microscopic events. The mean-field approximation describes time-dependent, ensemble average population properties, instead of keeping track of the behavior of individual neurons.

Mean-field models can be extended to describe the evolution of neural populations distributed in physical space. Considering the cortical sheet as a de facto continuum of the highly convoluted neural tissue (the neuropil), field theories of brains are developed using partial differential equations in space and time. The corresponding PDEs are wave equations. Consider a simple one-dimensional model to describe the dynamics of

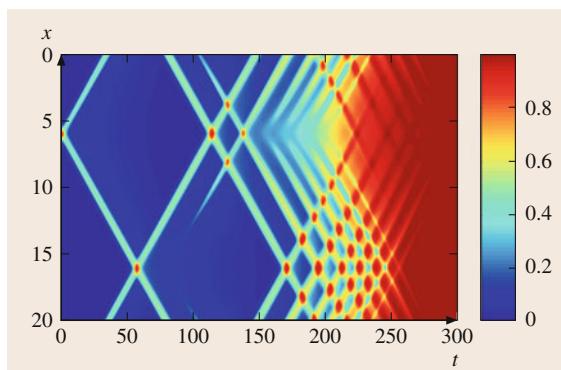

the current density  $\Phi(x, t)$  as a macroscopic variable. In the simple case of translational invariance of the connectivity function between arbitrary two points of the domain with exponential decay, the following form of the wave equation is obtained [33.100]

$$\begin{aligned} \frac{\partial^2 \Phi}{\partial t^2} + (\omega_0^2 - v^2 \Delta) \Phi + 2\omega_0 \frac{\partial \Phi}{\partial t} \\ = \left( \omega_0^2 + \omega_0 \frac{\partial}{\partial t} \right) S[\Phi(x, t) + P(x, t)]. \end{aligned} \quad (33.21)$$

Here  $\Delta = \partial^2 / \partial x^2$  is the Laplacian in one dimension,  $S(\cdot)$  is a sigmoid transfer function for firing rates,  $P(x, t)$  describes the effect of inputs;  $\omega_0 = v/\sigma$ , where  $v$  is the propagation velocity along lateral axons, and  $\sigma$  is the spatial relaxation constant of the applied exponential decay function [33.100]. The model can be extended to excitatory–inhibitory components. An example of simulations with a one-dimensional neural field model incorporating excitatory and inhibitory neurons is given in Fig. 33.19 [33.101]. The figure shows the propagation of two traveling pulses and the emergence of transient complex behavior ultimately leading to an elevated firing rate across the whole tissue [33.101]. For recent developments in brain field models, see [33.90, 102].

### Coupled Map Lattices for NNs

Spatiotemporal dynamics in complex systems has been modeled using coupled map lattices (CML) [33.103]. CMLs use continuous state space and discrete time and space coordinates. In other words, CMLs are defined on (finite or infinite lattices) using discrete time iterations. Using periodic boundary conditions, the array can be

**Fig. 33.19** Numerical simulations of a one-dimensional neural field model showing the interaction of two traveling pulses (after [33.101])

folded into a circle in one dimension, or into a torus for lattices of dimension 2 or higher. CML dynamics is described as follows

$$x_{n+1}(i) = (1-\varepsilon)f(x_n(i)) + \varepsilon \frac{1}{K} \sum_{k=-K/2}^{K/2} f(x_n(i+k)), \quad (33.22)$$

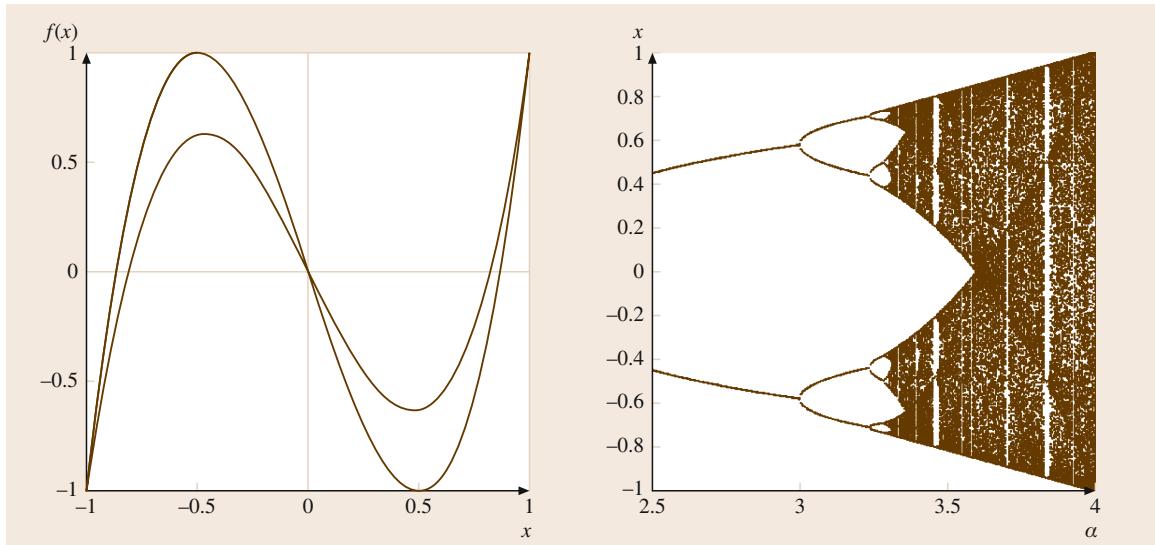

where  $x_n(i)$  is the value of node  $i$  at iteration step  $n$ ,  $i = 1, \dots, N$ ;  $N$  is the size of the lattice. Note that in (33.22) a periodic boundary condition applies.  $f(\cdot)$  is a nonlinear mapping function used in the iterations and  $\varepsilon$  is the coupling strength,  $0 \leq \varepsilon \leq 1$ .  $\varepsilon = 0$  means no coupling, while  $\varepsilon = 1$  is maximum coupling. The CML rule defined in (33.22) has two terms. The first term on the right-hand side is an iterative update of the  $i$ -th state, while the second term describes coupling between the units. Parameter  $K$  has a special role in coupled map lattices; it defines the size of the neighborhoods.  $K = N$  describes mean-field coupling, while smaller  $K$  values belong to smaller neighborhoods. The geometry of the system is similar to the ones given in Fig. 33.14. The case of local neighborhood is the upper left diagram in Fig. 33.14, while mean-field coupling is the lower right diagram. Similar rules have been defined for higher-dimensional lattices.

CMLs exhibit very rich dynamic behavior, including fixed points, limit cycles, and chaos, depending on the choice of control parameters,  $\varepsilon, K$ , and function  $f(\cdot)$  [33.103, 104]. An example of the cubic sigmoid function

$$f(x, a) = ax^3 - ax + x$$

is shown in Fig. 33.20, together with the bifurcation diagram with respect to parameter  $a$ . By increasing the value of parameter  $a$ , the map exhibits bifurcations from fixed point to limit cycle, and ultimately to the chaotic regime.

Complex CML dynamics has been used to design dynamic associative memory systems. In CML, each memory is represented as a spatially coherent oscillation and is learnt by a correlational learning rule operating in limit cycle or chaotic regimes. In such systems, both the memory capacity and the basin volume for each memory are larger in CML than in the Hopfield model employing the same learning rule [33.105]. CML chaotic memories reduce the problem of spurious memories, but they are not immune to it. Spurious memories prevent the system from exploiting its memory capacity to the fullest extent.

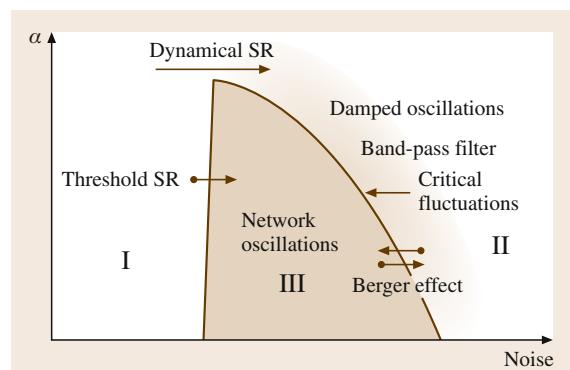

**Fig. 33.20a,b** Transfer function for CML: (a) shape of the cubic transfer function  $f(x, a) = ax^3 - ax + x$ ; (b) bifurcation diagram over parameter  $a$

### Stochastic Resonance

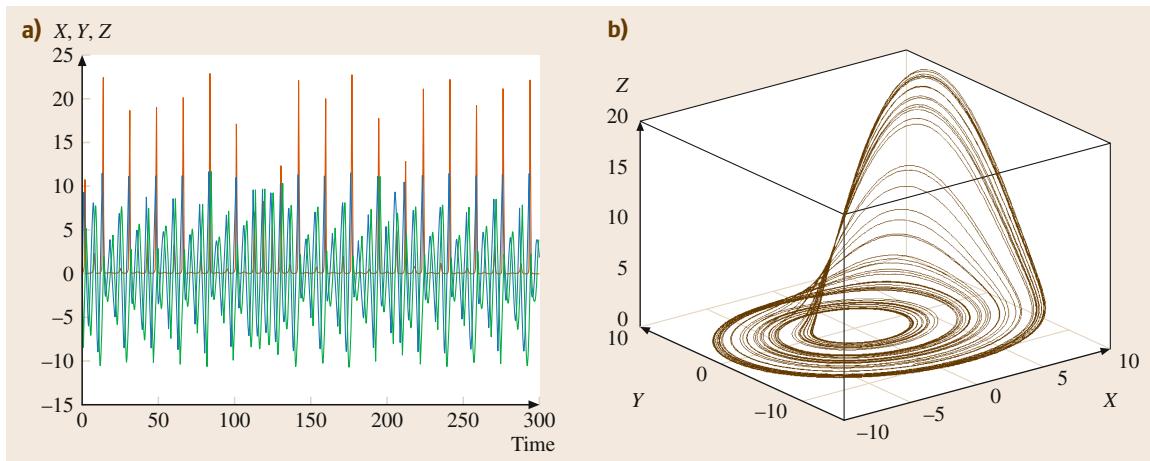

Field models of brain networks develop deterministic PDEs (Fokker–Planck equation) for macroscopic properties based on a statistical description of the underlying stochastic dynamics of microscopic neurons. In other words, they are deterministic systems at the macroscopic level. Stochastic resonance (SR) deals with conditions when a bistable or multistable system exhibits strong oscillations under weak periodic perturbations in the presence of random noise [33.106]. In a typical SR situation, the weak periodic carrier wave is insufficient to cross the potential barrier between the equilibria of a multistable system. Additive noise enables the system to surmount the barrier and exhibit oscillations as it transits between the equilibria. SR is an example of processes when properly tuned random noise improves the performance of a nonlinear system and it is highly relevant to neural signal processing [33.107, 108].

A prominent example of SR in a neural network with excitatory and inhibitory units is described in [33.109]. In the model developed, the activation rate of excitatory and inhibitory neurons is described by  $\mu_e$  and  $\mu_i$ , respectively. The ratio  $\alpha = \mu_e/\mu_i$  is an important parameter of the system. The investigated neural populations exhibit a range of dynamic behaviors, including convergence to fixed point, damped oscillations, and persistent oscillations. Figure 33.21

summarizes the main findings in the form of a phase diagram in the space of parameters  $\alpha$  and noise level. The diagram contains three regions. Region I is at low noise levels and it corresponds to oscillations decaying to a fixed point at an exponential rate. Region II corresponds to high noise, when the neural activity exhibits damped oscillations as it approaches the steady state. Region III, however, demonstrates sustained oscillations for an intermediate level of noise. If  $\alpha$  is above a critical value (see the tip of Region III),

**Fig. 33.21** Stochastic resonance in excitatory–inhibitory neural networks;  $\alpha$  describes the relative strength of inhibition. Region I: fixed point dynamics. Region II: damped oscillatory regime. Region III: sustained periodic oscillations illustrating stochastic resonance (after [33.109])

**Fig. 33.22a,b** Lorenz attractor in the chaotic regime; **(a)** time series of the variables  $X$ ,  $Y$ , and  $Z$ ; **(b)** butterfly-winged chaotic Lorenz attractor in the phase space spanned by variables  $X$ ,  $Y$ , and  $Z$

the activities in the steady state undergo a first-order phase transition at a critical noise level. The intensive oscillations in Region III at an intermediate noise level show that the output of the system (oscillations) can be enhanced by an optimally selected noise level.

The observed phase transitions may be triggered by neuronal avalanches, when the neural system is close to a critical state and the activation of a small number of neurons can generate an avalanche process of activation [33.110]. Neural avalanches have been described using self-organized criticality (SOC), which has been identified in neural systems [33.111]. There is much empirical evidence of the cortex conforming to the self-stabilized, scale-free dynamics with avalanches during the existence of some quasi-stable states [33.112, 113]. These avalanches maintain a metastable background state of activity.

Phase transitions have been studied in models with extended layers of excitatory and inhibitory neuron populations, respectively. A specific model uses random cellular neural networks to describe conditions with sustained oscillations [33.114]. The role of various control parameters has been studied, including noise level, inhibition, and rewiring. Rewiring describes long axonal connections to produce neural network architectures resembling connectivity patterns with short and long-range axons in the neuropil. By properly tuning the parameters, the system can reside in a fixed point regime in isolation, but it will switch to persistent oscillations under the influence of learnt input patterns [33.115].

### 33.2.3 Chaotic Neural Networks

#### Emergence of Chaos in Neural Systems

Neural networks as dynamical systems are described by the state vector  $X(t)$  which obeys the equation of motion (33.13). Dynamical systems can exhibit fixed point, periodic, and chaotic behaviors. Fixed points and periodic oscillations, and transitions from one to the other through bifurcation dynamics has been described in Sect. 33.2.2. The trajectory of a chaotic system does not converge to a fixed point or limit cycle, rather it converges to a chaotic attractor. Chaotic attractors, or strange attractors, have the property that they define a fractal set in the state space, moreover, chaotic trajectories close to each other at some point, diverge from each other exponentially fast as time evolves [33.116, 117].

An example of the chaotic Lorenz attractor is shown in Fig. 33.22. The Lorenz attractor is defined by a system of three ordinary differential equations (ODEs) with nonlinear coupling, originally derived for the description of the motion of viscous flows [33.118]. The time series belonging to variables  $X$ ,  $Y$ ,  $Z$  are shown in Fig. 33.22a for parameters in the chaotic region, while the strange attractor is illustrated by the trajectory in the phase space, see Fig. 33.22b.

#### Chaotic Neuron Model

In chaotic neural networks the individual components exhibit chaotic behavior, and the goal is to study the order emerging from their interaction. Nerve membranes produce propagating action potentials in a highly non-

linear process which can generate oscillations and bifurcations to chaos. Chaos has been observed in the giant axons of squid and it has been used to study chaotic behavior in neurons. The Hodgkin–Huxley equations can model nonlinear dynamics in the squid giant axon with high accuracy [33.58]. The chaotic neuron model of Aihara et al. is an approximation of the Hodgkin–Huxley equation and it reproduces chaotic oscillations observed in the squid giant axon [33.119, 120]. The model uses the following simple iterative map

$$x(t+1) = kx(t) - \alpha f(x(t)) + a, \quad (33.23)$$

where  $x(t)$  is the state of the chaotic neuron at time  $t$ ,  $k$  is a decay parameter,  $\alpha$  characterizes refractoriness,  $a$  is a combined bias term, and  $f(y(t))$  is a nonlinear transfer function. In the chaotic neuron model, the log sigmoid transfer function is used, see (33.17). Equation (33.23) combined with the sigmoid produces a piece-wise monotonous map, which generates chaos.

Chaotic neural networks composed of chaotic neurons generate spatio-temporal chaos and are able to retrieve previously learnt patterns as the chaotic trajectory traverses the state space. Chaotic neural networks are used in various information processing systems with abilities of parallel distributed processing [33.121–123]. Note that CMLs also consist of chaotic oscillators produced by a nonlinear local iterative map, like in chaotic neural networks. CMLs define a spatial relationship among their nodes to describe spatio-temporal fluctuations. A class of cellular neural networks combines the explicit spatial relationships similar to CMLs with detailed temporal dynamics using Cohen–Grossberg model [33.83] and it has been used successfully in neural network applications [33.124, 125].

### Collective Chaos in Neural Networks

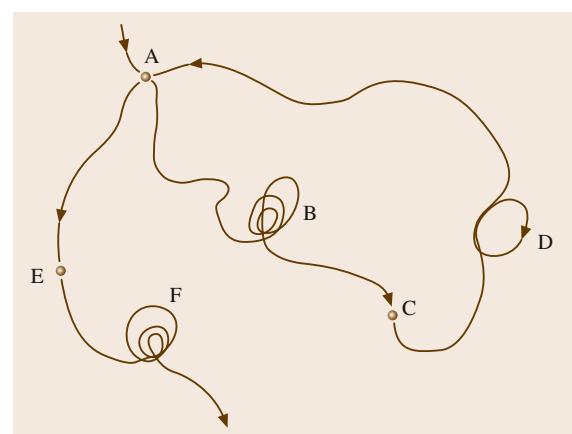

Chaos in neural networks can be an emergent macroscopic property stemming from the interaction of nonlinear neurons, which are not necessarily chaotic in isolation. Starting from the microscopic neural level up to the macroscopic level of cognition and consciousness, chaos plays an important role in neurodynamics [33.82, 126–129]. There are various routes to chaos in neural systems, including period-doubling bifurcations to chaos, chaotic intermittency, and collapse of a two-dimensional torus to chaos [33.130, 131].

Chaotic itinerary is a special form of chaos, which is between ordered dynamics and fully developed chaos. Chaotic itinerary describes the trajectory through high-dimensional state space of neural activity [33.132]. In chaotic itinerary the chaotic system

is destabilized to some degree but some traces of the trajectories remain. This describes an itinerant behavior between the states of the system containing destabilized attractors or *attractor ruins*, which can be fixed point, limit cycle, torus, or strange attractor with unstable directions. Dynamical orbits are attracted to a certain attractor ruin, but they leave via an unstable manifold after a (short or long) stay around it and move toward another attractor ruin. This successive chaotic transition continues unless a strong input is received. A schematic diagram is shown in Fig. 33.23, where the trajectory of a chaotic itinerant system is shown visiting attractor ruins. Chaotic itinerary is associated with perceptions and memories, the chaos between the attractor ruins is related to searches, and the itinerary is associated with sequences in thinking, speaking, and writing.

Frustrated chaos is a dynamical system in a neural network with a global attractor structure when local connectivity patterns responsible for stable oscillatory behaviors become intertwined, leading to mutually competing attractors and unpredictable itinerary between brief appearances of these attractors [33.133]. Similarly to chaotic itinerary, frustrated chaos is related to destabilization of the dynamics and it generates itinerant, wavering oscillations between the orbits of the network, the trajectories of which have been stable with the original connectivity pattern. Frustrated chaos is shown to belong to the family of intermittency type of chaos [33.134, 135].

To characterize chaotic dynamics, tools of statistical time series analysis are useful. The studies may involve time and frequency domains. Time domain analysis

**Fig. 33.23** Schematic illustration of itinerant chaos with a trajectory visiting attractor ruins (after [33.132])

includes attractor reconstruction, i.e., the attractor is depicted in the state space. Chaotic attractors have fractal dimensions, which can be evaluated using one of the available methods [33.136–138]. In the case of low-dimensional chaotic systems, the reconstruction can be illustrated using two or three-dimensional plots. An example of attractor reconstruction is given in Fig. 33.22 for the Lorenz system with three variables. Attractor reconstruction of a time series can be conducted using time-delay coordinates [33.139].

Lyapunov spectrum analysis is a key tool in identifying and describing chaotic systems. Lyapunov exponents measure the instability of orbits in different directions in the state space. It describes the rate of exponential divergence of trajectories that were once close to each other. The set of corresponding Lyapunov exponents constitutes the Lyapunov spectrum. The maximum Lyapunov exponent  $\Lambda^*$  is of crucial importance; as a positive leading Lyapunov exponent  $\Lambda^* > 0$  is the hallmark of chaos.  $X(t)$  describes the trajectory of the system in the phase space starting from  $X(0)$  at time  $t = 0$ . Denote by  $X_{\Delta x_0}(t)$  the perturbed trajectory starting from  $[X(0) + \Delta x_0]$ . The leading Lyapunov exponent can be determined using the following relationship [33.140]

$$\Lambda^* = \lim_{\substack{t \rightarrow \infty \\ \Delta x_0 \rightarrow 0}} t^{-1} \ln [|X_{\Delta x_0}(t) - X(t)| / |\Delta x_0|], \quad (33.24)$$

where  $\Lambda^* < 0$  corresponds to convergent behavior,  $\Lambda^* = 0$  indicates periodic orbits, and  $\Lambda^* > 0$  signifies chaos. For example, the Lorenz attractor has  $\Lambda^* = 0.906$ , indicating strong chaos (Fig. 33.24). Equation (33.24) measures the divergence for infinitesimal perturbations in the limit of infinite time series. In practical situations, especially for short time series, it is often difficult to distinguish weak chaos from random perturbations. One must be careful with conclusions about the presence of chaos when  $\Lambda^*$  has a value close to zero. Lyapunov exponents are widely used in brain monitoring using electroencephalogram (EEG) analysis, and various methods are available for characterization of normal and pathological brain conditions based on Lyapunov spectra [33.141, 142].

Fourier analysis conducts data processing in the frequency domain, see (33.5) and (33.6). For chaotic signals, the shape of the power spectra is of special interest. Power spectra often show  $1/f^\alpha$  power law behavior in log-log coordinates, which is the indication of scale-free system and possibly chaos. Power-law scaling in systems at SOC is suggested by a linear decrease

in log power with increasing log frequency [33.143]. Scaling properties of criticality facilitate the coexistence of spatially coherent cortical activity patterns for a duration ranging from a few milliseconds to a few seconds. Scale-free behavior characterizes chaotic brain activity both in time and frequency domains. For completeness, we mention the Hilbert space analysis as an alternative to Fourier methods. The analytic signal approach based on Hilbert analysis is widely used in brain monitoring.

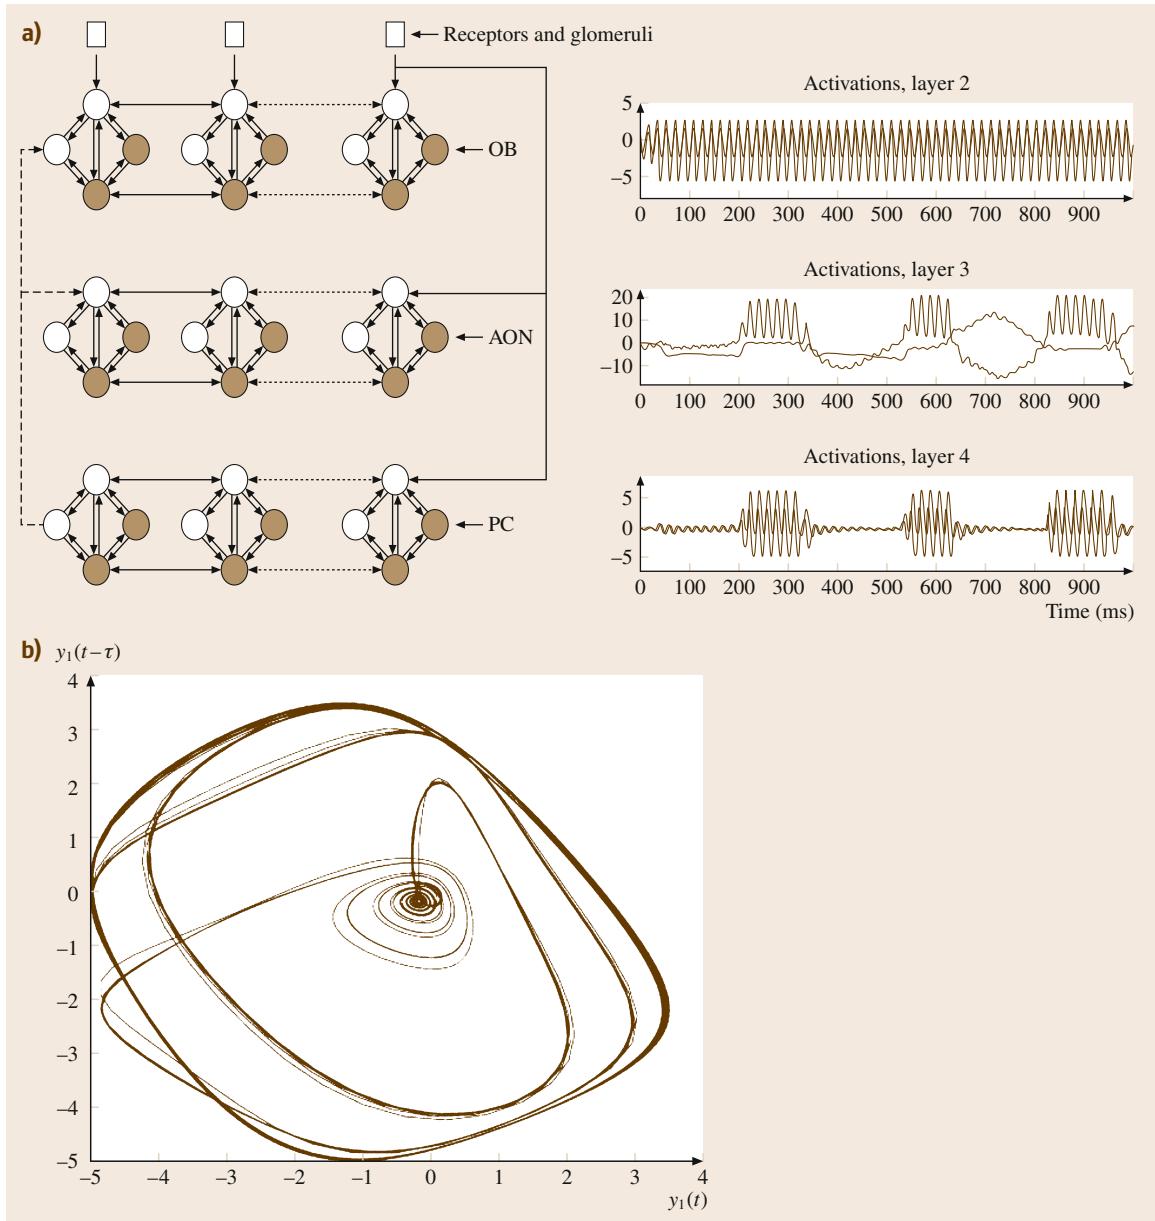

### Emergent Macroscopic Chaos in Neural Networks

Freeman's K model describes spatio-temporal brain chaos using a hierarchical approach. Low-level K sets were introduced in the 1970s, named in the honor of Aharon Kachalsky, an early pioneer of neural dynamics [33.82, 94]. K sets are multiscale models, describing an increasing complexity of structure and dynamics. K sets are mesoscopic models and represent an intermediate level between microscopic neurons and macroscopic brain structures. K-sets are topological specifications of the hierarchy of connectivity in neural populations in brains. K sets describe the spatial patterns of phase and amplitude of the oscillations generated by neural populations. They model observable fields of neural activity comprising electroencephalograms (EEGs), local field potentials (LFPs), and magnetoencephalograms (MEGs) [33.144]. K sets form a hierarchy for cell assemblies with components starting from K0 to KIV [33.145, 146].

K0 sets represent noninteractive collections of neurons forming cortical microcolumns; a K0 set models a neuron population of  $\approx 10^3 - 10^4$  neurons. K0 models dendritic integration in average neurons and an asymmetric sigmoid static nonlinearity for axon transmission. The K0 set is governed by a point attractor with zero output and stays at equilibrium except when perturbed. In the original K-set models, K0s are described by a state-dependent, linear second-order ordinary differential equation (ODE) [33.94]

$$ab \frac{d^2X(t)}{dt^2} + (a + b) \frac{dX(t)}{dt} + P(t) = U(t). \quad (33.25)$$

Here  $a$  and  $b$  are biologically determined time constants.  $X(t)$  denotes the activation of the node as a function of time.  $U(t)$  includes an asymmetric sigmoid function  $Q(x)$ , see (33.18), acting on the weighted sum of activation from neighboring nodes and any external input.

**Fig. 33.24a–c** KIII diagram and behaviors; **(a)** 3 double layer hierarchy of KIII and time series over each layer, exhibiting intermittent chaotic oscillations, **(b)** phase space reconstruction using delayed time coordinates

KI sets are made of interacting K0 sets, either excitatory or inhibitory with positive feedback. The dynamics of KI is described as convergence to a nonzero fixed point. If KI has sufficient functional connection density, then it is able to maintain a nonzero state of background activity by mutual excitation (or inhibition).

KI typically operates far from thermodynamic equilibrium. Neural interaction by stable mutual excitation (or mutual inhibition) is fundamental to understanding brain dynamics. KII sets consists of interacting excitatory and inhibitory KI sets with negative feedback. KII sets are responsible for the emergence of limit cy-

cle oscillation due to the negative feedback between the neural populations. Transitions from point attractor to limit cycle attractor can be achieved through a suitable level of feedback gain or by input stimuli, see Fig. 33.18.

KIII sets made up of multiple interacting KII sets. Examples include the sensory cortices. KIII sets generate broadband, chaotic oscillations as background activity by combined negative and positive feedback among several KII populations with incommensurate frequencies. The increase in nonlinear feedback gain that is driven by input results in the destabilization of the background activity and leads to the emergence of a spatial amplitude modulation (**AM**) pattern in KIII. KIII sets are responsible for the embodiment of meaning in **AM** patterns of neural activity shaped by synaptic interactions that have been modified through learning in KIII layers. The KIII model is illustrated in Fig. 33.24 with three layers of excitatory–inhibitory nodes. In Fig. 33.24a the temporal dynamics is illustrated in each layer, while Fig. 33.24b shows the phase space reconstruction of the attractor. This is a chaotic behavior resembling the dynamics of the Lorenz attractor in Fig. 33.22. KIV sets are made up of interacting KIII units to model intentional neurodynamics of the limbic system. KIV exhibits global phase transitions, which are the manifestations of hemisphere-wide cooperation through intermittent large-scale synchronization. KIV is the domain of Gestalt formation and preaffерence through the convergence of external and internal sensory signals leading to intentional action [33.144, 146].

### Properties of Collective Chaotic Neural Networks

KIII is an associative memory, encoding input data in spatio-temporal **AM** patterns [33.147, 148]. KIII chaotic memories have several advantages as compared to convergent recurrent networks:

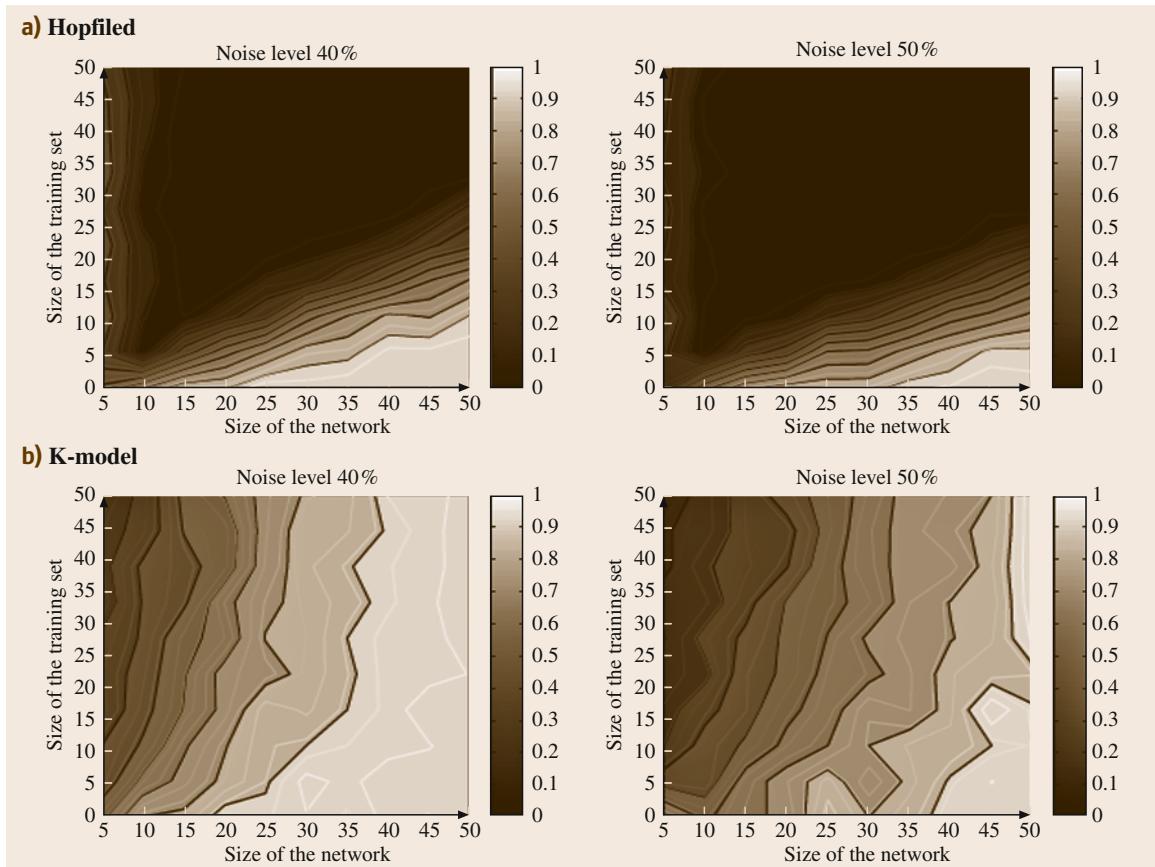

1. They produce robust memories based on relatively few learning examples even in noisy environment.
2. The encoding capacity of a network with a given number of nodes is exponentially larger than their convergent counterparts.
3. They can recall the stored data very quickly, just as humans and animals can recognize a learnt pattern within a fraction of a second.

The recurrent Hopfield neural network can store an estimated  $0.15N$  input patterns in stable attractors,

where  $N$  is the number of neurons [33.84]. Exact analysis by *Mceliece et al.* [33.149] shows that the memory capacity of the Hopfield network is  $N/(4\log N)$ . Various generalizations provide improvements over the initial memory gain [33.150, 151]. It is of interest to evaluate the memory capacity of the KIII memory. The memory capacity of chaotic networks which encode input into chaotic attractors is, in principle, exponentially increased with the number of nodes. However, the efficient recall of the stored memories is a serious challenge. The memory capacity of KIII as a chaotic associative memory device has been evaluated with noisy input patterns. The results are shown in Fig. 33.25, where the performance of Hopfield and KIII memories are compared; the top two plots are for Hopfield nets, while the lower two figures describe KIII results [33.152]. The light color shows recognition rate close to 100%, while the dark color means poor recognition approaching 0. The right-hand column has higher noise levels. The Hopfield network shows the well-known linear gain curve  $\approx 0.15$ . The KIII model, on the other hand, has a drastically better performance. The boundary separating the correct and incorrect classification domains is superlinear; it has been fitted with a fifth-order polynomial.

### Cognitive Implications of Intermittent Brain Chaos

Developments in brain monitoring techniques provide increasingly detailed insights into spatio-temporal neurodynamics and neural correlates of large-scale cognitive processing [33.74, 153–155]. Brains as large-scale dynamical systems have a basal state, which is a high-dimensional chaotic attractor with a dynamic trajectory wandering broadly over the attractor landscape [33.82, 126]. Under the influence of external stimuli, cortical dynamics is destabilized and condenses intermittently to a lower-dimensional, more organized subspace. This is the act of perception when the subject identifies the stimulus with a meaning in the context of its previous experience. The system stays intermittently in the condensed, more coherent state, which gives rise to a spatio-temporal **AM** activity pattern corresponding to the stimulus in the given context. The **AM** pattern is meta-stable and it disintegrates as the system returns to the high-dimensional chaotic basal state (less synchrony). Brain dynamics is described as a sequence of phase transitions with intermittent synchronization-desynchronization effects. The rapid emergence of synchronization can be initiated by (Hebian) neural assemblies that lock into synchronization

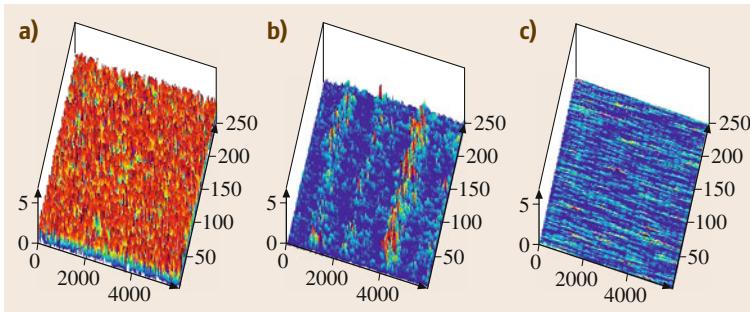

**Fig. 33.25a,b** Comparison of the memory capacity of (a) Hopfield and (b) KIII neural networks; the noise level is 40% (left); 50% (right); the lighter the color the higher the recall accuracy. Observe the linear gain for Hopfield networks and the superlinear (fifth-order) separation for KIII (after [33.152])

across widespread cortical and subcortical areas [33.82, 156, 157].

Intermittent oscillations in spatio-temporal neural dynamics are modeled by a neuropercolation approach. Neuropercolation is a family of probabilistic models based on the theory of probabilistic cellular automata on lattices and random graphs and it is motivated by structural and dynamical properties of neural populations. Neuropercolation constructs the hierarchy of interactive populations in networks as developed in Freeman K models [33.94, 144], but replace differential equations with probability distributions from the observed random networks that evolve in time [33.158]. Neuropercolation considers populations of cortical neurons which sustain their background state by mutual excitation, and their stability is guaranteed by the neural refractory periods. Neural populations transmit and re-

ceive signals from other populations by virtue of small-world effects [33.77, 159]. Tools of statistical physics and finite-size scaling theory are applied to describe critical behavior of the neuropil. Neuropercolation theory provides a mathematical approach to describe phase transitions and critical phenomena in large-scale, interactive cortical networks. The existence of phase transitions is proven in specific probabilistic cellular automata models [33.160, 161].

Simulations by neuropercolation models demonstrate the onset of large-scale synchronization-desynchronization behavior [33.162]. Figure 33.26 illustrates results of intermittent phase desynchronization for neuropercolation with excitatory and inhibitory populations. Three main regimes can be distinguished, separated by critical noise values  $\varepsilon_1 > \varepsilon_0$ . In Regime I  $\varepsilon > \varepsilon_1$ , Fig. 33.26a, the channels are not synchronous and

**Fig. 33.26a–c** Phase synchronization–desynchronization with excitatory–inhibitory connections in neuropercolation with 256 granule nodes; the  $z$ -axis shows the pairwise phase between the units. (a) No synchrony; (b) intermittent synchrony; (c) highly synchronized, frozen phase regime (after [33.162])

the phase values are distributed broadly. In Regime II  $\varepsilon_1 > \varepsilon > \varepsilon_0$ , Fig. 33.26b, the phase lags are drastically reduced indicating significant synchrony over extended time periods. Regime III is observed for high values of  $\varepsilon_0 > \varepsilon$ , when the channels demonstrate highly synchronized, frozen dynamics, see Fig. 33.26c. Sim-

ilar transitions can be induced by the relative strength of inhibition, as well as by the fraction of rewiring across the network [33.114, 115, 163]. The probabilistic model of neural populations reproduces important properties of the spatio-temporal dynamics of cortices and is a promising approach for large-scale cognitive models.

### 33.3 Memristive Neurodynamics

Sequential processing of fetch, decode, and execution of instructions through the classical von Neumann digital computers has resulted in less efficient machines as their ecosystems have grown to be increasingly complex [33.164]. Though modern digital computers are fast and complex enough to emulate the brain functionality of animals like spiders, mice, and cats [33.165, 166], the associated energy dissipation in the system grows exponentially along the hierarchy of animal intelligence. For example, to perform certain cortical simulations at the cat scale even at an 83 times slower firing rate, the IBM team has to employ Blue Gene/P (BG/P), a super computer equipped with 147 456 CPUs and 144 TBs of main memory. On the other hand, the human brain contains more than 100 billion neurons and each neuron has more than 20 000 synapses [33.167]. Efficient circuit implementation of synapses, therefore, is very important to build a brain-like machine. One active branch of this research area is cellular neural networks (CNNs) [33.168, 169], where lots of multiplication circuits are utilized in a complementary metal-oxide-semiconductor (CMOS) chip. However, since shrinking the current transistor size is very difficult, introducing a more efficient approach is essential for further development of neural network implementations.

The memristor was first authorized by Chua as the fourth basic circuit element in electrical circuits in 1971 [33.170]. It is based on the nonlinear character-

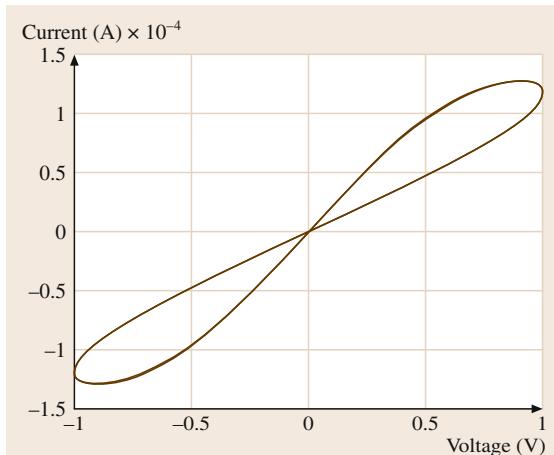

istics of charge and flux. By supplying a voltage or current to the memristor, its resistance can be altered. In this way, the memristor remembers information. In that seminal work, Chua demonstrated that the memristance  $M(q)$  relates the charge  $q$  and the flux  $\varphi$  in such a way that the resistance of the device will change with the applied electric field and time

$$M = \frac{d\varphi}{dq}. \quad (33.26)$$

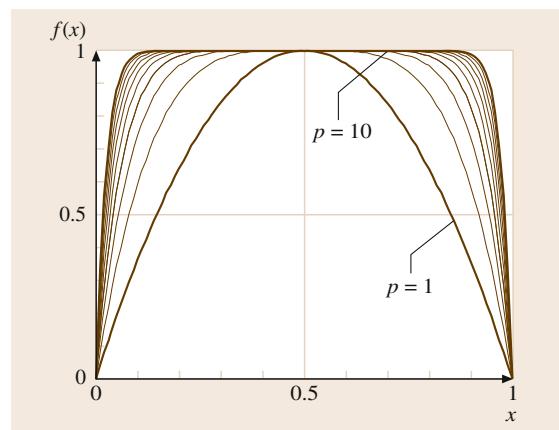

The parameter  $M$  denotes the memristance of a charge controlled memristor, measured in ohms. Thus, the memristance  $M$  can be controlled by applying a voltage or current signal across the memristor. In other words, the memristor behaves like an ordinary resistor at any given instance of time, where its resistance depends on the complete history of the device [33.170].

Although the device was proposed nearly four decades ago, it was not until 2008 that researchers from HP Labs showed that the devices they had fabricated were indeed two-terminal memristors [33.171]. Figure 33.27 shows the I–V characteristics of a generic memristor, where memristance behavior is observed for  $\text{TiO}_{2-x}$  layer with oxygen vacancies is placed on a perfect  $\text{TiO}_2$  layer, and these layers are sandwiched between platinum electrodes. In metal oxide materials, the switching from  $R_{\text{off}}$  to  $R_{\text{on}}$  and vice versa occurs as a result of ion migration, due to the enormous electric fields applied across

the nanoscale structures. These memristors have been fabricated using nanoimprint lithography and were successfully integrated on a CMOS substrate in [33.172]. Apart from these metal-oxide memristors, memristance has also been demonstrated using magnetic materials based on their magnetic domain wall motion and spin-torque induced magnetization switching in [33.173].

**Fig. 33.27** Typical  $I$ - $V$  characteristic of memristor (after [33.171]). The pinched hysteresis loop is due to the nonlinear relationship between the memristance current and voltage. The parameters of the memristor are  $R_{\text{on}} = 100 \Omega$ ,  $R_{\text{off}} = 16 \text{ k}\Omega$ ,  $R_{\text{init}} = 11 \text{ k}\Omega$ ,  $D = 10 \text{ nm}$ ,  $u_v = 10^{-10} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$ ,  $p = 10$  and  $V_{\text{in}} = \sin(2\pi t)$ . The memristor exhibits the feature of pinched hysteresis, which means that a lag occurs between the application and the removal of a field and its subsequent effect, just like the feature of neurons in the human brain

**Fig. 33.28** Window function for different integer  $p$

Furthermore, several different types of nonlinear memristor models have been investigated [33.174, 175]. One of them is the window model in which the state equation is multiplied by window function  $F_p(\omega)$ , namely

$$\frac{d\omega}{dt} = \mu_v \frac{R_{\text{on}}}{D} i(t) F_p(\omega), \quad (33.27)$$

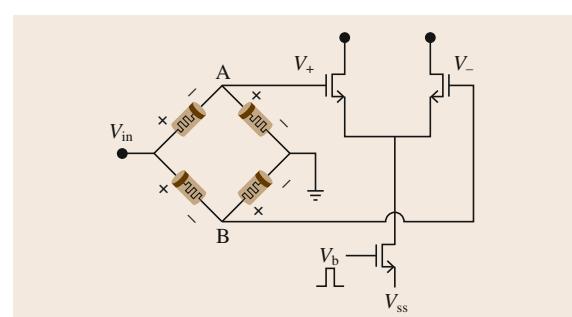

where  $p$  is an integer parameter and  $F_p(\omega)$  is defined by

$$F_p(\omega) = 1 - \left(2 \frac{\omega}{D} - 1\right)^{2p}, \quad (33.28)$$

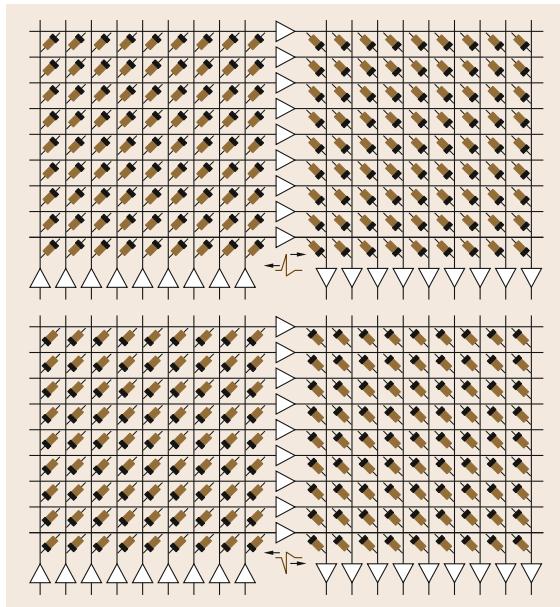

which is shown in Fig. 33.28.

### 33.3.1 Memristor-Based Synapses

The design of simple weighting circuits for synaptic multiplication between arbitrary input signals and weights is extremely important in artificial neural systems. Some efforts have been made to build neuron-like analog neural networks [33.178–180]. However, this research has gained limited success so far because of the difficulty in implementing the synapses efficiently. Based on the memristor, a novel weighting circuit was proposed by Kim et al. [33.176, 181, 182] as shown in Fig. 33.29. The memristors provide a bridge-like switching for achieving either positive or negative weighting. Though several memristors are employed to emulate a synapse, the total area of the memristors is less than that of a single transistor. To compensate for the spatial nonuniformity and nonideal response of the memristor bridge synapse, a modified chip-in-the-loop learning scheme suitable

**Fig. 33.29** Memristor bridge circuit. The synaptic weight is programmable by varying the input voltage. The weighting of the input signal is also performed in this circuit (after [33.176])

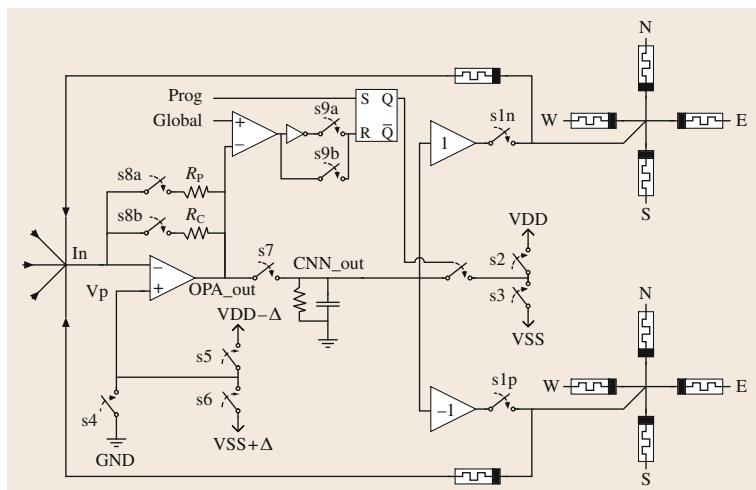

**Fig. 33.30** Neuromorphic memristive computer equipped with STDP (after [33.177])

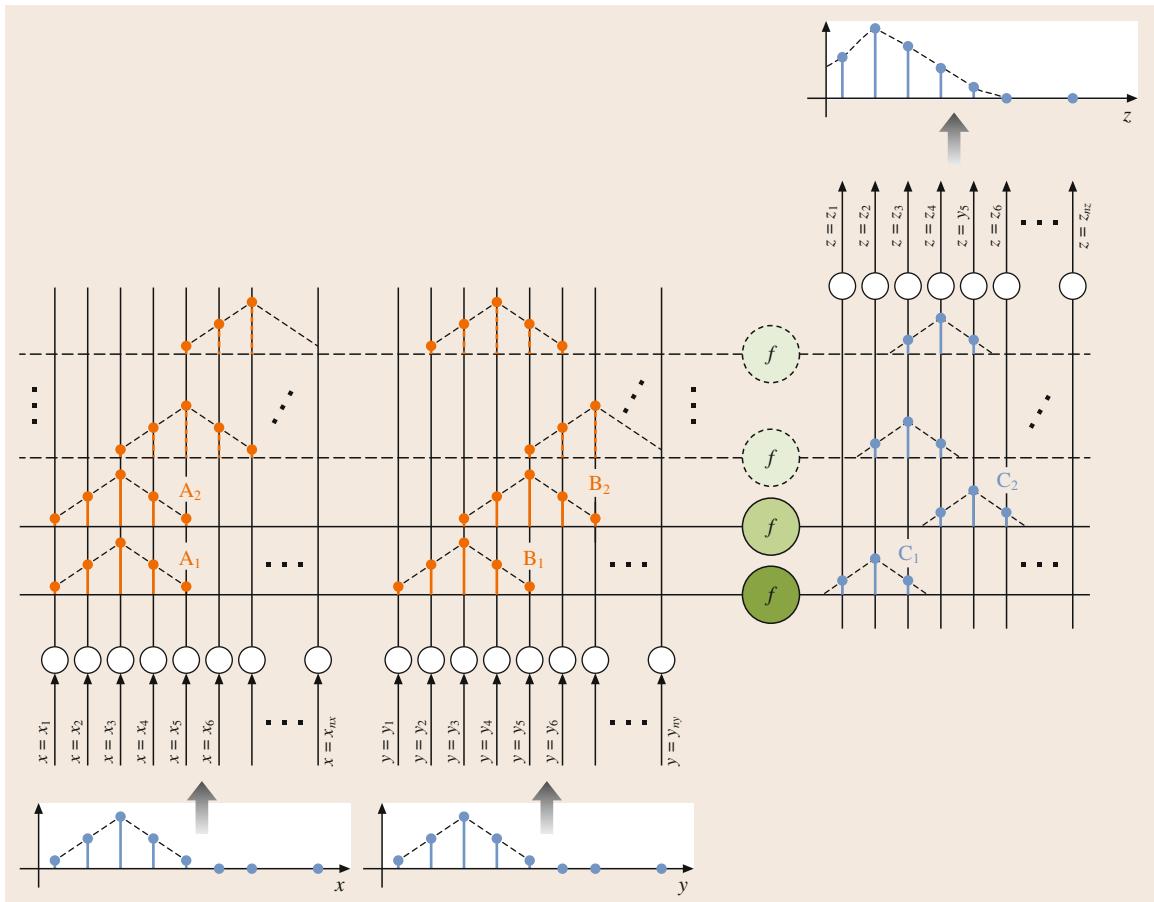

for the proposed neural network architecture is investigated [33.176]. In the proposed method, the initial learning is conducted by software, and the behavior of the software-trained network is learned via the hardware network by learning each of the single layered neurons of the network independently. The forward calculation of single layered neuron learning is implemented through circuit hardware and is followed by a weight updating phase assisted by a host com-

puter. Unlike conventional chip-in-the-loop learning, the need for the readout of synaptic weights for calculating weight updates in each epoch is eliminated by virtue of the memristor bridge synapse and the proposed learning scheme.

On the other hand, spike-timing-dependent learning (**STDP**), which is a powerful learning paradigm for spiking neural systems because of its massive parallelism, potential scalability, and inherent defect, fault, and failure-tolerance, can be implemented by using a crossbar memristive array combined with neurons that asynchronously generate spikes of a given shape [33.177, 185]. Such spikes need to be sent back through the neurons to the input terminal as in Fig. 33.30. The shape of the spikes turns out to be very similar to the neural spikes observed in realistic biological neurons. The **STDP** learning function obtained by combining such neurons with memristors is exactly obtained from neurophysiological experiments on real synapses. Such nanoscale synapses can be combined with **CMOS** neurons which is possible to create neuromorphic hardware several orders of magnitude denser than in conventional **CMOS**. This method offers better control over power dissipation; fewer constraints on the design of memristive materials used for nanoscale synapses; greater freedom in learning algorithms than traditional design of synapses since the synaptic learning dynamics can be dynamically turned on or off; greater control over the precise form and timing of the **STDP** equations; the ability to implement a variety of other learning laws besides **STDP**; better circuit diversity since the approach allows different learning laws to be implemented in different areas of a single chip

**Fig. 33.31** Memristor-based cellular neural networks cell (after [33.183])

**Fig. 33.32** Simple realization of MNN based on fuzzy concepts (after [33.184])

using the same memristive material for all synapses. Furthermore, an analog CMOS neuromorphic design utilizing STDP and memristor synapses is investigated for use in building a multipurpose analogy neuromorphic chip [33.186]. In order to obtain a multipurpose chip, a suitable architecture is established. Based on the technique of IBM 90 nm CMOS9RF, neurons are designed to interface with Verilog-A memristor synapses models to perform the XOR operation and edge detection function.

To make the neurons compatible with such new synapses, some novel training methods are proposed. For instance, *Manem* et al. proposed a variation-tolerant training method to efficiently reconfigure memristive synapses in a trainable threshold gate array (TTGA) system [33.187]. The training process is inspired from the gradient descent machine learning algorithm commonly used to train artificial threshold neural networks

known as perceptrons. The proposed training method is robust to the unpredictability of CMOS and nanocircuits with decreasing technology sizes, but also provides its own randomness in its training.

### 33.3.2 Memristor-Based Neural Networks

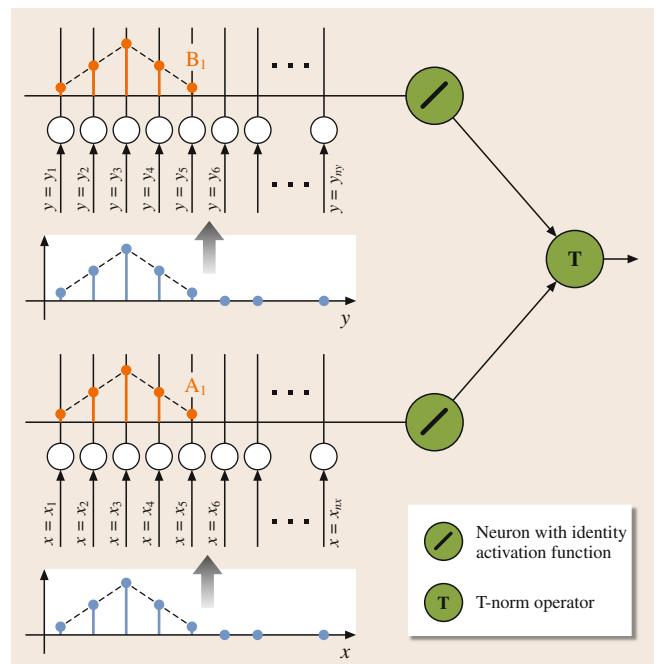

Employing memristor-based synapses, some results have been obtained about the memristor-based neural networks [33.183, 184, 188]. As the template weights in memristor-based neural networks (MNNs) are usually known and need to be updated between each template in a sequence of templates, there should be a way to rapidly change the weights. Meanwhile, the MNN cells need to be modified, as the programmable couplings are implemented by memristors which require programming circuits to isolate each other. *Lehtonen* and *Laiho* proposed a new cell of memristor-based cellular neural

network that can be used to program the templates. For this purpose, a voltage *global* is input into the cell. This voltage is used to convey the weight of one connection into the cells [33.183]. The level of virtual ground and switches are controlled so that the memristor connected to a particular neighbor is biased above the programming threshold, until it reaches the desired resistance value.

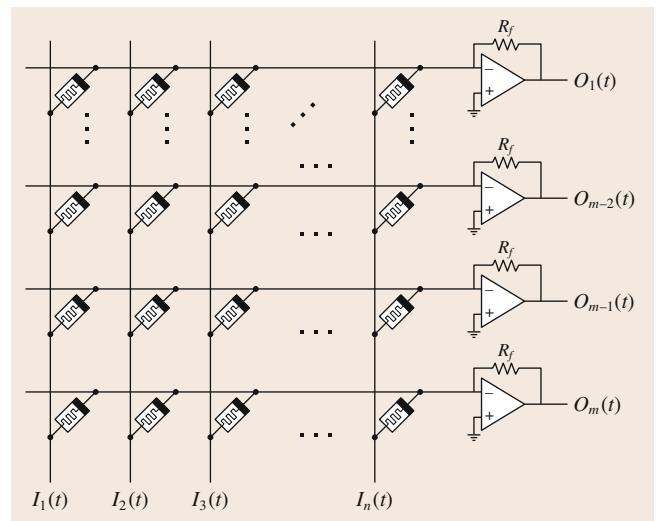

*Merrikh-Bayat et al.* presented a new way to explain the relationships between logical circuits and artificial neural networks, logical circuits and fuzzy logic, and artificial neural networks and fuzzy inference systems, and proposed a new neuro-fuzzy computing system, which can effectively be implemented via the memristor-crossbar structure [33.184]. A simple realization of MNNs is shown in Figs. 33.32–33.34. Figure 33.32 shows that it is possible to interpret the working procedure of conventional artificial neural network ANN without changing its structure. In this figure, each row of the structure implements a simple fuzzy rule or min-term. Figure 33.33 shows how the activation function of neurons can be implemented when the activation function is modeled by a *t*-norm operator. Matrix multiplication is performed by vector circuit in Fig. 33.34. This circuit consists of a simple memristor crossbar where each of its rows is connected to the virtually grounded terminal of an operational amplifier that plays the role of a neuron with identity activation function. The advantages of the proposed system are twofold: first, its hardware can be directly trained using the Hebbian learning rule and without the need to perform any optimization; second, this system has a great ability to deal with a huge number of input-output training data without facing problems like overtraining.

*Howard et al.* proposed a spiking neuro-evolutionary system which implements memristors as plastic connections [33.188]. These memristors provide a learning architecture that may be beneficial to the evolutionary design process that exploits parameter self-adaptation and variable topologies, allow the number of neurons, connection weights, and interneuronal connectivity pattern to emerge. This approach allows the evolution of networks with appropriate complexity to emerge whilst exploiting the memristive properties of the connections to reduce learning time.

To investigate the dynamic behaviors of memristor-based neural networks, *Zeng et al.* proposed the memristor-based recurrent neural networks (MRNNs) [33.189, 190] shown in Fig. 33.35, where  $x_i(\cdot)$  is the

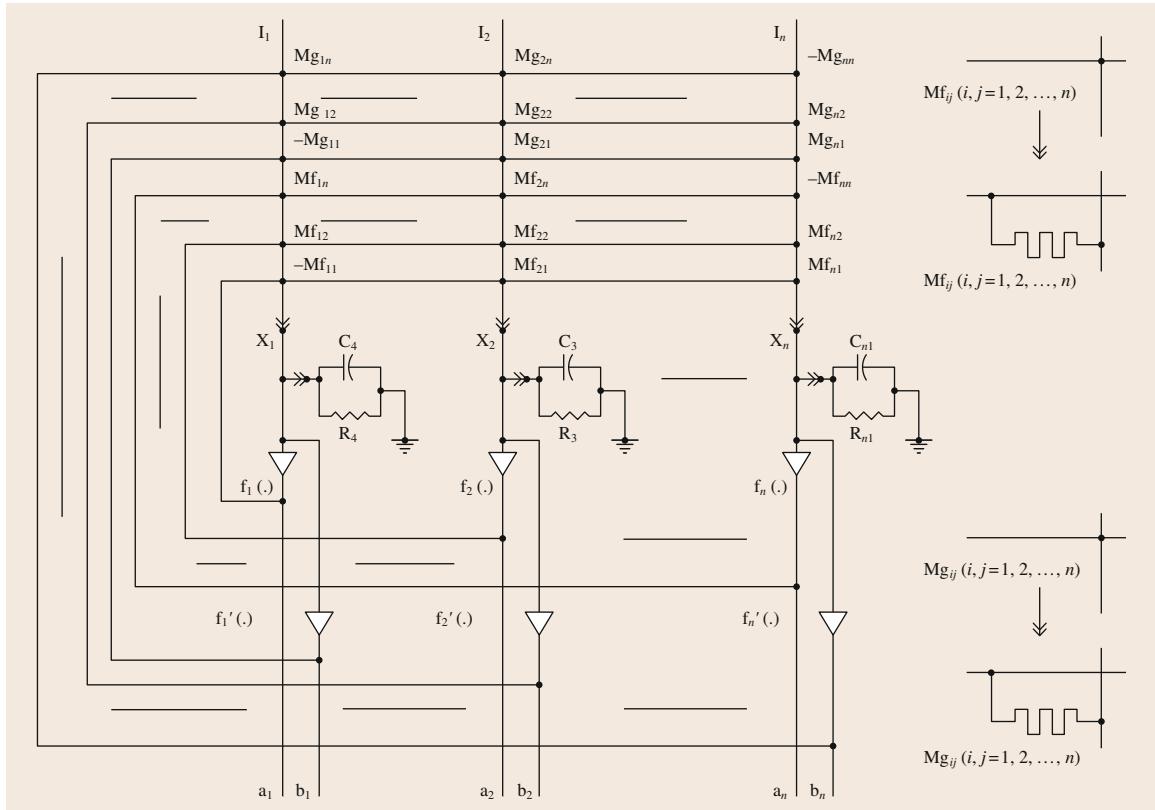

**Fig. 33.33** Implementation of the activation function of neurons (after [33.184])

**Fig. 33.34** Memristor crossbar-based circuit (after [33.184])

state of the  $i$ -th subsystem,  $f_j(\cdot)$  is the amplifier,  $M_{fj}$  is the connection memristor between the amplifier  $f_j(\cdot)$  and state  $x_i(\cdot)$ ,  $R_i$  and  $C_i$  are the resistor and capacitor,  $I_i$  is the external input,  $a_i, b_i$  are the outputs,  $i, j = 1, 2, \dots, n$ . The parameters in this neural network are

**Fig. 33.35** Circuit of a memristor-based recurrent network (after [33.189])

changed according to the state of the system, so this network is a state-dependent switching system. The dynamic behavior of this neural network with time-varying delays was investigated based on the Filippov theory and the Lyapunov method.

### 33.3.3 Conclusion

Memristor-based synapses and neural networks have been investigated by many scientists for their possi-

ble applications in analog, digital information processing, and memory and logic applications. However, the problem, of how to take advantage of the nonvolatile memory of memristors, nanoscale, low-power dissipation, and so on to design a method to process and store the information, which needs learning and memory, into the synapses of the memristor-based neural networks at the dynamical mapping space by a more rational space-partitioning method, is still an open issue. Further investigation is needed to shorten such a gap.

## 33.4 Neurodynamic Optimization

Optimization is omnipresent in nature and society, and an important tool for problem-solving in science, engineering, and commerce. Optimization problems arise in a wide variety of applications such as the design, planning, control, operation, and management of engineering systems. In many applications (e.g., online

pattern recognition and in-chip signal processing in mobile devices), real-time optimization is necessary or desirable. For such applications, conventional optimization techniques may not be competent due to stringent requirements on computational time. It is computationally challenging when optimization procedures are to

be performed in real time to optimize the performance of dynamical systems.

The brain is a profound dynamic system and its neurons are always active from birth to death. When a decision is to be made in the brain, many of its neurons are highly activated to gather information, search memory, compare differences, and make inferences and decisions. Recurrent neural networks are brain-like nonlinear dynamic system models and can be properly designed to imitate biological counterparts and serve as goal-seeking parallel computational models for solving optimization problems in a variety of settings. Neurodynamic optimization can be physically realized in designated hardware such as application-specific integrated circuits (**ASICs**) where optimization is carried out in a parallel and distributed manner, where the convergence rate of the optimization process is independent of the problem dimensionality. Because of the inherent nature of parallel and distributed information processing, neurodynamic optimization can handle large-scale problems. In addition, neurodynamic optimization may be used for optimizing dynamic systems in multiple time scales with parameter-controlled convergence rates. These salient features are particularly desirable for dynamic optimization in decentralized decision-making scenarios [33.191–194]. While population-based evolutionary approaches to optimization have emerged as prevailing heuristic and stochastic methods in recent years, neurodynamic optimization deserves great attention in its own right due to its close ties with optimization and dynamical systems theories, as well as its biological plausibility and circuit implementability with very large scale integration (**VLSI**) or optical technologies.

### 33.4.1 Neurodynamic Models

The past three decades witnessed the birth and growth of neurodynamic optimization. Although a couple of circuit-based optimization methods were developed earlier [33.195–197], it was perhaps *Hopfield* and *Tank* who spearheaded neurodynamic optimization research in the context of neural computation with their seminal work in the mid 1980s [33.198–200]. Since the inception, numerous neurodynamic optimization models in various forms of recurrent neural networks have been developed and analyzed, see [33.201–256], and the references therein. For example, *Tank* and *Hopfield* extended the continuous-time Hopfield network for linear programming and showed their experimental results with a circuit of operational amplifiers and

other discrete components on a breadboard [33.200]. *Kennedy* and *Chua* developed a circuit-based recurrent neural network for nonlinear programming [33.201]. It is proven that the state of the neurodynamics is globally convergent and an equilibrium corresponding to an approximate optimal solution of the given optimization problems.

Over the years, neurodynamic optimization research has made significant progress with models with improved features for solving various optimization problems. Substantial improvements of neurodynamic optimization theory and models have been made in the following dimensions:

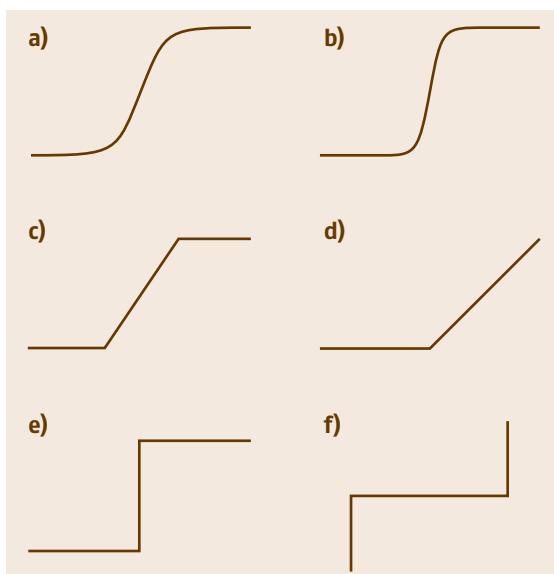

- i) Solution quality: designed based on smooth penalty methods with a finite penalty parameter; the earliest neurodynamic optimization models can converge to approximate solutions only [33.200, 201]. Later on, better models designed based on other design principles can guarantee to state or output convergence to exact optimal solutions of solvable convex and pseudoconvex optimization problems with or without any conditions [33.204, 205, 208, 210], etc.
- ii) Solvability scope: the solvability scope of neurodynamic optimization has been expanded from linear programming problems [33.200, 202, 208, 211, 212, 214–219, 223, 242, 244, 251], to quadratic programming problems [33.202–206, 210, 214, 217, 218, 220, 225, 226, 229, 233, 240–243, 247], to smooth convex programming problems with various constraints [33.201, 204, 205, 210, 214, 222, 224, 228, 230, 232, 234, 237, 245, 246, 257], to nonsmooth convex optimization problems [33.235, 248, 250–256], and recently to nonsmooth optimization with some nonconvex objective functions or constraints [33.239, 249, 254–256].
- iii) Convergence property: the convergence property of neurodynamic optimization models has been extended from near-optimum convergence [33.200, 201], to conditional exact-optimum global convergence [33.205, 208, 210], to guaranteed global convergence [33.204, 205, 214–216, 218, 219, 222, 226–228, 230, 232, 234, 240, 243, 245, 247, 250, 253, 256, 257], to faster global exponential convergence [33.206, 224, 225, 228, 233, 237, 239, 241, 246, 254], to even more desirable finite-time convergence [33.235, 248, 249, 251, 252, 255], with increasing convergence rate.
- iv) Model complexity: the neurodynamic optimization models for constrained optimization are essentially multilayer due to the introduction of instrumen-

tal variables for constraint handling (e.g., Lagrange multipliers or dual variables). The architectures of later neurodynamic optimization models for solving linearly constrained optimization problems have been reduced from multilayer structures to single-layer ones with decreasing model complexity to facilitate their implementation [33,243, 244, 251, 252, 254, 255].

Activation functions are a signature component of neural network models for quantifying the firing state activities of neurons. The activation functions in existing neurodynamic optimization models include smooth ones (e.g., sigmoid), as shown in Fig. 33.36a,b [33,200, 208–210], nonsmooth ones (e.g., piecewise-linear) as shown in Fig. 33.36c,d [33,203, 206], and even discontinuous ones as shown in Fig. 33.36e,f [33,243, 244, 251, 252, 254, 255].

### 33.4.2 Design Methods

The crux of neurodynamic optimization model design lies in the derivation of a convergent neurodynamic equation that prescribes the states of the neurodynamics. A properly derived neurodynamic equation can ensure that the states of neurodynamics reaches an equi-

**Fig. 33.36a–f** Three classes of activation functions in neurodynamic optimization models: smooth in (a) and (b), nonsmooth in (c) and (d), and discontinuous in (e) and (f)

librium that satisfies the constraints and optimizes the objective function. Although the existing neurodynamic optimization models are highly diversified with many different features, the design methods or principles for determining their neurodynamic equations can be categorized as follows:

- i) Penalty methods
- ii) Lagrange methods
- iii) Duality methods
- iv) Optimality methods.

#### Penalty Methods

Consider the general constrained optimization problem

$$\begin{aligned} & \text{minimize } f(x) \\ & \text{subject to } g(x) \leq 0, \\ & \quad h(x) = 0, \end{aligned}$$

where  $x \in \mathbb{R}^n$  is the vector of decision variables,  $f(x)$  is an objective function,  $g(x) = [g_1(x), \dots, g_m(x)]^\top$  is a vector-valued function, and  $h(x) = [h_1(x), \dots, h_p(x)]^\top$  is a vector-valued function.

A penalty method starts with the formulation of a smooth or nonsmooth energy function based on a given objective function  $f(x)$  and constraints  $g(x)$  and  $h(x)$ . It plays an important role in neurodynamic optimization. Ideally, the minimum of a formulated energy function corresponds to the optimal solution of the original optimization problem. For constrained optimization, the minimum of the energy function has to satisfy a set of constraints. Most early approaches formulate an energy function by incorporating objective function and constraints through functional transformation and numerical weighting [33,198–201]. Functional transformation is usually used to convert constraints to a penalty function to penalize the violation of constraints; e.g., a smooth penalty function is as follows

$$p(x) = \frac{1}{2} \sum_{i=1}^m \{[-g_i(x)]^+\}^2 + \sum_{j=1}^p [h_j(x)]^2,$$

where  $[y]^+ = \max\{0, y\}$ . Numerical weighting is often used to balance constraint satisfaction and objective optimization, e.g.,

$$E(x) = f(x) + wp(x),$$

where  $w$  is a positive weight.

In smooth penalty methods, neurodynamic equations are usually derived as the negative gradient flow of the energy function in the form of a differential equation

$$\frac{dx(t)}{dt} \propto -\nabla E(x(t)).$$

If the energy function is bounded below, the stability of the neurodynamics can be ensured. Nevertheless, the major limitation is that the neurodynamics designed using a smooth penalty method with any fixed finite penalty parameter can converge to an approximate optimal solution only, as a compromise between constraint satisfaction and objective optimization. One way to remedy the approximated limitation of smooth penalty design methods is to introduce a variable penalty parameter. For example, a time-varying delaying penalty parameter (called temperature) is used in deterministic annealing networks to achieve exact optimality with a slow cooling schedule [33.208, 210].

If the objective function or penalty function is nonsmooth, the gradient has to be replaced by a generalized gradient and the neurodynamics can be modeled using a differential inclusion [33.235, 248, 249, 251, 252, 255]. Two advantages of nonsmooth penalty methods over smooth ones are possible constraint satisfaction and objective optimization with some finite penalty parameters and finite-time convergence of the resulting neurodynamics. Needless to say, nonsmooth neurodynamics are much more difficult to analyze to guarantee their stability.

### Lagrange Methods

A Lagrange method for designing a neurodynamic optimization model begins with the formulation of a Lagrange function (Lagrangian) instead of an energy function [33.204, 205]. A typical Lagrangian is defined as

$$L(x, \lambda, \mu) = f(x) + \sum_{i=1}^m \lambda_i g_i(x) + \sum_{j=1}^p \mu_j h_j(x),$$

where  $\lambda = (\lambda_1, \dots, \lambda_m)^\top$  and  $\mu = (\mu_1, \dots, \mu_p)^\top$  are Lagrange multipliers, for inequality constraints  $g(x)$  and equality constraints  $h(x)$ , respectively.

According to the saddle-point theorem, the optimal solution can be determined by minimizing the Lagrangian with respect to  $x$  and maximizing it with respect to  $\lambda$  and  $\mu$ . Therefore, neurodynamic equations

can be derived in an augmented space

$$\begin{aligned}\epsilon \frac{dx(t)}{dt} &= -\nabla_x L(x(t), \lambda(t), \mu(t)), \\ \epsilon \frac{d\lambda(t)}{dt} &= -\nabla_\lambda L(x(t), \lambda(t), \mu(t)), \\ \epsilon \frac{d\mu(t)}{dt} &= -\nabla_\mu L(x(t), \lambda(t), \mu(t)),\end{aligned}$$

where  $\epsilon$  is a positive time constant. The equilibrium of the Lagrangian neurodynamics satisfy the Lagrange necessary optimality conditions.

### Duality Methods

For convex optimization, the objective functions of primal and dual problems reach the same value at their optima. In view of this duality property, the duality methods for designing neurodynamic optimization models begin with the formulation of an energy function consisting of a duality gap between the primal and dual problems and a constraint-based penalty function, e.g.,

$$E(x, y) = \frac{1}{2}(f(x) - f_d(y))^2 + p(x) + p_d(y),$$

where  $y$  is a vector of dual variables,  $f_d(y)$  is the dual objective function to be maximized,  $p(x)$  and  $p_d(y)$  are, respectively, smooth penalty functions to penalize the violations of constraints of primal (original) and dual problems. The corresponding neurodynamic equation can be derived with guaranteed global stability as the negative gradient flow of the energy function similarly as in the aforementioned smooth penalty methods [33.216, 218, 222, 226, 258, 259]. Neurodynamic optimization models designed by using duality design methods can guarantee global convergence to the exact optimal solutions of convex optimization problems without any parametric condition.

In addition, using duality methods, dual networks and their simplified/improved versions can be designed for quadratic programming with reduced model complexity by mapping their global convergent optimal dual state variables to optimal primal solutions via linear or piecewise-linear output functions [33.240, 247, 260–263].

### Optimality Methods

The neurodynamic equations of some recent models are derived based on optimality conditions (e.g., the

Karush–Kuhn–Tucker condition) and projection methods. Basically, the methods are to map the equilibrium of the designed neurodynamic optimization models to the equivalent equalities given by optimality conditions and projection equations (i.e., all equilibria essentially satisfy the optimality conditions) [33.225, 227, 228]. For several types of common geometric constraints (such as nonnegative constraints, bound constraints, and spherical constraints), some projection operators map the neuron state variables onto the convex feasible regions by using their activation functions and avoid the use of excessive dual variables as in the dual networks, and thus lower the model complexity. For neurodynamic optimization models designed using optimality methods, stability analysis is needed explicitly to ensure that the resulting neurodynamics are stable.

Once a neurodynamic equation has been derived and its stability is proven, the next step is to determine the architecture of the neural network in terms of the neurons and connections based on the derived neurodynamic equation. The last step is usually devoted to simulation or emulation to test the performance of the neural network numerically or physically. The simulation/emulation results may reveal additional properties or characteristics for further analysis or model redesign.

### 33.4.3 Selected Applications

Over the last few decades, neurodynamic optimization has been widely applied in many fields of science, engineering, and commerce, as highlighted in the following selected nine areas.

#### Scientific Computing

Neurodynamic optimization models have been developed for solving linear equations and inequalities and computing inverse or pseudoinverse matrices [33.240, 264–268].

#### Network Routing

Neurodynamic optimization models have been developed or applied for shortest-path routing in networks modeled by using weighted directed graphs [33.258, 269–271].

#### Machine Learning

Neurodynamic optimization has been applied for support vector machine learning to take the advantages of its parallel computational power [33.272–274].

#### Data Processing

The data processing applications of neurodynamic optimization include, but are not limited to, sorting [33.275–277], winners-take-all selection [33.240, 277, 278], data fusion [33.279], and data reconciliation [33.254].

#### Signal/Image Processing

The applications of neurodynamic optimization for signal and image processing include, but are not limited to, recursive least-squares adaptive filtering, overcomplete signal representations, time delay estimation, and image restoration and reconstruction [33.191, 203, 204, 280–283].

#### Communication Systems

The telecommunication applications of neurodynamic optimization include beamforming [33.284, 285]) and simulations of DS-CDMA mobile communication systems [33.229].

#### Control Systems

Intelligent control applications of neurodynamic optimization include pole assignment for synthesizing linear control systems [33.286–289] and model predictive control for linear/nonlinear systems [33.290–292].

#### Robotic Systems

The applications of neurodynamic optimization in intelligent robotic systems include real-time motion planning and control of kinematically redundant robot manipulators with torque minimization or obstacle avoidance [33.259–263, 267, 293–298] and grasping force optimization for multifingered robotic hands [33.299].

#### Financial Engineering

Recently, neurodynamic optimization was also applied for real-time portfolio selection based on an equivalent probability measure to optimize the asset distribution in financial investments; [33.255, 300].

### 33.4.4 Concluding Remarks

Neurodynamic optimization provides a parallel distributed computational model for solving many optimization problems. For convex and convex-like optimization, neurodynamic optimization models are available with guaranteed optimality, expended applicability, improved convergence properties, and reduced model complexity. Neurodynamic optimization approaches have been demonstrated to be effective and efficient for

many applications, especially those with real-time solution requirements.

The existing results can still be further improved to expand their solvability scope, increase their convergence rate, or reduce their model complexity. With the view that neurodynamic approaches to global optimization and discrete optimization are much more

interesting and challenging, it is necessary to develop neurodynamic models for nonconvex optimization and combinatorial optimization. In addition, neurodynamic optimization approaches could be more widely applied for many other application areas in conjunction with conventional and evolutionary optimization approaches.

# 34. Computational Neuroscience – Biophysical Modeling of Neural Systems

Harrison Stratton, Jennie Si

Only within the past few decades have we had the tools capable of probing the brain to search for the fundamental components of cognition. Modern numerical techniques coupled with the fabrication of precise electronics have allowed us to identify the very substrates of our own minds. The pioneering work of Hodgkin and Huxley provided us with the first biologically validated mathematical model describing the flow of ions across the membranes of giant squid axon. This model demonstrated the fundamental principles underlying how the electrochemical potential difference, maintained across the neuronal membrane, can serve as a medium for signal transmission. This early model has been expanded and improved to include elements not originally described through collaboration between biologists, computer scientists, physicists and mathematicians. Multi-disciplinary efforts are required to understand this system that spans multiple orders of magnitude and involves diverse cellular signaling cascades. The massive amount of data published concerning specific functionality within neural networks is currently one of the major challenges faced in neuroscience. The diverse and sometimes disparate data collected across many laboratories must be collated into the same framework before we can transition to a general theory explaining the brain. Since this broad field would typically be the subject of its own textbook, here we will focus on the fundamental physical relationships that can be used to understand biological processes in the brain.

## 34.1 Anatomy and Physiology of the Nervous System

The animal brain is undoubtedly a unique organ that has evolved from humble beginnings starting with small

groups of specialized cells in organisms long ago. The vast complexity found within the cortices of the mam-

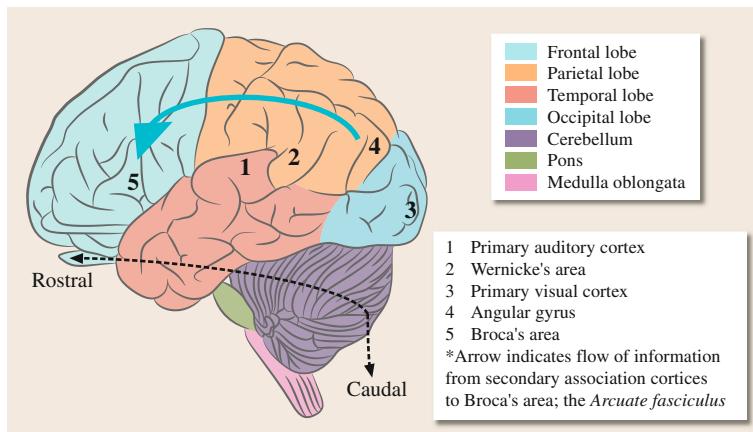

malian brain is the result of selection across countless generations. The purpose of these early cells is in principle consistent with the function of our entire brain. Both serve to assess environmental variables in order to produce output that is situationally relevant. This production of appropriate behavioral responses is essential for an organism to successfully obtain resources in complex and often hostile surroundings. The morphology of the brain is species dependent. Its structure is functionally correlated to the necessary output a specific animal requires to survive in a particular environment. For example, the commonly used laboratory mouse has a brain structure that is coarsely similar to a human. However, the mouse possesses particularly enlarged olfactory bulbs situated in the front of the skull. This is in great contrast to the human olfactory centers that are considerably smaller, but perform the same function. This dramatic difference in the size of the olfactory bulb relates to differences in environmental variables that exist between lab mice and humans. In contrast to humans, mice live in environments where scent is a highway of information. Odorant molecules can provide crucial signals regarding changes to the environment that indicate such things as the approach of a predator or the presence of food. In contrast, humans have evolved a diverse set of methods for gathering food and avoiding predators that are highly dependent upon visual stimulation. As a consequence of this developmental variable, our brains have evolved to efficiently process visual stimuli with incredible speed and acuity [34.1]. This paradigm of form fits function exists throughout nature and allows experimentalists to take advantage of shared anatomical and physiological characteristics. By adjusting for differences in evolutionary history, we can confidently perform experiments on neurons from other animals. This data can then be extended and translated to gather information about the properties of our own nervous system. From this point on, unless otherwise specified, any reference to the nervous system refers to that of higher mammal species including rodents and primates, and humans.

### 34.1.1 Introduction to the Anatomy of the Nervous System

Cells of the nervous system arise from ectodermal embryonic tissue and generally develop into two distinct groups: the cells of the peripheral nervous system (**PNS**) and those of the central nervous system (**CNS**).

The brain and the spinal cord together constitute the **CNS**, with the nerves of the body (peripheral nerves) and autonomic ganglion forming the **PNS**. The **PNS** refers to neurons and sensory organs located outside the blood brain barrier (**BBB**) created by the meninges, which is a three-layer, dynamic, protective system isolating the **CNS** from the circulatory system. Additionally, the primary immune system does not extend into the brain, leaving it particularly vulnerable. Exploration of the **PNS** has formed the foundation of neuroscience research because these neurons tend to be large and easy to locate and remove for experimental examination. While many of the foundational principles of neuroscience were discovered within the **PNS**, the **CNS** has been the primary target of most recent neuroscience research. This is primarily due to the emergence of the frontal cortices as the substrate for conscious thought and action. The **CNS** contains many sub-regions that can be broadly separated into the spinal cord, the brainstem, cerebellar cortex, and cerebral cortex. Increasing complexity can be observed moving from spinal cord to frontal cortex, which demonstrates that the most forward structures are the most recently evolved. The recently evolved frontal cortex structures are of high interest to neuroscience researchers and are the subject of many computational investigations attempting to elicit their function [34.2].

The human brain is divided into four major regions (Fig. 34.1): the cortex, which includes the four lobes of the brain, the midbrain, the brainstem, and the cerebellum. The brainstem, midbrain, and cerebellum, also known as subcortical regions were the first to evolve and play various roles in the regulation of basic physiological function and relay of information to the cortex. The brainstem continues caudally as the spinal cord and contains numerous nuclei for the processing of information generated by spinal neurons. The midbrain is of particular importance concerning the integration and transmission of information from the spinal cord and brainstem to the cortex. The thalamus, part of the midbrain, is often called the gateway to the cerebral cortex as it is located centrally and retains projections to all parts of the cortex, and thus plays a pivotal role in the transmission of subcortical information to various association areas of the cortex. The cortex is divided into four lobes including frontal, parietal, temporal, and occipital. Each lobe contains areas of specialized function as well as areas of association. Incoming sensory information requires

**Fig. 34.1** A cartoon representation of the human brain with the major lobes colored according to the key *on the left*. The blue arrow highlights, as an example, a specific pathway that heavily contributes to the output of language by bringing together auditory and visual information in the parietal lobe. This information that contains associations between stimuli is then forwarded to the frontal cortex where it is integrated with the rest of the bodies' sensory information and will guide the output of speech sounds

context, hence information first travels to the areas of specialized function and subsequently traverses various association areas for integration before reaching its target of motor output [34.3]. An example of this flow of information within the cortex is depicted in Fig. 34.1, which details the progression of information from the primary auditory cortex for deciphering sound to Broca's area, which is involved in speech production. Figure 34.1 also demonstrates the general anatomy of the human brain, including the brainstem, cerebellum, and cortex.

Reviewed simply, the flow of information throughout this comprehensive system begins in sensory cells and ends in motor output via peripheral nerves. Sensory cells, such as mechanoreceptors for tactile sensation, transduce and forward signals to the spinal cord for first level processing. Sensory fibers run specifically along the dorsal surface of the spinal cord and ascend the entirety of the cord. Some synapse locally on the spinal cord and others project fully to the cortical surface of the brain. The information from sensory cells is first received in the proximal cortex, associations between stimuli are made, and this information is again relayed to the front of the brain where it is used to form a plan of action based on the specific input pattern. The front of the brain then begins a processing cascade that flows back toward the central sulcus of the brain and output motor neurons are triggered. These output signals descend the brain as a large bundle that go on to form the ventral surface of the spinal cord, where they either end on a local spinal neuron or are routed distally to a muscle. For a more complete discussion of neural anatomy and information processing, please refer to Kandel et al. [34.1].

### 34.1.2 Sensation – Environmental Signal Detection

Transduction of physical environmental stimuli into electrical and chemical signals is the common function shared by all sensory systems. This transduction provides baseline input to the brain from an array of sensors placed throughout the body in the skin, eyes, ears, mouth, and nose. These highly specialized cells respond only to the application of very precise external stimuli. While each receptor cell is specialized for a specific signal, there is much variation within each sensory system, allowing the most pertinent information to be extracted from the environment. An example of this variation exists within the eye, where there are two primary detector cell types: rods and cones [34.4]. The former is involved in the sensation of light and dark and the latter for the perception of colors. Even within the collection of cone cells there are further specializations that allow for the detection of various color wavelengths most specifically red, blue, and green. A similar pattern is observed in cells of the inner ear, where hair cells are housed in osseous cavities lined with membrane. This makes these cells specialized for the detection of vibrations in the air occurring at different frequencies. Sensory specialization is further mapped onto the brain where distinct regions of the cortex correspond to specific environmental stimuli or motor output patterns. Sensation is a vital part of cognition as the representation of the world we each possess is built upon our own unique sensory experiences. This literally means that we have shaped the surfaces of our cortices based on our experiences as individuals.

### 34.1.3 Associations – The Foundation of Cognition

The brain is an integrative structure capable of transforming sensory stimuli while forming associations between stimuli based on temporal and local parameters. Sensory integration allows organisms to relate pertinent information about environmental variables in real time based on successful behavioral patterns of the past. The mechanism driving these associative properties of the brain has been the subject of countless scientific endeavors yielding a basic understanding. Although progress has been made in understanding how the nervous system adapts to the environment, there are countless questions that emerge as new discoveries are made that require a constant revision of parameters. Kandel [34.5] was among the first to develop experiments capable of demonstrating the molecular and cellular mechanisms underlying learning within a biological system.

Developing associations across a variety of sensory pathways is a major constituent of learning within animals. These associations are formed by altering cellular physiology based on input experience for a certain neuron or population of connected neurons. This cellular learning is the foundation for consciousness and there are many processes at the cellular level that contribute

to learning in different ways. Some association mechanisms directly alter the number of synapses between neurons based on a history of communication between the cells, where other processes will affect the cell's DNA to accommodate a certain input pattern [34.6]. All of the mechanisms that influence learning in the brain have yet to be defined, which leaves a large opportunity for conjecture as to what constitutes learning and what does not. Modeling maintains a distinct advantage, as models of cellular communication and learning can be prototyped in silico to account for the large number of modifications occurring over time. The output of these models can then logically guide our search for learning mechanisms within the brain by outlining a possible path where learning mechanisms could be discovered. While we understand that associations between neurons and glial cells likely form the basis of cognition, we have yet been able to recreate this phenomenon to completely explain its nature. This is partly due to the fact that the mammalian brain is so large and contains so many networks that detection and characterization of all changes occurring within the system simultaneously is extremely difficult. To resolve this issue, many neuroscientists have turned to using model organisms that provide a reduced set of neurons with which to experiment and demonstrate fundamental theories.

## 34.2 Cells and Signaling Among Cells

The brain is composed of two major cell types: neurons and glial cells. Both of these cell types are essential for the brain to function properly. Standard models place electrically excitable neurons in a signaling role with glial cells serving an indispensable support role although emerging evidence suggests glial cells could be more heavily involved with signaling than previously thought. The majority of research in computational neuroscience focuses on modeling neurons and their role in generating conscious behavior. This is largely due to the fact that their maintenance of a potential difference across the membrane serves as an efficient and robust communication pathway that can be modeled using established electrical dynamics. Unlike other cells of the body the neuron is a non-differentiating cell, which means it does not continuously undergo cellular mitosis or meiosis. This simple difference in the life cycle of these cells affords them an indispensable role in the animal nervous system – memory. Each cell in

the body has an innate type of memory that begins by receiving messages from their environment at the membrane. These signals can sometimes propagate into the nucleus where alterations in DNA can occur, which will ultimately affect the function of the cell. Neurons have this type of DNA memory but also form connections with their neighboring cells or even cells that are located in other brain regions [34.7]. Because neurons do not divide these connections are not reset and can last for periods of time that are much longer than the life cycle of a typical cell. Connections between neurons are called synapses and form the fundamental communication element in the nervous system.

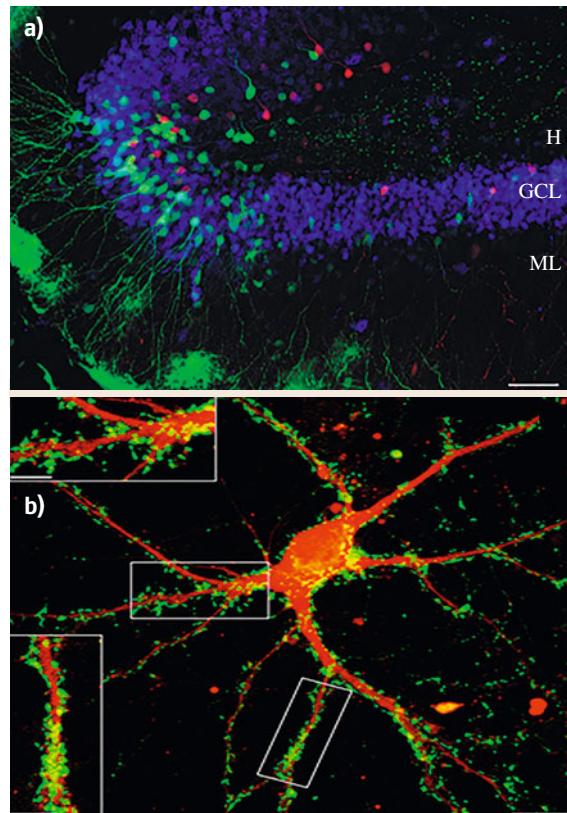

### 34.2.1 Neurons – Electrically Excitable Cells

Neurons are composed of a cell body referred to as the soma, which contains membrane-bound organelles that are found in most cells, in addition to one or more

protoplasmic projections: an axon and dendrites. The soma contains the nucleus and is the central portion of the neuron. Among neurons, the most common pathway for signal transmission is from the axon terminal of one neuron to another's dendrites, which then relays the signal to the neuron's soma and on to the axon to be transmitted to another neuron. In particular, dendrites receive and conduct electrochemical signals from other neurons to the soma and play an integral role in determining the extent to which action potentials are generated. Dendrites are composed of many branches called dendritic trees and can create extensive and unique branched networks between neurons. The axon is the anatomical structure through which action potentials are transmitted away from the soma to other neurons or other types of cells such as muscles, ganglia, or glands [34.8]. Axons vary in length tremendously and bundle together to form large peripheral nerves that course from the spinal cord to the toe. They vary in composition depending upon their location in the PNS or the CNS and may be myelinated or unmyelinated. Myelin is a fatty, dielectric insulating layer that speeds signal conduction along the axon by forming discrete regions of low resistance and high conduction velocity. In between the discrete myelinated portions of axon, there are *nodes of Ranvier* to repeat the signal along the next segment of axon. Axons normally maintain an equal radius throughout their course and terminate at a synapse, where the electrochemical signal will be transmitted from the neuron to the target cell, which may be another neuron or another type of cell. A synapse is formed by the end(s) of one neuron's axon, called the axon terminal and the dendrites, axon, or soma of the receiving neuron. The synapse is fundamentally a transducer that converts electrical signals from a membrane potential wave to a chemical signal that modifies the state of a downstream cell [34.9].

Neurons are classified by the branching pattern and location of their dendrites and axons, their physiological function and location within the nervous system. Structural and functional classification, and the type of neurotransmitter released are relevant to modeling and will be reviewed. Structurally, neurons are classified as unipolar, pseudo-unipolar, bipolar, or multi-polar. Unipolar neurons contain one protoplasmic projection that divides distally into sensory and transmitting portions of an axon. Bipolar neurons retain two projections from the soma, one from which dendrites extend and the other from which the axon extends. The majority of neurons are multipolar neurons, which normally contain one long axon and many dendritic projections.

Figure 34.2a exemplifies bipolar, hippocampal neurons and Fig. 34.2b demonstrates the anatomy of a cortical, glutamatergic neuron. Functionally, neurons can be classified according to their electrophysiology and be described as tonic, phasic, or fast-spiking. However, it is more effective to describe the different firing patterns experienced by neurons, as most neurons exhibit variable firing patterns. Tonic firing involves continuous responses to stimuli and recurrent generation of

**Fig. 34.2** (a) Fluorescently labeled hippocampal slice showing neuronal cell bodies stained in blue with neuronal nuclei antibody (NeuN). The GFP (green fluorescent protein) and RFP (red fluorescent protein) labeled neurons extending their processes are of dentate granule cell origin and have matured over the course of the experiment as this slice was imaged at postnatal day 53. (b) Here we see a neuron that has had its cell body stained with a red fluorescent marker and presynaptic glutamate receptors indicated in green. The sheer volume of presynaptic targets can be seen here along with two segments that have been selected and magnified to give a better view of how synapses cover the dendrite surface

action potentials. Tonic firing patterns are observed in large excitatory neurons during basal levels of activity to provide constant communication between elements of the network. Phasic firing patterns consist of bursts of action potentials, often in quick succession that has dramatic downstream effects. Bursting and phasic firing are highly studied phenomena that often signal a shift in steady state activity levels in the circuits where they are observed. Along with the branching patterns of dendrites and axons, neurons may be classified by the type of neurotransmitter released at synapses. The two dominant neurotransmitters in the brain are glutamate and gamma-aminobutyric acid (**GABA**), which generally mediate excitatory and inhibitory neurotransmission respectively [34.10].

### 34.2.2 Glial Cells – Supporting Neural Networks

Glial cells are fundamentally different from neurons in that they do not form synapses with other cells and generally do not maintain a membrane potential. Although they are not directly involved in signaling between neurons through synaptic means, these cells play a large role in the maintenance of synapses as well as signal integrity. There are four major types of glial cells in the brain: oligodendrocytes, astrocytes, ependymal cells, and micro-glial cells [34.11]. Oligodendrocytes secrete myelin, the insulating dielectric material covering axons, which facilitates signal transmission over longer distances. Ependymal cells line the ventricles of the brain and secrete the cerebral spinal fluid that bathes the brain and provides a route for expulsion of waste and the intake of nutrients. Micro-glial cells act as a type of immune system for the brain by digesting dead cells and collecting material that should not be present or could be damaging to cells of the brain. Astrocytes are abundant, star-shaped cells that generally surround neurons and provide nutrition and oxygen, and remove waste that could be toxic to a neuron if left to accumulate via cerebral spinal fluid. This astrocyte driven waste-removal system is essential for normal physiological function and structurally resembles the lymphatic system found in the rest of the body's tissues. Remarkably, new evidence suggests astrocytes may actually participate in synaptic communication, and that communication may be bi-directional [34.12]. Communication between astrocytes and neurons has yet to be fully characterized and provides an opportune target for new venture into neural network modeling. This new evidence of implicating astrocytes will shift our understanding of the

brain as a communications structure and will open new questions that can be addressed using computational models. The current models of non-linear neural systems are already complex and must be altered to account for the evidence present in this new paradigm.

### 34.2.3 Transduction Proteins – Cellular Signaling Mechanisms

All cells of the body contain functional proteins embedded in their lipid bi-layer that are responsible for transducing environmental signals across the cellular membrane. The incredible variety of proteins present in the nervous system serves as mediators of cellular communication. Each protein will have its own unique structure depending on its function, and there are large groups of proteins that all share common properties such as the g-protein coupled receptors (**GPCRs**), ligand gated ion channels, passive ion channels, and a plethora of others. All of these will not be defined here as the classification and physiology of membrane proteins can be considered the subject of a whole field and are reviewed in detail by *Grillner* in [34.12]. The most important protein varieties for our consideration are those that control the flow of ions across the lipid bi-layer, which can be achieved in a number of ways. Some directly pass ions through a small pore in their center that is selective to certain ion species based on their electron distribution. Others use stored chemical energy to transfer a subset of ions outside of the cell while bringing others into the cell allowing a gradient to be established by using stored cellular energy to push ions against their potential energy gradient.

### 34.2.4 Electrochemical Potential Difference – Signaling Medium

Neurons carry information to their targets in the form of fluctuations of their membrane potential. Changes in the value of the membrane potential can trigger a variety of cellular signals including the opening of voltage gated proteins or the release of chemical neurotransmitters at a synapse [34.13]. As mentioned earlier, neurons generate their membrane potential by selectively transporting ions across the cellular membrane using energy, normally in the form of adenosine triphosphate (**ATP**). With the right combination of proteins neurons are able to shift their membrane potential in response to communication from other cells in a discrete fashion. This discrete wave along the membrane is known as an ac-

tion potential and is only generated by a neuron once a certain level of activation has been attained. A single neuron in a network must receive communication from other cells, normally at its dendrites, which will cause the accumulation of positive ions inside the cell. Once the positive ions have accumulated to a certain critical level the cell will generate an action potential that flows down the axon to the cell's targets. This action potential is the fundamental signaling unit within the nervous system and triggers the release of neurotransmitters when it arrives at a synapse. Once an action potential has been generated there is a period where the cell cannot create another wave, and this time is known as the absolute refractory period.

The potential energy across the membrane is a complex value that results from the transport of ions against their concentration gradient (Fig. 34.3). If these ions were left to freely diffuse the membrane potential would eventually deteriorate as each ion moved toward its own value of equilibrium potential. This equilibrium

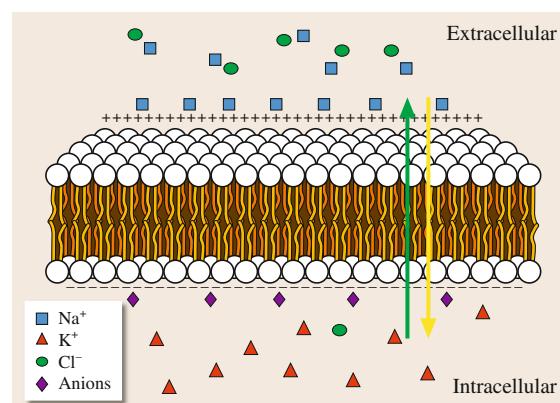

potential, also known as the reversal potential or the Nernst potential, can be calculated using the following relationship for any ionic species  $x$

$$E_x = \frac{RT}{zF} \ln \frac{[X]_o}{[X]_i} . \quad (34.1)$$

In the above equation, known as the Nernst equation,  $E_x$  represents the equilibrium potential for a certain ion species with  $[X]_o$  and  $[X]_i$  representing the external and internal concentrations of the ion, respectively [34.14]. Additionally,  $R$  is the Rydberg constant,  $T$  is the temperature in kelvin,  $z$  is the atomic number of the ion, and  $F$  is the Faraday constant followed by the natural logarithm of the concentration difference. At the reversal potential for an ionic species there is a net force of zero on ions in the system and these particles will be at rest. From this relationship we can see that the energy driving the fluctuations in membrane potential originates from both electrical and chemical sources.

While the Nernst equation is capable of determining the reversal potential for a single ionic species, physiological systems often have many additional ions that participate in cellular signaling. The Nernst equation was expanded to form the Goldman–Hodgkin–Katz equation that yields the membrane potential in a resting system composed of multiple ionic species as shown below

$$u = \frac{RT}{F} \ln \frac{P_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl^-} [Cl^-]_i}{P_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl^-} [Cl^-]_o} . \quad (34.2)$$

**Fig. 34.3** The lipid bi-layer is composed of phosphate groups on the extra and intracellular faces of the membrane with a variety of lipids attached that essentially will self-assemble when dissolved in water at the appropriate concentration. The extra cellular surface has a net positive charge relative to the cytoplasmic side that is relatively negative. The membrane acts as a semi-permeable barrier that prevents the passage of molecules based on their attraction to water. Here we see that potassium ions have accumulated within the cell along with positive anions and sodium, and chloride can be found outside the cell due to the action of specific transporters embedded in the membrane. The asymmetric distribution of charge across the membrane causes a potential difference to exist in terms of both the electrical potential of the ions and their chemical nature to diffuse down their concentration gradient

**Table 34.1** Here we see the concentration distribution of different salt species as they are found within a voltage clamp experiment using a segment of giant squid axon. These values will be different in each experimental preparation and should be considered carefully as small variations can have large implications for the firing patterns observed. Take note that here there are no positive anions present as the center of the giant squid axon is devoid of organelles unlike the inside of a mammalian neuron of the central nervous system that would likely contain many

| Ion                | Cytoplasmic concentration | Extracellular concentration | Equilibrium potential |
|--------------------|---------------------------|-----------------------------|-----------------------|
| K <sup>+</sup>     | 400                       | 20                          | -75                   |
| Na <sup>+</sup>    | 50                        | 440                         | +55                   |
| Cl <sup>-</sup>    | 52                        | 560                         | -60                   |
| Organic anions (-) | 385                       | None                        | None                  |

Here  $u$  is the resting membrane potential of the cellular system under consideration and the constants are the same as shown above in the Nernst equation [34.15]. However, instead of relying solely upon the concentration of the particular ion inside and outside the cell here we can see that the number of ion channels, represented by the variable  $P$ , is also taken into account. Here  $P$  is the membrane's permeability to that particular ionic species in the unit cm/s. This equation is used to calculate the membrane potential of a particular physiological system with multiple internal and external salt species such as potassium, sodium, and chloride. Notice that the relationship between membrane potential and chloride concentration is the inverse due to its negative valence.

The simplest description for the maintenance of the membrane potential derives from the asymmetric distribution of ions across the cell's semi-permeable membrane. The concentrations displayed above were the first calculated for any neuron and were measured

from the axon of a giant squid. By carefully measuring the potential difference between the inside of the axon and the external solution Hodgkin and Huxley were able to determine the amount of current flowing across the axon's membrane under varying conditions [34.16]. The potential difference between the inside and outside of the cell is generated by manipulating the concentration of each ion with respect to its charge. Through careful observation of Table 34.1 above one can note that this resting condition will lead to a state where the cell is relatively negative on the inner membrane and positive along the outer wall of the membrane. It is this relative potential that varies along the surface of the neural membrane and it is what is responsible for carrying information along the length of the cell. These concentrations are considered bulk values and hardly ever deviate from these concentrations unless a period of sustained firing has occurred, where the cell can deplete this potential difference.

## 34.3 Modeling Biophysically Realistic Neurons

### 34.3.1 Electrical Properties of Neurons

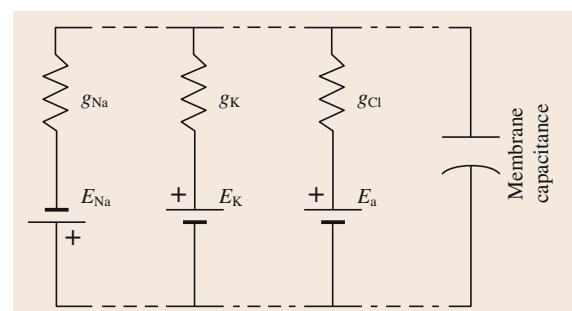

When modeling a system one must first consider its physical dimensions and elements in order to construct a model that is true to reality and mathematically sound. By investigating the most fundamental structure of a neuron it is simple to see how this system can be easily related to that of an electronic capacitor. We have a system composed of two electrically conductive mediums, the extracellular fluid and the cytoplasm, which are separated by a dielectric layer that is also the phospholipid bi-layer. Therefore, from this description of a neuron we can generate the following relationship for the membrane potential

$$u = \frac{Q}{C}, \quad (34.3)$$

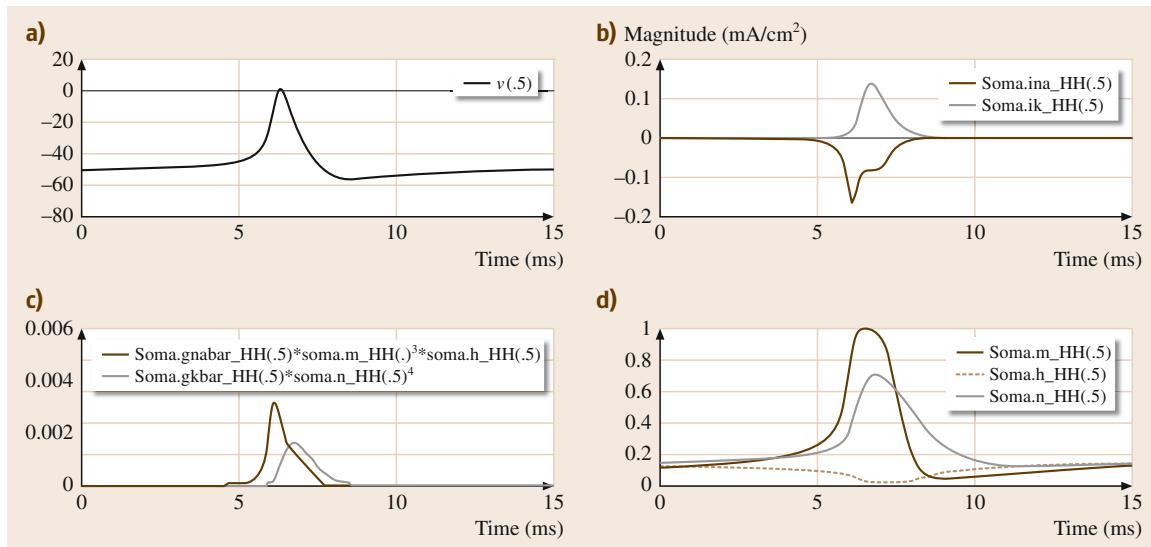

where  $u$  represents the potential across the membrane and it is equal to the quotient of the charge along the membrane surface  $Q$  and the capacitance of the membrane itself  $C$  [34.17]. From this relationship it is clear that the membrane potential relies on the species and number of charges distributed across the membrane surface as well as the lipid constituents of the bi-layer. The capacitance of the membrane in a neuron is generally around  $1 \mu\text{F}/\text{cm}^2$  but this can fluctuate depending

on the local ionic and lipid composition. Four major ionic currents are most often found in the cellular membrane and considered in a biologically realistic model (Fig. 34.4).

Similarly to electrical capacitors, neurons are reliant upon dynamic currents that flow through the membrane

**Fig. 34.4** A schematic equivalent circuit diagram of the four major ionic currents most often found in the cellular membrane. The resistors represent the varying conductivity of membrane channels for each ion and the batteries are each ion's respective concentration gradient. On the right we can see the membrane has an inherent capacitive current that acts to slow the spread of membrane currents and is manifested by the physical structure of the cell

**Fig. 34.5** (a) The membrane potential measured at the middle of a spherical single compartment model cell denoted by  $v(.5)$ . The cell has Hodgkin–Huxley type current dynamics. The y axis shows membrane potential at the center of the cell,  $v(.5)$ , and the x axis represents time in ms. (b) The blue trace shows the total magnitude, in mA/cm<sup>2</sup>, of the outward potassium current within the Hodgkin–Huxley (HH) model. The trace red shows the total magnitude of the inward HH sodium current in the same units of mA/cm<sup>2</sup>. (c) The red trace is the variable  $g_{Na}+m^3h$  as shown in (34.5). The blue trace shows the potassium gating constant  $g_K+n^4$  also from (34.5). (d) The state of each of the gating variables  $m$ ,  $n$ , and  $h$  where the value 1 represents fully open and 0 represents fully closed or inactivated channels. This simulation was conducted within the NEURON simulation environment with a single compartment of area 29 000 μ<sup>2</sup>, initialized at −50 mV, with physiological concentrations of calcium, chloride, potassium, and sodium ions

into and out of the cell. One of the most important ions is potassium ( $K^+$ ), which conducts current based on the following relationship,  $i_K = (\gamma_K \times u) - (\gamma_K \times E_K) = \gamma_K \times (u - E_K)$ , where  $\gamma$  is the ionic conductance,  $u$  is the membrane potential, and  $E$  is the ionic reversal potential. The final term on the right-hand side of the equation is known as the electromotive force and can be calculated independently for each ionic current. This relationship shows how a neuron with both membrane potential and a potassium concentration gradient produces net potassium current. This potassium current can be generalized across the entire surface using this relationship,  $g_K = N_K \times \gamma_K$ , where  $g$  is the ionic conductance,  $N$  is the number of channels open at rest, and ( $\gamma$ ) is the permeability of an individual potassium channel. Determination of individualized channel conductance is performed in a lab setting using the patch clamp technique to isolate single ion channels. Once isolated, these channels can be tested using pharmacological techniques to determine their single channel conductivity [34.18]. These experiments are very sensitive and must be performed for each channel of interest

within the model as they cannot be represented without accurate biological data.

Describing a neuron as a capacitor yields interesting properties that we can infer about neurons from the large established set of knowledge regarding capacitance. The innate capacitive nature of the membrane actually affects the passage of current and, therefore, is relevant to our discussion here. When current is injected into our capacitive system it is inherently slowed based upon the time course of the current injection and the capacitance of the system represented by this relation  $\Delta u = \frac{I_C \times \Delta t}{C}$ . Therefore, the magnitude of the change in potential across the capacitor is relative to the duration of the current, presenting a natural latency in signal transmission that must be accounted for when modeling.

### 34.3.2 Early Empirical Models – Hodgkin and Huxley

Investigation into the structure of the brain began with improvements to the light microscope in the early

twentieth century. As characterization of cellular types progressed rapidly, understanding of cellular physiology lagged quite far behind. This is largely due to the fact that the technology to manipulate individual cells had yet to be invented. To go around this problem Hodgkin and Huxley used an axon harvested from a giant squid as their experimental system. This allowed them to easily observe the behavior of the experimental preparation while functionally examining changes that occurred at the microscopic level. In general, this model also describes the segment of neuron as a capacitor with  $x$  ionic currents and applied current as shown here

$$C \frac{du}{dt} = - \sum_x I_x(t) + I(t) . \quad (34.4)$$

This model uses three ionic current components including potassium, sodium, and a non-specific leak current that are described below

$$\begin{aligned} \sum_x I_x &= g_{\text{Na}^+} m^3 h (u - E_{\text{Na}^+}) \\ &\quad + g_{\text{K}^+} n^4 (u - E_{\text{K}^+}) + g_L (u - E_L) . \end{aligned} \quad (34.5)$$

Each of the terms above represents a specific ion with a gating variable that has been experimentally fitted to display the characteristics of each specific channel. A simulation of these parameters in a model cell expressing the standard Hodgkin–Huxley type channels is displayed in Fig. 34.5. In this case, the sodium current is determined using two different gating variables because it has two distinct phases, activation and inactivation. During the inactivation phase the conduction pore of the channel is blocked by a string of intracellular positive amino acids that literally plug the channel closed. This is distinct from potassium or leak channels that do not have an inactivation mechanism built into the protein. The differential form of each gating variable for the Hodgkin–Huxley model is shown below (Tables 34.2 and 34.3) in terms of the experimentally determined parameters  $\alpha$  and  $\beta$

$$\begin{aligned} m' &= \alpha_m(u)(1-m) - \beta_m(u) , \\ n' &= \alpha_n(u)(1-n) - \beta_n(u)n , \\ h' &= \alpha_h(u)(1-h) - \beta_h(u) . \end{aligned} \quad (34.6)$$

These values were obtained during initial laboratory experimentation by Hodgkin and Huxley using the gi-

ant squid axon in vitro. These results have been adjusted to set the resting membrane potential at a value of 0 mV instead of the typical  $-65$  mV as is seen in many modern interpretations.

This model has been expanded and interpreted for many systems outside the giant squid axon, and a general form for determining gating variables is shown here

$$\theta' = - \frac{1}{\tau_\theta(u)} [\theta - \theta_0(u)] . \quad (34.7)$$

In this differential form,  $\Theta$  represents a particular gating variable of interest. When the membrane voltage  $u$ , is fixed at a certain value then  $\Theta$  approaches  $\theta_0(u)$  with a time constant represented by  $\tau_\theta(u)$ . These values can be calculated using the transformation equations shown below

$$\begin{aligned} \theta_0(u) &= \frac{\alpha_\theta(u)}{[\alpha_\theta(u) + \beta_\theta(u)]} , \\ \tau_\theta(u) &= \frac{1}{[\alpha_\theta(u) + \beta_\theta(u)]} . \end{aligned} \quad (34.8)$$

**Table 34.2** Parameters associated with dynamics of ions within biological membranes, specifically of the giant squid. The first column shows the gating variables associated with each ionic species. The center column is the equilibrium potential that can be found for each ion within the system and is shown in millivolts. On the right the overall conductance of each ionic species within the model of action potential generation and membrane potential maintenance is shown

| Ion species – gating variables ( $\theta$ ) | Reversal potential $E_\theta$ (mV) | Conductance $g_\theta$ (mS/cm <sup>2</sup> ) |
|---------------------------------------------|------------------------------------|----------------------------------------------|
| Na <sup>+</sup> ( $\theta = m, h$ )         | 115                                | 120                                          |
| K <sup>+</sup> ( $\theta = n$ )             | -12                                | 36                                           |
| L – no gating                               | 10.6                               | 0.3                                          |

**Table 34.3** Gating variables with specific relationships that describe the particular function of each of the gating variables

| Gating variable ( $\theta$ ) | $\alpha_\theta$ (u/mV)                      | $\beta_\theta$ (u/mV)          |
|------------------------------|---------------------------------------------|--------------------------------|
| $n$                          | $\frac{(0.1 - 0.01u)}{[e^{(1-0.1u)} - 1]}$  | $0.125e^{-\frac{u}{80}}$       |
| $m$                          | $\frac{(2.5 - 0.1u)}{[e^{(2.5-0.1u)} - 1]}$ | $4e^{-\frac{u}{18}}$           |
| $h$                          | $0.07e^{-\frac{u}{20}}$                     | $\frac{1}{[e^{(3-0.1u)} + 1]}$ |

### 34.3.3 Compartmental Modeling – Anatomical Reduction

Consider a simple case of a neuron with a spherical cell body. The time course of the potential change across the membrane can be described using the following

$$\Delta u(t) = I_m R_m \left(1 - e^{-\frac{t}{\tau}}\right). \quad (34.9)$$

In the above relationship  $I_m$  and  $R_m$  are the membrane current and resistance, respectively. The rightmost term contains  $e$  to the power of time divided by the membrane time constant  $\tau$ .

Spatially, the current in our spherical cell body will decay along the length of the membrane according to the relationship below

$$\Delta u(x) = \Delta u_0 e^{-x/\omega}. \quad (34.10)$$

Above we can see that the spatial decay of potential relies upon the potential where the current was initially injected  $\Delta u_0$ ,  $x$  is the distance from the site of the current injection, and  $\omega$  is the membrane length constant. This constant is defined as,  $\omega = \sqrt{r_m/r_a}$ , where  $r_m$  is the membrane resistance and  $r_a$  is the axial resistance along the length of the compartment. The length constant is also dependent upon the radius of the segment with large axons conducting current more easily than smaller axons. In addition, each cell has individualized values of membrane and axial resistance that are based on the particular distribution of protein and cellular organelles in each experimental scenario.

### 34.3.4 Cable Equations – Connecting Compartments

One of the most convenient ways of modeling a neuron is by simplifying its neural structure. This can be done by approximating the shape of parts of the cell surface as cylinders (Fig. 34.6), since this is very close to the real shape of a neuronal process. By starting with a simple cylinder, we can consider this as the fundamental unit for computation where quantities regulating the system will be derived and repeated along the length of the model neuron [34.19]. The one-dimensional cable equation can effectively describe the propagation of current along a length of cylinder that does not branch as shown below

$$\frac{\partial V}{\partial T} + F(V) = \frac{\partial^2 V}{\partial X^2}. \quad (34.11)$$

In the above,  $V$  and  $F$  are both independent functions of time and space represented by  $T$  and  $X$ , respectively. Since most neurons are branched we can consider a neuron to be composed of many one-dimensional elements that can be arranged to form the branching structure. The boundary conditions of each cylinder are used to calculate specific values within each region of membrane. To derive this relationship one must first consider conservation of charge as shown here,

$$\sum i_a - \int_A i_m dA = 0,$$

where the leftmost term is the sum of axial currents entering the section and  $i_m$  represents the integrated transmembrane currents over the entire segment area. Expanding this description to include an electrode current source  $s$  we obtain the following relationship,

$$\sum i_a - \int_A i_m dA + \int_A i_s dA = 0.$$

The electrode current can be simplified to a point source of current due to the fact that most electrode current sources are much smaller than the cell itself.

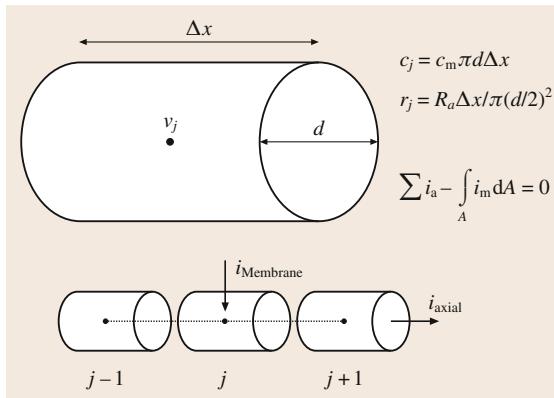

To simplify our model we can split the neuron up into  $j$  compartments of size  $m$  and area  $A$ . All the properties of the compartment can be represented as the average at the middle of the compartment shown here,  $i_{mj} A_j = \sum_k i_{akj}$ . The current between compartments can be defined using Ohm's law where the voltage drop between compartments is divided by the axial resistance between compartmental centers  $i_{akj} = (v_k - v_j)/r_{jk}$ . Therefore, our compartment can then be described using the following relationship,  $i_{mj} A_j = \sum_k (v_k - v_j)/r_{jk}$ . The total membrane current can then be found using this expression,

$$i_{mj} A_j = c_j \frac{dv_j}{dt} + i_{ion}(v_j, t),$$

where  $c_j$  is the compartmental capacitance and  $i_{ion}(v_j, t)$  is a function that captures the varying values of ion channel conductance in the membrane.

A set of branched cables can be constructed from individual segments to yield a set of differential equations that follow the form shown in (34.12) below

$$c_j \frac{dv_j}{dt} + i_{ion}(v_j, t) = \sum_k \frac{(v_k - v_j)}{r_{jk}}. \quad (34.12)$$

**Fig. 34.6** Generalized diagram of a single compartment representing a segment of a neuron in a biophysical model using cable equations. Below, three compartments are shown to indicate axial and membrane current components that are represented by their summated valued at the center of each compartment [34.6]

In order for the equations above to be completely valid we must assume that the axial current flow between various compartments can be closely approximated by calculating the value of the current at the center of each compartment. This implies that the current can vary linearly across compartments with the compartment size chosen specifically to account for any spatial variations that may exist within the experimental system,

$$C_j \frac{dv_j}{dt} + i_{\text{ion}}(v_j, t) = \frac{v_{j-1} - v_j}{r_{j-1, k}} + \frac{v_{j+1} - v_j}{r_{j+1, k}}. \quad (34.13)$$

The above is a special case (34.14), which was discussed [34.5], where specific attention is paid to the axial current in adjacent compartments when a uniformly

distributed current passes through an initial neuronal segment with constant diameter [34.20]. Compartments have length  $\Delta x$  and diameter  $d$ . The capacitance can be written as  $C_m \pi d \Delta x$  and the axial resistance of each compartment is defined as  $R_a \Delta x / \pi (d/2)^2$ , where  $C_m$  is the specific membrane capacitance and  $R_a$  is the specific cytoplasmic resistivity. Manipulation of (34.13) using the above consideration then yields the following (34.14)

$$C_m \frac{dv_j}{dt} + i_j(v_j, t) = \left( \frac{d}{4R_a} \right) \left( \frac{v_{j+1} - 2v_j + v_{j-1}}{\Delta x^2} \right). \quad (34.14)$$

Here the total ionic current specified above has been replaced with  $i_j(v_j, t)$ , a term that expands our consideration of injected ions by using a current density function. Now, if we consider the case where compartment size becomes infinitely small and the right-hand side then reduces to the second partial derivative of membrane potential with respect to the distance from the compartment of interest  $j$ . This reduction yields (34.15) below

$$C_m \frac{dv}{dt} + i(v, t) = \left( \frac{d}{4R_a} \right) \left( \frac{\partial^2 V}{\partial x^2} \right). \quad (34.15)$$

After multiplying both sides by the membrane resistance and with a simple application of Ohm's law we can see that  $iR_m = v$  and, therefore, we find

$$C_m R_m \frac{dv}{dt} + v = \left( \frac{dR_m}{4R_a} \right) \left( \frac{\partial^2 v}{\partial x^2} \right). \quad (34.16)$$

This relationship can be scaled using the constants for time  $\tau_m = R_m C_m$  and space  $\omega = \sqrt{r_m/r_a}$ , respectively.

## 34.4 Reducing Computational Complexity for Large Network Simulations

### 34.4.1 Reducing Computational Complexity – Large Scale Models

The Hodgkin–Huxley model [34.21] sets the foundation for mathematically modeling detailed temporal dynamics of how action potentials in neurons are initiated and propagated. The set of nonlinear ordinary differential equations of the form (34.4)–(34.6) were developed to describe the electrical characteristics of the squid giant axon. Given the many different mem-

brane currents that may be involved in the firing of an action potential, the Hodgkin–Huxley model represents the simplest possible representation of neuronal dynamics yet realistically captures the biophysical relationship between the voltage and time dependence of cell membrane currents. Even so, it is a daunting task to study a large neural network based on interconnected neurons each of which is modeled by Hodgkin–Huxley equations. The effort made in [34.22, 23] is a good illustration of the inherent challenges. Even on a single

neuron level, recent studies have shown that it would be easier to tune parameters in a less biophysically realistic model under the general scope of *integrate-and-fire*, or threshold models, which approximate the pulse-like electrical activity as a threshold process. Or in other words, such models are less sensitive in their model parameters and thus provide more robust and accurate model fitting results given profiles of injected current waveforms [34.24–26]. These threshold models are easy to work with but they are phenomenological approaches to modeling true neural behavior. It would not be possible to use these models to study membrane voltage profile over a precise time course, and it would be impossible to assess environmental parameters such as temperature change, chemical environment change, pharmacological manipulations of the ion channels and their impact on the membrane dynamics.

Given the many challenges of mathematical modeling of realistic neurons and neuronal networks under fine spatial and temporal resolution, great efforts have been made on several fronts to advance the study of neural network dynamic behaviors. Common to all approaches, the role of time in neuronal activities is emphasized and, thus, the models are usually described by nonlinear ordinary differential equations. In the following, we will examine some of these dynamic models that are built on different premises and considerations.

### 34.4.2 Firing Rate-Based Dynamic Models

The neural firing rate-based encoding scheme assumes that information about environmental stimulus is contained in the firing rates of the neurons. Thus, the specific spike times are under-represented. Sufficient evidence points out that in most sensory systems, the firing rate increases, generally non-linearly, with increasing stimulus intensity, and measurement of firing rates has become a standard tool for describing the properties of all types of sensory or cortical neurons, partly due to the relative ease of measuring rates experimentally. However, this approach neglects all the information possibly contained in the exact timing of the spikes [34.1]. Maybe it is inefficient, but the rate coding is robust and easy to measure and thus has been used as a standard or basic tool for studying sensory or cortical neuron characteristics in association with external stimuli or behaviors. The class of firing rate-based dynamic models mainly takes into account two considerations. First, these models account for a population of

neurons in the model. As such, these models aim at simulating large-scale neural network behaviors. Second, these models were motivated by associative memory processes where the time reflects the memory recall process.

Consider a population of neurons, and let  $r_i(t)$  denote the mean firing rate of a target neuron  $i$ , and  $r_j(t)$ ,  $j \in N_i = \{j/j \text{ is presynaptic to } i\}$ , the mean firing rates of all neurons presynaptic to neuron  $i$ . Let  $h_i(t)$  be the input to target neuron  $i$ , which is

$$h_i(t) = \sum_{j \in N_i} w_{ij}(t)r_j(t). \quad (34.17)$$

Equation (34.17) takes into account all presynaptic neurons' contributions weighted by synaptic efficacy  $w_{ij}$ . A representative class of the firing rate model as studied extensively in the artificial neural networks community, which was first popularized by Hopfield [34.27], can then be described at the fixed-point of an associative memory process as

$$r_i(t) = \Theta \left( \sum_{j \in N_i} w_{ij}(t)r_j(t) \right). \quad (34.18)$$

In (34.18),  $\Theta(\cdot)$  is considered a gain function. Consequently the firing rate dynamics associated with this associative memory process can be defined by introducing a time constant  $\tau$  in the associative network as

$$\tau \frac{dr_i(t)}{dt} = -r_i(t) + \Theta \left( \sum_{j \in N_i} w_{ij}(t)r_j(t) \right). \quad (34.19)$$

The firing rate model (34.19) also has another interesting interpretation where the mean firing rate  $r_i(t)$  is considered to be the spatial averaged neural potential  $F_i(t)$  of neuron  $i$  due to contributions from a local population of neurons  $j \in N_i = \{j/j \text{ is presynaptic to } i\}$ . As such, (34.19) becomes

$$\tau \frac{dF_i(t)}{dt} = -F_i(t) + \Theta \left( \sum_{j \in N_i} w_{ij}(t)F_j(t) \right). \quad (34.20)$$

The model described by (34.20) was used for the analysis of a large neural network where slow neural dynamics were assumed in order to describe spatially homogeneous motoneurons [34.28].

### 34.4.3 Spike Response Model

The spike response model [34.29] uses response kernels to account for the integral effect of presynaptic action potentials. With two linear kernels and under a simple renewal assumption, it can be shown that the spike response model (**SRM**) is a generalization of the integrate-and-fire neuron. The spike response model describes the membrane potential  $u_i(t)$  of neuron  $i$  as

$$u_i(t) = \eta(t - \hat{t}_i) + \int_0^{\infty} \kappa(t - \hat{t}_i, s) I^{\text{ext}}(t - s) ds, \quad (34.21)$$

where  $\eta$  represents the typical form of an action potential, which includes both depolarization and repolarization, as well as the process of settling down to the resting potential;  $\hat{t}_i$  stands for neuron  $i$  firing an action potential at that time. Also in the equation, the kernel  $\kappa(t - \hat{t}_i, s)$  is a linear impulse response function of the membrane potential to a unit input current. Imagine it as a time course of an additive membrane potential to

the membrane potential of neuron  $i$  after its action potential fired at  $\hat{t}_i$ . The term  $I^{\text{ext}}(t - s)$  accounts for all external driving currents.

According to the spike response model, an action potential is fired if the membrane potential  $u_i(t)$  crosses the threshold  $\theta(t - \hat{t}_i)$  from below, where it is noted that this threshold value is a function of  $(t - \hat{t}_i)$ . The consideration of using a dynamic threshold in a phenomenological neuron model was proven to be an important contributor to the success of using **SRM** for spike-time prediction under random conductance injection [34.30]. Actually, **SRM** outperformed a standard leaky integrate-and-fire model significantly when tested on the same experimental data. In [34.14], the authors performed an analytical reduction from the full conductance-based model to the spike response model for fast spiking neurons. After estimating the three parameters in the **SRM**, namely the kernels  $(t - \hat{t}_i)$ ,  $\kappa(t - \hat{t}_i, s)$ , and the dynamic threshold  $\theta(t - \hat{t}_i)$ , the authors show that the full conductance-based model of a fast-spiking neuron model is well approximated by a single variable **SRM** model.

## 34.5 Conclusions

In this chapter we have provided an introduction to some established modeling approaches to studying biological neural systems. Motivations behind these models are twofold. First and foremost, biological realism is considered to be of the utmost importance. Given the complex nature of a biological neuron, reduced-order neuronal models that can be or have been validated by the Hodgkin–Huxley model or biological data have been developed. As discussed, these models only scratch the surface of providing an accurate and realistic account of a real neural system, not even a specific brain area or something capable of explaining a behavioral parameter completely and thoroughly. Nonetheless, this decade has probably seen the most progress in terms of computational modeling approaches to understanding the brain. The International Neuroinformatics

Coordinating Facility (**INCF**) was established about 10 years ago with a focus on coordinating and promoting neuroinformatics research activities. Their activities are based on maintenance of database and computational infrastructure to support neuroscience research and applications. The grand scale and ambitious neural modeling project of simulating a human brain in the next 10 years led by Henry Markram is another example of the urgency and timeliness of studying the brain by using advanced computing machinery. The wonders of new technology have certainly provided us with the tools critical to pondering some of the most challenging questions about the brain. An insurmountable amount of work has yet to be done to fill the huge gap between a single neuron and its model proposed by Hodgkin–Huxley and the true understanding of the human brain.

# 35. Computational Models of Cognitive and Motor Control

Ali A. Minai

Most of the earliest work in both experimental and theoretical/computational system neuroscience focused on sensory systems and the peripheral (spinal) control of movement. However, over the last three decades, attention has turned increasingly toward *higher* functions related to cognition, decision making and voluntary behavior. Experimental studies have shown that specific brain structures – the prefrontal cortex, the premotor and motor cortices, and the basal ganglia – play a central role in these functions, as does the dopamine system that signals reward during reinforcement learning. Because of the complexity of the issues involved and the difficulty of direct observation in deep brain structures, computational modeling has been crucial in elucidating the neural basis of cognitive control, decision making, reinforcement learning, working memory, and motor control. The resulting computational models are also very useful in engineering domains such as robotics, intelligent agents, and adaptive control. While it is impossible to encompass the totality of such modeling work, this chapter provides an overview of significant efforts in the last 20 years.

It also outlines many of the theoretical issues underlying this work, and discusses significant experimental results that motivated the computational models.

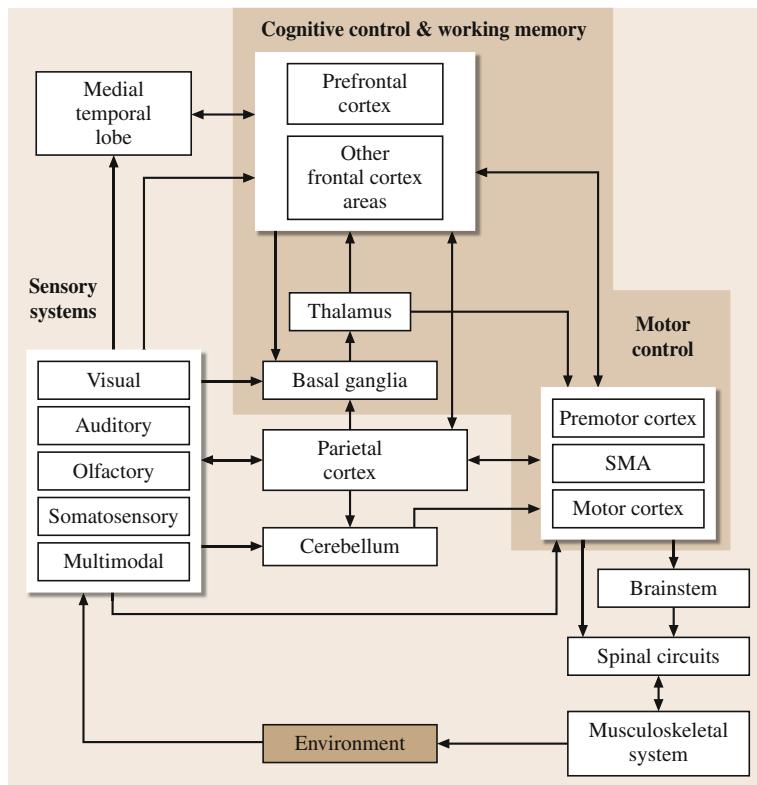

## 35.1 Overview

Mental function is usually divided into three parts: perception, cognition, and action – the so-called *sense-think-act cycle*. Though this view is no longer held dogmatically, it is useful as a structuring framework for discussing mental processes. Several decades of theory and experiment have elucidated an intricate, multiconnected functional architecture for the brain [35.1, 2] – a simplified version of which is shown in Fig. 35.1. While all regions and functions shown – and many not shown – are important, this figure provides a summary of the main brain regions involved in perception, cognition, and action. The highlighted blocks in Fig. 35.1 are

discussed in this chapter, which focuses mainly on the higher level mechanisms for the control of behavior.

The control of action (or behavior) is, in a real sense, the primary function of the nervous system. While such actions may be voluntary or involuntary, most of the interest in modeling has understandably focused on voluntary action. This chapter will follow this precedent.

It is conventional to divide the neural substrates of behavior into *higher* and *lower* levels. The latter involves the musculoskeletal apparatus of action (muscles, joints, etc.) and the neural networks of the spinal

**Fig. 35.1** A general schematic of primary signal flow in the nervous system. Many modulatory regions and connections, as well as several known connections, are not shown. The shaded areas indicate the components covered in this chapter

cord and brainstem. These systems are seen as representing the actuation component of the action system, which is controlled by the higher level system comprising cortical and subcortical structures. This division between a controller (the brain) and the plant (the body and spinal networks), which parallels the models used in robotics, has been criticized as arbitrary and unhelpful [35.3, 4], and there has recently been a shift of interest toward more embodied views of cognition [35.5, 6]. However, the conventional division is useful for organizing material covered in this chapter, which focuses primarily on the higher level systems, i.e., those above the spinal cord and the brainstem.

The higher level system can be divided further into a *cognitive control* component involving action selection, configuration of complex actions, and the learning of appropriate behaviors through experience, and a *motor control* component that generates the control signals for the lower level system to execute the selected action. The latter is usually identified with the motor cortex (M1), premotor cortex (PMC), and the supplementary motor area (SMA), while the former is seen as involv-

ing the prefrontal cortex (PFC), basal ganglia (BG), the anterior cingulate cortex (ACC) and other cortical and subcortical regions [35.7]. With regard to the generation of actions per se, an influential viewpoint for the higher level system is summarized by Doya [35.8]. It proposes that higher level control of action has three major loci: the cortex, the cerebellum, and the BG. Of these, the cortex – primarily the M1 – provides a self-organized repertoire of possible actions that, when triggered, generate movement by activating muscles via spinal networks, the cerebellum implements fine motor control configured through error-based supervised learning [35.9], and the BG provide the mechanisms for selecting among actions and learning appropriate ones through reinforcement learning [35.10–13]. The motor cortex and cerebellum can be seen primarily as motor control (though see [35.14]), whereas the BG falls into the domain of cognitive control and working memory (WM). The PFC is usually regarded as the locus for higher order choice representations, plans, goals, etc. [35.15–18], while the ACC is thought to be involved in conflict monitoring [35.19–21].

## 35.2 Motor Control

Given its experimental accessibility and direct relevance to robotics, motor control has been a primary area of interest for computational modeling [35.22–24]. Mathematical, albeit non-neural, theories of motor control were developed initially within the framework of dynamical systems. One of these directions led to models of action as an emergent phenomenon [35.3, 25–33] arising from interactions among preferred coordination modes [35.34]. This approach has continued to yield insights [35.29] and has been extended to multiactuator situations as well [35.33, 35–37]. Another approach within the same framework is the *equilibrium point hypothesis* [35.38, 39], which explains motor control through the change in the equilibrium points of the musculoskeletal system in response to neural commands. Both these dynamical approaches have paid relatively less attention to the neural basis of motor control and focused more on the phenomenology of action in its context. Nevertheless, insights from these models are fundamental to the emerging synthesis of action as an embodied cognitive function [35.5, 6].

A closely related investigative tradition has been developed from the early studies of gaits and other rhythmic movements in cats, fish, and other animals [35.40–45], leading to computational models for *central pattern generators* (CPGs), which are neural networks that generate characteristic periodic activity patterns autonomously or in response to control signals [35.46]. It has been found that rhythmic movements can be explained well in terms of CPGs – located mainly in the spinal cord – acting upon the coordination modes inherent in the musculoskeletal system. The key insight to emerge from this work is that a wide range of useful movements can be generated by modulation of these CPGs by rather simple motor control signals from the brain, and feedback from sensory receptors can shape these movements further [35.43]. This idea was demonstrated in recent work by Ijspeert et al. [35.47] showing how the same simple CPG network could produce both swimming and walking movements in a robotic salamander model using a simple scalar control signal.

While rhythmic movements are obviously important, computational models of motor control are often motivated by the desire to build humanoid or biomorphic robots, and thus need to address a broader range of actions – especially aperiodic and/or voluntary movements. Most experimental work on aperiodic movement has focused on the paradigm of manual reaching [35.30, 48–64]. However, seminal work has also been done

with complex reflexes in frogs and cats [35.65–72], isometric tasks [35.73, 74], ball-catching [35.75], drawing and writing [35.60, 76–81], and postural control [35.71, 72, 82, 83].

A central issue in understanding motor control is the *degrees of freedom problem* [35.84] which arises from the immense redundancy of the system – especially in the context of multijoint control. For any desired movement – such as reaching for an object – there are an infinite number of control signal combinations from the brain to the muscles that will accomplish the task (see [35.85] for an excellent discussion). From a control viewpoint, this has usually been seen as a problem because it precludes the clear specification of an objective function for the controller. To the extent that they consider the generation of specific control signals for each action, most computational models of motor control can be seen as direct or indirect ways to address the degrees of freedom problem.

### 35.2.1 Cortical Representation of Movement

It has been known since the seminal work by Penfield and Boldrey [35.86] that the stimulation of specific locations in the M1 elicit motor responses in particular locations on the body. This has led to the notion of a motor homunculus – a map of the body on the M1. However, the issue of exactly what aspect of movement is encoded in response to individual neurons is far from settled. A crucial breakthrough came with the discovery of *population coding* by Georgopoulos et al. [35.49]. It was found that the activity of specific neurons in the hand area of the M1 corresponded to reaching movements in particular directions. While the tuning of individual cells was found to be rather broad (and had a sinusoidal profile), the joint activity of many such cells with different tuning directions coded the direction of movement with great precision, and could be decoded through neurally plausible estimation mechanisms. Since the initial discovery, population codes have been found in other regions of the cortex that are involved in movement [35.49, 53, 54, 60, 77–80, 87]. Population coding is now regarded as the primary basis of directional coding in the brain, and is the basis of most brain-machine interfaces (BMI) and brain-controlled prosthetics [35.88, 89]. Neural network models for population coding have been developed by several researchers [35.90–93], and popula-

tion coding has come to be seen as a general neural representational strategy with application far beyond motor control [35.94]. Excellent reviews are provided in [35.95, 96]. Mathematical and computational models for Bayesian inference with population codes are discussed in [35.97, 98].

An active research issue in the cortical coding of movement is whether it occurs at the level of *kinematic variables*, such as direction and velocity, or in terms of *kinetic variables*, such as muscle forces and joint torques. From a cognitive viewpoint, a kinematic representation is obviously more useful, and population codes suggest that such representations are indeed present in the motor cortex [35.48, 53, 54, 60, 77–80, 99, 100] and PFC [35.15, 101]. However, movement must ultimately be constructed from the appropriate kinetic variables, i.e., by controlling the forces generated by specific muscles and the resulting joint torques. Studies have indicated that some neurons in the M1 are indeed tuned to muscle forces and joint torques [35.58, 59, 73, 99, 100, 102, 103]. This apparent multiplicity of cortical representations has generated significant debate among researchers [35.74]. One way to resolve this issue is to consider the kinetic and kinematic representations as dual representations related through the constraints of the musculoskeletal system. However, Shah et al. [35.104] have used a simple computational model to show that neural populations tuned to kinetic or kinematic variables can act jointly in motor control without the need for explicit coordinate transformations.

Graziano et al. [35.105] studied movements elicited by the sustained electrode stimulation of specific sites in the motor cortex of monkeys. They found that different sites led to specific complex, multijoint movements such as bringing the hand to the mouth or lifting the hand above the head regardless of the initial position. This raises the intriguing possibility that individual cells or groups of cells in the M1 encode goal-directed movements that can be triggered as units. The study also indicated that this encoding is not open-loop, but can compensate – at least to some degree – for variation or extraneous perturbations. The M1 and other related regions (e.g., the supplementary motor area and the PMC) appear to encode spatially organized maps of a few *canonical* complex movements that can be used as basis functions to construct other actions [35.105–107]. A neurocomputational model using self-organized feature maps has been proposed in [35.108] for the representation of such canonical movements.

In addition to rhythmic and reaching movements, there has also been significant work on the neural

basis of sequential movements, with the finding that such neural codes for movement sequences exist in the supplementary motor area [35.109–111], cerebellum [35.112, 113], BG [35.112], and the PFC [35.101]. Coding for multiple goals in sequential reaching has been observed in the parietal cortex [35.114].

### 35.2.2 Synergy-based Representations

A rather different approach to studying the construction of movement uses the notion of motor primitives, often termed *synergies* [35.63, 115, 116]. Typically, these synergies are manifested in coordinated patterns of spatiotemporal activation over groups of muscles, implying a force field over posture space [35.117, 118]. Studies in frogs, cats, and humans have shown that a wide range of complex movements in an individual subject can be explained as the modulated superposition of a few synergies [35.63, 65–72, 115, 119, 120]. Given a set of  $n$  muscles, the  $n$ -dimensional time-varying vector of activities for the muscles during an action can be written as

$$\mathbf{m}^q(t) = \sum_{k=1}^N c_k^q \mathbf{g}_k(t - t_k^q), \quad (35.1)$$

where  $\mathbf{g}_k(t)$  is a time-varying synergy function that takes only nonnegative values,  $c_k^q$  is the gain of the  $k$ th synergy used for action  $q$ , and  $t_k^q$  is the temporal offset with which the  $k$ th synergy is triggered for action  $q$  [35.69]. The key point is that a broad range of actions can be constructed by choosing different gains and offsets over the same set of synergies, which represent a set of hard-coded basis functions for the construction of movements [35.120, 121]. Even more interestingly, it appears that the synergies found empirically across different subjects of the same species are rather consistent [35.67, 72], possibly reflecting the inherent constraints of musculoskeletal anatomy. Various neural loci have been suggested for synergies, including the spinal cord [35.67, 107, 122], the motor cortex [35.123], and combinations of regions [35.85, 124].

Though synergies are found consistently in the analysis of experimental data, their actual existence in the neural substrate remains a topic for debate [35.125, 126]. However, the idea of constructing complex movements from motor primitives has found ready application in robotics [35.127–132], as discussed later in this chapter. A hierarchical neurocomputational model of motor synergies based on attractor networks has recently been proposed in [35.133, 134].

### 35.2.3 Computational Models of Motor Control

Motor control has been modeled computationally at many levels and in many ways, ranging from explicitly control-theoretic models through reinforcement-based models to models based on emergent dynamical patterns. This section provides a brief overview of these models.

As discussed above the **M1**, premotor cortex (**PMC**) and the supplementary motor area (**SMA**) are seen as providing self-organized *codes* for specific actions, including information on direction, velocity, force, low-level sequencing, etc., while the **PFC** provides higher level codes needed to construct more complex actions. These codes, comprising a *repertoire* of actions [35.10, 106], arise through self-organized learning of activity patterns in these cortical systems. The **BG** system is seen as the primary locus of selection among the actions in the cortical repertoire. The architecture of the system involving the cortex, **BG**, and the thalamus, and in particular the internal architecture of the **BG** [35.135], makes this system ideally suited to selectively disinhibiting specific cortical regions, presumably activating codes for specific actions [35.10, 136, 137]. The **BG** system also provides an ideal substrate for learning appropriate actions through a dopamine-mediated reinforcement learning mechanism [35.138–141].

Many of the influential early models of motor control were based on control-theoretic principles [35.142–144], using forward and inverse kinematic and dynamic models to generate control signals [35.55, 57, 145–150] – see [35.146] for an excellent introduction. These models have led to more sophisticated ones, such as **MOSAIC** (modular selection and identification for control) [35.151] and **AVITEWRITE** (adaptive vector integration to endpoint handwriting) [35.81]. The **MOSAIC** model is a mixture of experts, consisting of many parallel modules, each comprising three subsystems. These are: A forward model relating motor commands to predicted position, a responsibility predictor that estimates the applicability of the current module, and an inverse model that learns to generate control signals for desired movements. The system generates motor commands by combining the recommendations of the inverse models of all modules weighted by their applicability. Learning in the model is based on a variant of the EM algorithm. The model in [35.57] is a comprehensive neural model with both cortical and spinal components, and builds upon the earlier VITE model in [35.55]. The **AVITEWRITE** model [35.81], which is

a further extension of the VITE model, can generate the complex movement trajectories needed for writing by using a combination of pre-specified phenomenological motor primitives (synergies). A cerebellar model for the control of timing during reaches has been presented by *Barto* et al. [35.152].

The use of neural maps in models of motor control was pioneered in [35.153, 154]. These models used self-organized feature maps (**SOFMs**) [35.155] to learn visuomotor coordination. *Baraduc* et al. [35.156] presented a more detailed model that used multiple maps to first integrate posture and desired movement direction and then to transform this internal representation into a motor command. The maps in this and most subsequent models were based on earlier work by [35.90–93]. An excellent review of this approach is given in [35.94]. A more recent and comprehensive example of the map-based approach is the **SURE-REACH** (sensorimotor, unsupervised, redundancy-resolving control architecture) model in [35.157] which focuses on exploiting the redundancy inherent in motor control [35.84]. Unlike many of the other models, which use neutrally implausible error-based learning, **SURE-REACH** relies only on unsupervised and reinforcement learning. Maps are also the central feature of a general cognitive architecture called **ERA** (epigenetic robotics architecture) by *Morse* et al. [35.158].

Another successful approach to motor control models is based on the use of motor primitives, which are used as basis functions in the construction of diverse actions. This approach is inspired by the experimental observation of motor synergies as described above. However, most models based on primitives implement them nonneurally, as in the case of **AVITEWRITE** [35.81]. The most systematic model of motor primitives has been developed by *Schaal* et al. [35.129–132]. In this model, motor primitives are specified using differential equations, and are combined after weighting to produce different movements. Recently, *Matsubara* et al. [35.159] have shown how the primitives in this model can be learned systematically from demonstrations. *Drew* et al. [35.123] proposed a conceptual model for the construction of locomotion using motor primitives (synergies) and identified the characteristics of such primitives experimentally. A neural model of motor primitives based on hierarchical attractor networks has been proposed recently in [35.133, 134, 160], while *Neilson* and *Neilson* [35.85, 124] have proposed a model based on coordination among adaptive neural filters.

Motor control models based on primitives can be simpler than those based on trajectory tracking because the controller typically needs to choose only the weights (and possibly delays) for the primitives rather than specifying details of the trajectory (or forces). Among other things, this promises a potential solution to the degrees of freedom problem [35.84] since the coordination inherent in the definition of motor primitives reduces the effective degrees of freedom in the system. Another way to address the degrees of freedom problem is to use an optimal control approach with a specific objective function. Researchers have proposed objective functions such as minimum jerk [35.161], minimum torque [35.162], minimum acceleration [35.163], or minimum energy [35.85], but an especially interesting idea is to optimize the distribution of variability across the degrees of freedom in a task-dependent way [35.144, 164–167]. From this perspective, motor control trades off variability in task-irrelevant dimensions for greater accuracy in task-relevant ones. Thus, rather than specifying a trajectory, the controller focuses only on correcting consequential errors. This also explains the experimental observation that motor tasks achieve their goals with remarkable accuracy while using highly variable trajectories to achieve the same goal. Trainin et al. [35.168] have shown that the optimal control principle can be used to explain the observed neural coding of movements in

the cortex. Biess et al. [35.169] have proposed a detailed computational model for controlling an arm in three-dimensional space by separating the spatial and temporal components of control. This model is based on optimizing energy usage and jerk [35.161], but is not implemented at the neural level.

An alternative to these prescriptive and constructivist approaches to motor control is provided by models based on dynamical systems [35.3, 25–27, 29, 31–33]. The most important way in which these models diverge from the others is in their use of emergence as the central organizational principle of control. In this formulation, control programs, structures, primitives, etc., are not preconfigured in the brain–body system, but emerge under the influence of task and environmental constraints on the affordances of the system [35.33]. Thus, the dynamical systems view of motor control is fundamentally ecological [35.170], and like most ecological models, is specified in terms of low-dimensional state dynamics rather than high-dimensional neural processes. Interestingly, a correspondence can be made between the dynamical and optimal control models through the so-called *uncontrolled manifold* concept [35.31, 33, 39, 171]. In both models, the dimensions to be controlled and those that are left uncontrolled are decided by external constraints rather than internal prescription, as in classical models.

### 35.3 Cognitive Control and Working Memory

A lot of behavior – even in primates – is automatic, or almost so. This corresponds to actions (or internal behaviors) so thoroughly embedded in the sensorimotor substrate that they emerge effortlessly from it. In contrast, some tasks require significant cognitive effort for one or more reason, including:

1. An automatic behavior must be suppressed to allow the correct response to emerge, e.g., in the Stroop task [35.172].
2. Conflicts between incoming information and/or recalled behaviors must be resolved [35.19, 20].
3. More contextual information – e.g., social context – must be taken into account before acting.
4. Intermediate pieces of information need to be stored and recalled during the performance of the task, e.g., in sequential problem solving.

5. The timing of subtasks within the overall task is complex, e.g., in delayed-response tasks or other sequential tasks [35.173].

Roughly speaking, the first three fall under the heading of *cognitive control*, and the latter two of *working memory*. However, because of the functions are intimately linked, the terms are often subsumed into each other.

#### 35.3.1 Action Selection and Reinforcement Learning

Action selection is arguably the central component of the cognitive control process. As the name implies, it involves selectively triggering an action from a repertoire of available ones. While action selection is a complex

process involving many brain regions, a consensus has emerged that the **BG** system plays a central role in its mechanism [35.10, 12, 14]. The architecture of the **BG** system and the organization of its projections to and from the cortex [35.135, 174, 175] make it ideally suited to function as a state-dependent gating system for specific functional networks in the cortex. As shown in Fig. 35.2, the hypothesis is that the striatal layer of the **BG** system, receiving input from the cortex, acts as a pattern recognizer for the current cognitive state. Its activity inhibits specific parts of the globus pallidus (**GPI**), leading to disinhibition of specific neural assemblies in the cortex – presumably allowing the behavior/action encoded by those assemblies to proceed [35.10]. The associations between cortical activity patterns and behaviors are key to the functioning of the **BG** as an action selection system, and the configuration and modulation of these associations are thought to lie at the core of cognitive control. The neurotransmitter dopamine (**DA**) plays a key role here by serving as a reward signal [35.138–140] and modulating reinforcement learning [35.176, 177] in both the **BG** and the cortex [35.141, 178–180].

### 35.3.2 Working Memory

All nontrivial behaviors require task-specific information, including relevant domain knowledge and the relative timing of subtasks. These are usually grouped under the function of **WM**. An influential model of **WM** in [35.181] identifies three components in **WM**: (1) a *central executive*, responsible for attention, decision making, and timing; (2) a *phonological loop*, responsible for processing incoming auditory information, maintaining it in short-term memory, and rehearsing utterances; and (3) a *visuospatial sketchpad*, responsible for processing and remembering visual information, keeping track of *what* and *where* information, etc. An *episodic buffer* to manage relationships between the other three components is sometimes included [35.182]. Though already rather abstract, this model needs even more generalized interpretation in the context of many cognitive tasks that do not directly involve visual or auditory data. Working memory function is most closely identified with the **PFC** [35.183–185].

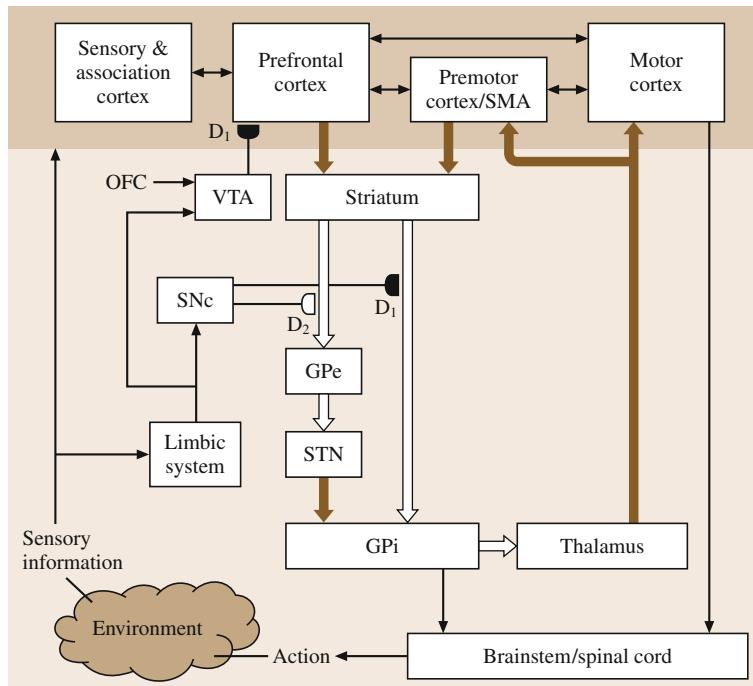

Almost all studies of **WM** consider only short-term memory, typically on the scale of a few seconds [35.186]. Indeed, one of the most significant – though lately controversial – results in **WM** research is the finding that only a small number of items can

be *kept in mind* at any one time [35.187, 188]. However, most cognitive tasks require context-dependent repertoires of knowledge and behaviors to be enabled collectively over longer periods. For example, a player must continually think of chess moves and strategies over the course of a match lasting several hours. The configuration of context-dependent repertoires for extended periods has been termed *long-term working memory* [35.189].

### 35.3.3 Computational Models of Cognitive Control and Working Memory

Several computational models have been proposed for cognitive control, and most of them share common features. The issues addressed by the models include action selection, reinforcement learning of appropriate actions, decision making in choice tasks, task sequencing and timing, persistence and capacity in **WM**, task switching, sequence learning, and the configuration of context-appropriate workspaces. Most of the models discussed below are neural with a range of biological plausibility. A few important nonneural models are also mentioned.

A comprehensive model using spiking neurons and incorporating many biological features of the **BG** system has been presented in [35.13, 193]. This model focuses only on the **BG** and explicitly on the dynamics of dopamine modulation. A more abstract but broader model of cognitive control is the *agents of the mind* model in [35.14], which incorporates the cerebellum as well as the **BG**. In this model, the **BG** provide the action selection function while the cerebellum acts to refine and amplify the choices. A series of interrelated models have been developed by *O'Reilly, Frank et al.* [35.17, 179, 194–199]. All these models use the adaptive gating function of the **BG** in combination with the **WM** function of the prefrontal cortex to explain how executive function can arise without explicit top-down control – the so-called *homunculus* [35.196, 197]. A comprehensive review of these and other models of cognitive control is given in [35.200]. Models of goal-directed action mediated by the **PFC** have also been presented in [35.201] and [35.202]. *Reynolds and O'Reilly et al.* [35.203] have proposed a model for configuring hierarchically organized representations in the **PFC** via reinforcement learning. Computational models of cognitive control and working have also been used to explain mental pathologies such as schizophrenia [35.204].

**Fig. 35.2** The action selection and reinforcement learning substrate in the BG. Wide filled arrows indicate excitatory projections while wide unfilled arrows represent inhibitory projections. Linear arrows indicate generic excitatory and inhibitory connectivity between regions. The inverted D-shaped contacts indicate modulatory dopamine connections that are crucial to reinforcement learning. Abbreviations: SMA = supplementary motor area; SNC = substantia nigra pars compacta; VTA = ventral tegmental area; OFC = orbitofrontal cortex; GPe = globus pallidus (external nuclei); GPi = globus pallidus (internal nuclei); STN = subthalamic nucleus; D<sub>1</sub> = excitatory dopamine receptors; D<sub>2</sub> = inhibitory dopamine receptors. The primary neurons of GPi are inhibitory and active by default, thus keeping all motor plans in the motor and premotor cortices in check. The neurons of the striatum are also inhibitory but usually in an inactive *down* state (after [35.190]). Particular subgroups of striatal neurons are activated by specific patterns of cortical activity (after [35.136]), leading first to disinhibition of specific actions via the direct input from striatum to GPi, and then by re-inhibition via the input through STN. Thus the system gates the triggering of actions appropriate to current cognitive contexts in the cortex. The dopamine input from SNC projects a *reward* signal based on limbic system state, allowing desirable context-action pairs to be reinforced (after [35.191, 192]) – though other hypotheses also exist (after [35.14]). The dopamine input to PFC from the VTA also signals reward and other task-related contingencies

An important aspect of cognitive control is switching between tasks at various time-scales [35.205, 206]. *Imamizu et al.* [35.207] compared two computational models of task switching – a mixture-of-experts (MoE) model and MOSAIC – using brain imaging. They concluded that task switching in the PFC was more consistent with the MoE model and that in the parietal cortex and cerebellum with the MOSAIC model.

An influential abstract model of cognitive control is the *interactive activation model* in [35.208, 209]. In this model, learned behavioral schemata contend for activation based on task context and cognitive

state. While this model captures many phenomenological aspects of behavior, it is not explicitly neural. *Botvinick and Plaut* [35.173] present an alternative neural model that relies on distributed neural representations and the dynamics of recurrent neural networks rather than explicit schemata and contention. *Dayan et al.* [35.210, 211] have proposed a neural model for implementing complex rule-based decision making where decisions are based on sequentially unfolding contexts. A partially neural model of behavior based on the CLARION cognitive model has been developed in [35.212].

Recently, Grossberg and Pearson [35.213] have presented a comprehensive model of WM called LIST PARSE. In this model, the term *working memory* is applied narrowly to the storage of temporally ordered items, i.e., lists, rather than more broadly to all short-term memory. Experimentally observed effects such as recency (better recall of late items in the list) and primacy (better recall of early items in the list) are explained by this model, which uses the concept of *competitive queuing* for sequences. This is based on the observation [35.101, 214] that multiple elements of a behavioral sequence are represented in the PFC as simultaneously active codes with activation levels representing the temporal order. Unlike the WM models discussed in the previous paragraph, the WM in LIST PARSE is embedded within a full cognitive control model with action selection, trajectory generation, etc. Many other neural models for chains of actions have also been proposed [35.214–224].

Higher level cognitive control is characterized by the need to fuse information from multiple sensory modalities and memory to make complex decisions. This has led to the idea of a *cognitive workspace*. In the *global workspace theory* (GWT) developed in [35.225], information from various sensory, episodic, semantic, and motivational sources comes together in a global workspace that forms brief, task-specific integrated representations that are broadcast to all subsystems for use in WM. This model has been implemented computationally in the *intelligent distribution agent* (IDA) model by Franklin et al. [35.226, 227]. A neurally implemented workspace model has been developed by Dehaene et al. [35.172, 228, 229] to explain human subjects' performance on effortful cognitive tasks (i.e., tasks that require suppression of automatic responses), and the basis of consciousness. The construction of cognitive workspaces is closely related to the idea of long-term working memory [35.189]. Unlike short-term working memory, there are few computational models for long-term working memory. Neural models seldom cover long periods, and implicitly assume that a chaining process through recurrent networks (e.g., [35.173]) can maintain internal attention. Iyer et al. [35.230, 231] have proposed an explicitly neurodynamical model of this function, where a stable but modulatable pattern of activity called a *graded attractor* is used to selectively bias parts of the cortex in the context-dependent fashion. An earlier model was proposed in [35.232] to serve a similar function in the hippocampal system.

Another class of models focuses primarily on single decisions within a task, and assume an underlying stochastic process [35.186, 233–235]. Typically, these models address two-choice short-term decisions made over a second or two [35.186]. The decision process begins with a starting point and accumulates information over time resulting in a diffusive (random walk) process. When the diffusion reaches one of two boundaries on either side of the starting point, the corresponding decision is made. This elegant approach can model such concrete issues as decision accuracy, decision time, and the distribution of decisions without any reference to the underlying neural mechanisms, which is both its chief strength and its primary weakness. Several connectionist models have also been developed based on paradigms similar to the diffusion approach [35.236–238]. The neural basis of such models has been discussed in detail in [35.239]. A population-coding neural model that makes Bayesian decisions based on cumulative evidence has been described by Beck et al. [35.98].

Reinforcement learning [35.176] is widely used in many engineering applications, but several models go beyond purely computational use and include details of the underlying brain regions and neurophysiology [35.141, 240]. Excellent reviews of such models are provided in [35.241–243]. Recently, models have also been proposed to show how dopamine-mediated learning could work with spiking neurons [35.244] and population codes [35.245].

Computational models that focus on working memory per se (i.e., not on the entire problem of cognitive control) have mainly considered how the requirement of selective temporal persistence can be met by biologically plausible neural networks [35.246, 247]. Since working memories must bridge over temporal durations (e.g., in remembering a cue over a delay period), there must be some neural mechanism to allow activity patterns to persist selectively in time. A natural candidate for this is attractor dynamics in recurrent neural networks [35.248, 249], where the recurrence allows some activity patterns to be stabilized by reverberation [35.250]. The neurophysiological basis of such persistent activity has been studied in [35.251]. A central feature in many models of WM is the role of dopamine in the PFC [35.252–254]. In particular, it is believed that dopamine sharpens the response of PFC neurons involved in WM [35.255] and allows for reliable storage of timing information in the presence of distractors [35.246]. The model in [35.246, 252] includes several biophysical details such as the effect of dopamine on different ion channels and its differential

modulation of various receptors. More abstract neural models for WM have been proposed in [35.256] and [35.257].

A especially interesting type of attractor network uses the so-called *bump attractors* – spatially localized patterns of activity stabilized by local network connectivity and global competition [35.258]. Such a network has been used in a biologically plausible model of WM in the PFC in [35.259], which demonstrates that the memory is robust against distracting

stimuli. A similar conclusion is drawn in [35.180] based on another bump attractor model of working memory. It shows that dopamine in the PFC can provide robustness against distractors, but robustness against internal noise is achieved only when dopamine in the BG locks the state of the striatum. Recently, Mongillo et al. [35.260] have proposed the novel hypothesis that the persistence of neural activity in WM may be due to calcium-mediated facilitation rather than reverberation through recurrent connectivity.

## 35.4 Conclusion

This chapter has attempted to provide an overview of neurocomputational models for cognitive control, WM, and motor control. Given the vast body of both experimental and computational research in these areas, the review is necessarily incomplete, though every attempt has been made to highlights the major issues, and to provide the reader with a rich array of references covering the breadth of each area.

The models described in this chapter relate to several other mental functions including sensorimotor integration, memory, semantic cognition, etc., as well as to areas of engineering such as robotics and agent systems. However, these links are largely excluded from the chapter – in part for brevity, but mainly because most of them are covered elsewhere in this Handbook.

# Cognitive Architectures and Agents

Sebastien Hélie, Ron Sun

Part D | 36.1

A cognitive architecture is the essential structures and processes of a domain-generic computational cognitive model used for a broad, multiple-level, multiple domain analysis of cognition and behavior. This chapter reviews some of the most popular psychologically-oriented cognitive architectures, namely adaptive control of thought-rational (**ACT-R**), Soar, and CLARION. For each cognitive architecture, an overview of the model, some key equations, and a detailed simulation example are presented. The example simulation with **ACT-R** is the initial learning of the past tense of irregular verbs in English (developmental psychology), the example simulation with Soar is the well-known missionaries and cannibals problem (problem solving), and the example simulation with CLARION is a complex mine field navigation task (autonomous learning). This presentation is followed by a discussion of how cognitive architectures can be used in multi-agent social simulations. A detailed cognitive social simulation with CLARION is presented to reproduce results from organizational decision-making. The chapter concludes with a discussion of the impact of neural network modeling on cognitive architectures and a comparison of the different models.

## 36.1 Background

Cognitive theories are often underdetermined by data [36.1]. As such, different theories, with very little in common, can sometimes be used to account for the very same phenomena [36.2]. This problem can be resolved by adding constraints to cognitive theories. The most intuitive approach to adding constraints to any scientific theory is to collect more data. While experimental psychologists have come a long way toward this

goal in over a century of psychology research, the gap between empirical and theoretical progress is still significant.

Another tactic that can be adopted toward constraining psychological theories is *unification* [36.1]. Newell argued that more data could be used to constrain a theory if the theory was designed to explain a wider range of phenomena. In particular, these *unified* (i.e., in-

tegrative) cognitive theories could be put to the test against well-known (stable) regularities that have been observed in psychology. So far, these integrative theories have taken the form of *cognitive architectures*, and some of them have been very successful in explaining a wide range of data.

A cognitive architecture is the essential structures and processes of a domain-generic computational cognitive model used for a broad, multiple-level, multiple-domain analysis of cognition and behavior [36.3]. Specifically, cognitive architectures deal with componential processes of cognition in a structurally and mechanistically well-defined way. Their function is to provide an essential framework to facilitate more detailed exploration and understanding of various components and processes of the mind. In this way, a cognitive architecture serves as an initial set of assumptions to be used for further development. These assumptions may be based on available empirical data (e.g., psychological or biological), philosophical thoughts and arguments, or computationally inspired hypotheses concerning psychological processes. A cognitive architecture is useful and important precisely because it provides a comprehensive initial framework for further modeling and simulation in many task domains.

While there are all kinds of cognitive architectures in existence, in this chapter we are concerned specifically with psychologically-oriented cognitive architectures (as opposed to software engineering-oriented cognitive architectures, e.g., LIDA [36.4], or neurally-oriented cognitive architectures, e.g., ART [36.5]). Psychologically-oriented cognitive architectures are particularly important because they shed new light on human cognition and, therefore, they are useful tools for advancing the understanding of cognition. In understanding cognitive phenomena, the use of computational simulation on the basis of cognitive architectures forces one to think in terms of processes, and in terms of details. Instead of using vague, purely conceptual theories, cognitive architectures force theoreticians to think clearly. They are, therefore, critical tools in the study of the mind. Cognitive psychologists who use cognitive architectures must specify a cognitive mechanism in sufficient detail to allow the resulting models to be implemented on computers and run as simulations. This approach requires that important elements of the models be spelled out explicitly, thus aiding in developing better, conceptually clearer theories. It is certainly true that more specialized, narrowly-scoped models may also serve this purpose, but they are not

as generic and as comprehensive and thus may not be as useful to the goal of producing general intelligence.

It is also worth noting that psychologically-oriented cognitive architectures are the antithesis of expert systems. Instead of focusing on capturing performance in narrow domains, they are aimed to provide broad coverage of a wide variety of domains in a way that mimics human performance [36.6]. While they may not always perform as well as expert systems, business and industrial applications of intelligent systems increasingly require broadly-scoped systems that are capable of a wide range of intelligent behaviors, not just isolated systems of narrow functionalities. For example, one application may require the inclusion of capabilities for raw image processing, pattern recognition, categorization, reasoning, decision-making, and natural language communications. It may even require planning, control of robotic devices, and interactions with other systems and devices. Such requirements accentuate the importance of research on broadly-scoped cognitive architectures that perform a wide range of cognitive functionalities across a variety of task domains (as opposed to more specialized systems).

In order to achieve general computational intelligence in a psychologically-realistic way, cognitive architectures should include only minimal initial structures and independently learn from their own experiences. Autonomous learning is an important way of developing additional structure, bootstrapping all the way to a full-fledged cognitive model. In so doing, it is important to be careful to devise only minimal initial learning capabilities that are capable of *bootstrapping*, in accordance with whatever phenomenon is modeled [36.7]. This can be accomplished through environmental cues, structures, and regularities. The avoidance of overly complicated initial structures, and thus the inevitable use of autonomous learning, may often help to avoid overly representational models that are designed specifically for the task to be achieved [36.3]. Autonomous learning is thus essential in achieving generality in a psychologically-realistic way.

### 36.1.1 Outline

The remainder of this chapter is organized as follows. The next three sections review some of the most popular cognitive architectures that are used in psychology and cognitive science. Specifically, Sect. 36.2 reviews ACT-R, Sect. 36.3 reviews Soar, and Sect. 36.4 reviews CLARION. Each of these sections includes an overview of the architecture, some key equations, and

a detailed simulation example. Following this presentation, Sect. 36.5 discusses how cognitive architectures can be used in multi-agent cognitive social simulations and presents a detailed example with CLARION. Finally, Sect. 36.6 presents a general discussion and compares the models reviewed.

## 36.2 Adaptive Control of Thought-Rational (ACT-R)

**ACT-R** is one of the oldest and most successful cognitive architectures. It has been used to simulate and implement many cognitive tasks and applications, such as the Tower of Hanoi, game playing, aircraft control, and human-computer interactions [36.8]. **ACT-R** is based on three key ideas [36.9]:

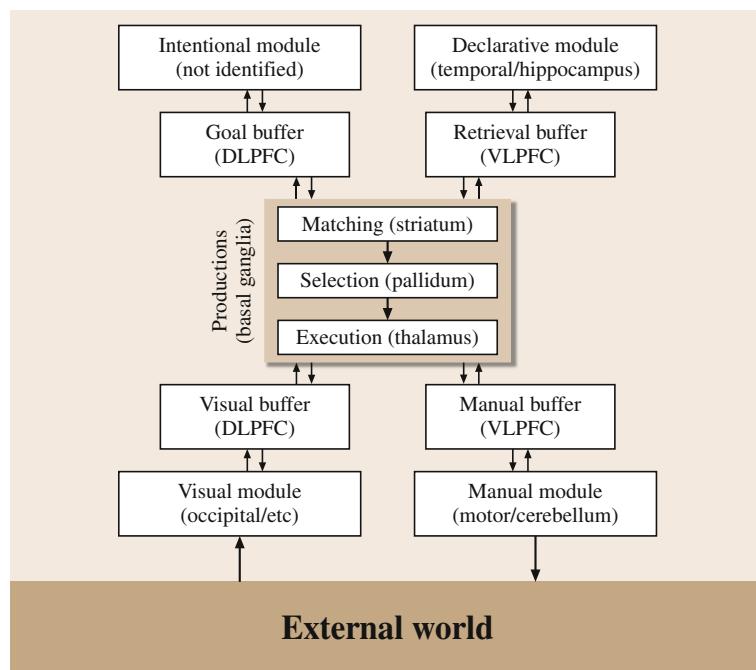

- Rational analysis
- The distinction between procedural and declarative memories
- A modular structure linked with communication buffers (Fig. 36.1).

According to the rational analysis of cognition (first key idea; [36.10]), the cognitive architecture is optimally tuned to its environment (within its computational limits). Hence, the functioning of the architecture can be understood by investigating how optimal behavior in a particular environment would be implemented.

According to Anderson, such optimal adaptation is achieved through evolution [36.10].

The second key idea, the distinction between declarative and procedural memories, is implemented by having different modules in **ACT-R**, each with its own representational format and learning rule. Briefly, procedural memory is represented by production rules (similar to a production system) that can act on the environment through the initiation of motor actions. In contrast, declarative memory is passive and uses chunks to represent world knowledge that can be accessed by the procedural memory but does not interact directly with the environment through motor actions.

The last key idea in **ACT-R** is modularity. As seen in Fig. 36.1, procedural memory (i. e., the production system) cannot directly access information from the other modules: the information has to go through dedicated buffers. Each buffer can hold a single chunk at any time. Hence, buffers serve as information processing

**Fig. 36.1** General architecture of **ACT-R**. DLPFC = dorsolateral prefrontal cortex; VLPFC = ventrolateral prefrontal cortex (after [36.11], by courtesy of the American Psychological Association)

bottlenecks in **ACT-R**. This restricts the amount of information available to the production system, which in turn limits the processing that can be done by this module at any given time. Processing within each module is encapsulated. Hence, all the modules can operate in parallel without much interference. The following subsections describe the different **ACT-R** modules in more details.

### 36.2.1 The Perceptual-Motor Modules

The perceptual-motor modules in **ACT-R** include a detailed representation of the output of perceptual systems, and the input of motor systems [36.8]. The visual module is divided into the well-established ventral (what) and dorsal (where) visual streams in the primate brain. The main function of the dorsal stream is to find the location of features in a display (e.g., red-colored items, curved-shaped objects) without identifying the objects. The output from this module is a location chunk, which can be sent back to the central production system. The function of the ventral stream is to identify the object at a particular location. For instance, the central production system could send a request to the dorsal stream to find a red object in a display. The dorsal stream would search the display and return a chunk representing the location of a red object. If the central production system needs to know the identity of that object, the location chunk would be sent to the ventral stream. A chunk containing the object identity (e.g., a fire engine) would then be returned to the production system.

### 36.2.2 The Goal Module

The goal module serves as the context for keeping track of cognitive operations and supplement environmental stimulations [36.8]. For instance, one can do many different operations with a pen picked up from a desk (e.g., write a note, store it in a drawer, etc.). What operation is selected depends primarily on the goal that needs to be achieved. If the current goal is to clean the desk, the appropriate action is to store the pen in a drawer. If the current goal is to write a note, putting the pen in a drawer is not a useful action.

In addition to providing a mental context to select appropriate production rules, the goal module can be used in more complex problem-solving tasks that need subgoaling [36.8]. For instance, if the goal is to play a game of tennis, one first needs to find an opponent. The goal module must create this subgoal that needs

to be achieved before moving back to the original goal (i.e., playing a game of tennis). Note that goals are centralized in a unique module in **ACT-R** and that production rules only have access to the goal buffer. The current goal to be achieved is the one in the buffer, while later goals stored in the goal module are not accessible to the production. Hence, the *play a game of tennis* goal is not accessible to the production rules while the *find an opponent* subgoal is being pursued.

### 36.2.3 The Declarative Module

The declarative memory module contains knowledge about the world in the form of chunks [36.8]. Each chunk represents a piece of knowledge or a concept (e.g., fireman, bank, etc.). Chunks can be accessed effortfully by the central production system, and the probability of retrieving a chunk depends on the chunk activation

$$P_i = \left[ 1 + e^{-\frac{(B_i + \sum_j W_j S_{ji} - \tau)}{\varepsilon}} \right]^{-1}, \quad (36.1)$$

where  $P_i$  is the probability of retrieving chunk  $i$ ,  $B_i$  is the base-level activation of chunk  $i$ ,  $S_{ji}$  is the association strength between chunks  $j$  and  $i$ ,  $W_j$  is the amount of attention devoted to chunk  $j$ ,  $\tau$  is the activation threshold, and  $\varepsilon$  is a noise parameter. It is important to note that the knowledge chunks in the declarative module are passive and do not do anything on their own. The function of this module is to store information so that it can be retrieved by the central production system (which corresponds to procedural memory). Only in the central production system can the knowledge be used for further reasoning or to produce actions.

### 36.2.4 The Procedural Memory

The procedural memory is captured by the central production rule module and fills the role of a central executive processor. It contains a set of rules in which the conditions can be matched by the chunks in all the peripheral buffers and the output is a chunk that can be placed in one of the buffers. The production rules are chained serially, and each rule application takes a fixed amount of psychological time. The serial nature of central processing constitutes another information processing bottleneck in **ACT-R**.

Because only one production rule can be fired at any given time, its selection is crucial. In **ACT-R**, each production rule has a utility value that depends on: a) its

probability of achieving the current goal, b) the value (importance) of the goal, and c) the cost of using the production rule [36.8]. Specifically,

$$U_i = P_i G - C_i, \quad (36.2)$$

where  $U_i$  is the utility of production rule  $i$ ,  $P_i$  is the (estimated) probability that selecting rule  $i$  will achieve the goal,  $G$  is the value of the current goal, and  $C_i$  is the (estimated) cost of rule  $i$ . The most useful rule is always selected in every processing cycle, but the utility values can be noisy, which can result in the selection of suboptimal rules [36.12]. Rule utilities are learned online by counting the number of times that applying a rule has achieved the goal. Anderson [36.10] has shown that the selection according to these counts is optimal in the Bayesian sense. Also, production rules can be made more efficient by using a process called *production compilation* [36.12, 13]. Briefly, if two production rules are often fired in succession and the result is positive, a new production rule is created which directly links the conditions from the first production rule to the action following the application of the second production rule. Hence, the processing time is cut in half by applying only one rule instead of two.

### 36.2.5 Simulation Example: Learning Past Tenses of Verbs

General computational intelligence requires the abstraction of regularities to form new rules (e.g., rule induction). A well-known example in psychology is children learning English past tenses of verbs [36.13]. This classical result shows that children's accuracy in producing the past tense of irregular verbs follows a U-shaped curve [36.14]. Early in learning, children have a separate memory representation for the past tense of each verb (and no conjugation rule). Hence, the past tenses of irregular verbs are used mostly correctly (Phase 1). After moderate training, children notice that most verbs can be converted to their past tense by adding the suffix *-ed*. This leads to the formulation of a default rule (e.g., to find the past tense of a verb, add the suffix *-ed* to the verb stem). This rule is a useful heuristic and works for all regular verbs in English. However, children tend to overgeneralize and (incorrectly) apply the rule to irregular verbs. This leads to errors and the low point of the U-shaped curve (Phase 2). Finally, children learn that there are exceptions to the default rule and memorize the past tense of irregular verbs. Performance improves again (Phase 3).

In ACT-R, the early phase of training uses instance-based retrieval (i.e., retrieving the chunk representing each verb's past tense using (36.1)). The focus of the presentation is on the induction of the default rule, which is overgeneralized in Phase 2 and correctly applied in Phase 3. This is accomplished by joining two production rules. First, consider the following memory retrieval rule used in Phase 1 [36.12]:

#### 1. Retrieve-past-tense:

IF the goal is to find the past tense of a word  $w$ :  
THEN issue a request to declarative memory for the past tense of  $w$ .

If a perfect match is retrieved from declarative memory, a second rule is used to produce the (probably correct) response. However, if Rule 1 fails to retrieve a perfect match, the verb past tense is unknown and an analogy rule is used instead [36.12]:

#### 2. Analogy-find-pattern:

IF the goal is to find the past tense of word  $w_1$ ;  
AND the retrieval buffer contains past tense  $w_2$ -suffix of  $w_2$ :  
THEN set the answer to  $w_1$ -( $w_2$ -suffix).

This rule produces a form of generalization using an analogy. Because Rule 2 always follows Rule 1, they can be combined using production compilation [36.12]. Also,  $w_2$  is likely to be a regular verb, so  $w_2$ -suffix is likely to be *-ed*. Hence, combining Rules 1 and 2 yields [36.12]:

#### 3. Learned-rule:

IF the goal is to find the past tense of word  $w$ :  
THEN set the answer to  $w$ -*ed*

which is the default rule that can be used to accurately find the past tense of regular verbs. The U-shaped curve representing the performance of children learning irregular verbs can thus be explained with ACT-R as follows [36.13]: In Phase 1, Rule 3 does not exist and Rule 1 is applied to correctly conjugate irregular verbs. In Phase 2, Rule 3 is learned and has proven useful with regular verbs (thus increasing  $P_i$  in (36.2)). Hence, it is often selected to incorrectly conjugate irregular verbs. In phase 3, the irregular verbs become more familiar as more instances have been encountered. This increases their base-level activation in declarative memory ( $B_i$  in (36.1)), which facilitates retrieval and increases the likelihood that Rule 1 is selected to correctly conjugate the irregular verbs. More details about this simulation can be found in [36.13].

## 36.3 Soar

Soar was the original unified theory of cognition proposed by Newell [36.1]. Soar has been used successfully in many problem solving tasks such as Eight Puzzle, the Tower of Hanoi, Fifteen Puzzle, Think-a-Dot, and Rubik's Cube. In addition, Soar has been used for many military applications such as training models for human pilots and mission rehearsal exercises. According to the Soar theory of intelligence [36.15], human intelligence is an approximation of a knowledge system [36.9]. Hence, the most important aspect of intelligence (natural or artificial) is the use of all available knowledge [36.16], and failures of intelligence are failures of knowledge [36.17].

All intelligent behaviors can be understood in terms of problem solving in Soar [36.9]. As such, Soar is implemented as a set of *problem-space computational models* (PSCM) that partition the knowledge into goal relevant ways [36.16]. Each PSCM implicitly contains the representation of a problem space defined by a set of states and a set of operators that can be visualized using a decision tree [36.17]. In a decision tree representation, the nodes represent the states, and one moves around from state to state using operators (the branches/connections in the decision tree). The objective of a Soar agent is to move from an initial state to one of the goal states, and the best operator is always selected at every time step [36.16]. If the knowledge in the model is insufficient to select a single best operator at a particular time step, an impasse is reached, and a new goal is created to resolve the impasse. This new goal defines its own problem space and set of operators.

### 36.3.1 Architectural Representation

The general architecture of Soar is shown in Fig. 36.2. The main structures are a working memory and a long-term memory. Working memory is a blackboard where all the relevant information for the current decision cycle is stored [36.17]. It contains a goal representation, perceptual information, and relevant knowledge that can be used as conditions to fire rules. The outcome of rule firing can also be added to the working memory to cause more rules to fire. The long-term memory contains associative rules representing the knowledge in the system (in the form of  $IF \rightarrow THEN$  rules). The rules in long-term memory can be grouped/organized to form operators.

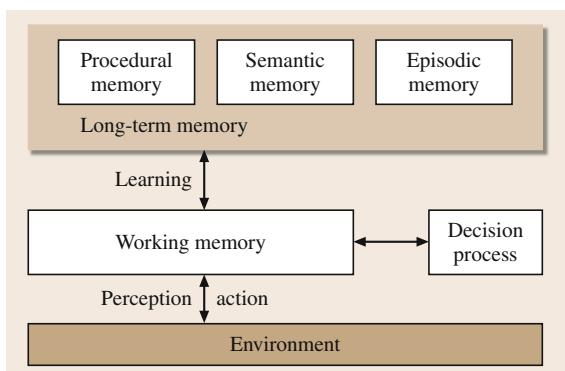

### 36.3.2 The Soar Decision Cycle

In every time step, Soar goes through a six-step decision cycle [36.17]. The first step in Soar is to receive an input from the environment. This input is inserted into working memory. The second step is called the *elaboration phase*. During this phase, all the rules matching the content of working memory fire in parallel, and the result is put into working memory. This, in turn, can create a new round of parallel rule firing. The elaboration phase ends when the content of working memory is stable, and no new knowledge can be added in working memory by firing rules.

The third step is the proposal of operators that are applicable to the content in working memory. If no operator is applicable to the content of working memory, an impasse is reached. Otherwise, the potential operators are evaluated and ordered according to a symbolic preference metric. The fourth step is the selection of a single operator. If the knowledge does not allow for the selection of a single operator, an impasse is reached. The fifth step is to apply the operator. If the operator does not result in a change of state, an impasse is reached. Finally, the sixth step is the output of the model, which can be an external (e.g., motor) or an internal (e.g., more reasoning) action.

### 36.3.3 Impasses

When the immediate knowledge is insufficient to reach a goal, an impasse is reached and a new goal is created to resolve the impasse. Note that this subgoal produces its own problem space with its own set of states and

**Fig. 36.2** The general architecture of Soar. The subdivision of long-term memory is a new addition in Soar 9

operators. If the subgoal reaches an impasse, another subgoal is recursively created to resolve the second impasse, and so on. There are four main types of impasses in Soar [36.17]:

1. No operator is available in the current state.  
*New goal:* Find an operator that is applicable in the current state.
2. An operator is applicable in the current state, but its application does not change the current state.  
*New goal:* Modify the operator so that its application changes the current state. Alternatively, the operator can be modified so that it is no longer deemed applicable in the current state.
3. Two or more operators are applicable in the current state but neither one of them is preferred according to the symbolic metric.  
*New goal:* Further evaluate the options and make one of the operators preferred to the others.
4. More than one operator is applicable, and there is knowledge in working memory favoring two or more operators in the current state.  
*New goal:* Resolve the conflict by removing from working memory one of the contradictory preferences.

Regardless of which type of impasse is reached, resolving an impasse is an opportunity for learning in Soar [36.17]. Each time a new result is produced while achieving a subgoal, a new rule associating the current state with the new result is added in the long-term memory to ensure that the same impasse will not be reached again in the future. This new rule is called a *chunk* to distinguish it from rules that were pre-coded by the modeler (and learning is called *chunking*).

### 36.3.4 Extensions

Unlike ACT-R (and CLARION, as described next), Soar was originally designed as an artificial intelligence model [36.16]. Hence, initially, more attention was paid to functionality and performance than to psychological realism. However, Soar has been used in psychology and Soar 9 has been extended to increase its psychological realism and functionality [36.18]. This version of the architecture is illustrated in Fig. 36.2. First, the long-term memory has been further subdivided in correspondence with psychology theory [36.19]. The associative rules are now part of the procedural memory. In addition to the procedural memory, the long-term memory now also includes a semantic and an episodic

memory. The semantic memory contains knowledge structures representing factual knowledge about the world (e.g., the earth is round), while the episodic memory contains a snapshot of the working memory representing an *episode* (e.g., Fido the dog is now sitting in front of me).

At the subsymbolic level, Soar 9 includes activations in working memory to capture recency/usefulness (as in ACT-R). In addition, Soar 9 uses non-symbolic (numerical) values to model operator preferences. These are akin to utility functions and are used when symbolic operators are insufficient to select a single operator [36.20]. When numerical preferences are used, an operator is selected using a Boltzmann distribution

$$P(O_i) = \frac{e^{S(O_i)/\tau}}{\sum_j e^{S(O_j)/\tau}}, \quad (36.3)$$

where  $P(O_i)$  is the probability of selecting operator  $i$ ,  $S(O_i)$  is the summed support (preference) for operator  $i$ , and  $\tau$  is a randomness parameter. Numerical operator preferences can be learned using reinforcement learning.

Finally, recent work has been initiated to add a clustering algorithm that would allow for the creation of new symbolic structures and a visual imagery module to facilitate symbolic spatial reasoning (not shown in Fig. 36.2). Also, the inclusion of emotions is now being considered (via appraisal theory [36.21]).

### 36.3.5 Simulation Example: Learning in Problem Solving

Nason and Laird [36.20] proposed a variation of Soar that includes a reinforcement learning algorithm (following the precedents of CLARION and ACT-R) to learn numerical preference values for the operators. In this implementation (called Soar-RL), the preferences are replaced by  $Q$ -values [36.22] that are learned using environmental feedback. After the  $Q$ -value of each relevant operator has been calculated (i.e., all the operators available in working memory), an operator is stochastically selected (as in (36.3)).

Soar-RL has been used to simulate the missionaries and cannibals problem. The goal in this problem is to transport three missionaries and three cannibals across a river using a boat that can carry at most two persons at a time. Several trips are required, but the cannibals must never outnumber the missionaries on either riverbank. This problem has been used as a benchmark in

problem-solving research because, if the desirability of a move is evaluated in terms of the number of people that have crossed the river (which is a common assumption), a step backward must be taken midway in solving the problem (i.e., a move that reduces the number of peoples that crossed the river must be selected).

In the Soar-RL simulation, the states were defined by the number of missionaries and cannibals on each side of the river and the location of the boat. The operators were boat trips transporting people, and the  $Q$ -values of the operators were randomly initialized. Also, to emphasize the role of reinforcement learning in solving this problem, chunking was disengaged. Hence, the only form of adaptation was the adjustment

of the operator  $Q$ -values. Success states (i.e., all people crossed the river) were rewarded, failure states (i.e., cannibals outnumbering missionaries on a riverbank) were punished, and all other states received neutral reinforcement.

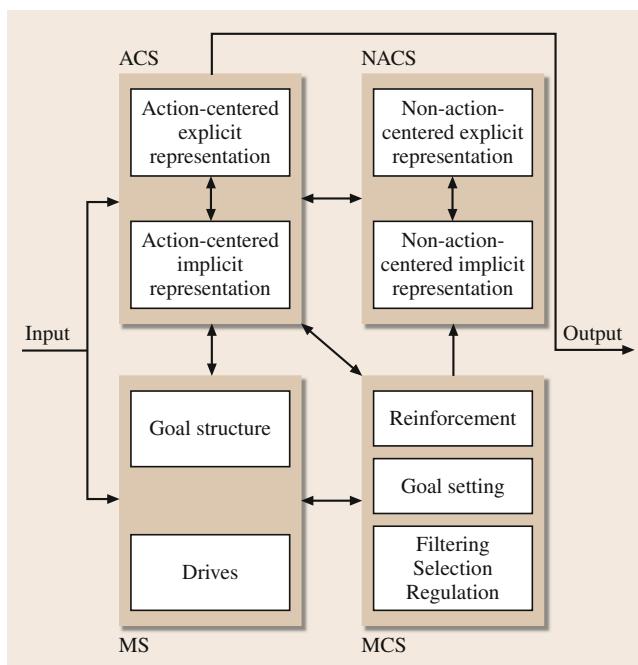

Using this simulation methodology, Soar-RL generally learned to solve the missionaries and cannibals problem. Most errors resulted from the stochastic decision process [36.20]. *Nason* and *Laird* also showed that the model performance can be improved fivefold by adding a symbolic preference preventing an operator at time  $t$  from undoing the result of the application of an operator at time  $t - 1$ . More details on this simulation can be found in [36.20].

## 36.4 CLARION

CLARION is an integrative cognitive architecture consisting of a number of distinct subsystems with a dual representational structure in each subsystem (implicit versus explicit representations). CLARION is the

newest of the reviewed architectures, but it has already been successfully applied to several tasks such as navigation in mazes and mine fields, human reasoning, creative problem solving, and cognitive social simulations. CLARION is based on the following basic principles [36.24]. First, humans can learn with or without much a priori specific knowledge to begin with, and humans learn continuously from on-going experience in the world. Second, there are different types of knowledge involved in human learning (e.g., procedural vs. declarative, implicit vs. explicit; [36.24]), and different types of learning processes are involved in acquiring different types of knowledge. Third, motivational processes as well as meta-cognitive processes are important and should be incorporated in a psychologically realistic cognitive architecture. According to CLARION, all three principles are required to achieve general computational intelligence. An overview of the architecture is shown in Fig. 36.3.

The CLARION subsystems include the action-centered subsystem (ACS), the non-action-centered subsystem (NACS), the motivational subsystem (MS), and the meta-cognitive subsystem (MCS). The role of the ACS is to control actions, regardless of whether the actions are for external physical movements or for internal mental operations. The role of the NACS is to maintain general knowledge. The role of the MS is to provide underlying motivations for perception, action, and cognition, in terms of providing impetus and feedback (e.g., indicating whether or not outcomes are satisfactory). The role of the MCS is to monitor, direct, and modify dynamically the operations of the other subsystems.

**Fig. 36.3** The CLARION architecture. ACS stands for the action-centered subsystem, NACS the non-action-centered subsystem, MS the motivational subsystem, and MCS the meta-cognitive subsystem (after [36.23])

Each of these interacting subsystems consists of two *levels* of representations. In each subsystem, the top level encodes explicit (e.g., verbalizable) knowledge and the bottom level encodes implicit (e.g., non-verbalizable) knowledge. The two levels interact, for example, by cooperating through a combination of the action recommendations from the two levels, respectively, as well as by cooperating in learning through bottom-up and top-down processes. Essentially, it is a dual-process theory of mind [36.24].

### 36.4.1 The Action-Centered Subsystem

The **ACS** is composed of a top and a bottom level. The bottom level of the **ACS** is modular. A number of neural networks co-exist, each of which is adapted to a specific modality, task, or group of input stimuli. These modules can be developed in interacting with the world (computationally, through various decomposition methods [36.25]). However, some of them are formed evolutionarily, reflecting hardwired instincts and propensities [36.26]. Because of these networks, CLARION is able to handle very complex situations that are not amenable to simple rules.

In the top level of the **ACS**, explicit symbolic conceptual knowledge is captured in the form of explicit symbolic rules (for details, see [36.24]). There are many ways in which explicit knowledge may be learned, including independent hypothesis testing and bottom-up learning. The basic process of bottom-up learning is as follows: if an action implicitly decided by the bottom level is successful, then the model extracts an explicit rule that corresponds to the action selected by the bottom level and adds the rule to the top level. Then, in subsequent interactions with the world, the model verifies the extracted rule by considering the outcome of applying the rule. If the outcome is not successful, then the rule should be made more specific; if the outcome is successful, the agent may try to generalize the rule to make it more universal [36.27]. After explicit rules have been learned, a variety of explicit reasoning methods may be used. Learning explicit conceptual representations at the top level can also be useful in enhancing learning of implicit reactive routines at the bottom level [36.7]. The action-decision cycle in the **ACS** can be described by the following steps:

1. Observe the current state of the environment
2. Compute the value of each possible action in the current state in the bottom level

3. Compute the value of each possible action in the current state in the top level
4. Choose an appropriate action by stochastically selecting or combining the values in the top and bottom levels
5. Perform the selected action
6. Update the top and bottom levels according to the received feedback (if any)
7. Go back to Step 1.

### 36.4.2 The Non-Action-Centered Subsystem

The **NACS** may be used for representing general knowledge about the world (i.e., the semantic memory and the episodic memory), and for performing various kinds of memory retrievals and inferences. The **NACS** is also composed of two levels (a top and a bottom level) and is under the control of the **ACS** (through its actions).

At the bottom level, *associative memory* networks encode non-action-centered implicit knowledge. Associations are formed by mapping an input to an output (such as mapping 2 + 3 to 5). Backpropagation [36.7, 28] or Hebbian [36.29] learning algorithms can be used to establish such associations between pairs of inputs and outputs. At the top level of the **NACS**, a general knowledge store encodes explicit non-action-centered knowledge [36.29, 30]. In this network, chunks (passive knowledge structures, similar to ACT-R) are specified through dimensional values (features). A node is set up in the top level to represent a chunk. The chunk node connects to its corresponding features represented as individual nodes in the bottom level of the **NACS** [36.29, 30]. Additionally, links between chunk nodes encode explicit associations between pairs of chunks, known as *associative rules*. Explicit associative rules may be learned in a variety of ways [36.24].

During reasoning, in addition to applying associative rules, similarity-based reasoning may be employed in the **NACS**. Specifically, a known (given or inferred) chunk may be automatically compared with another chunk. If the similarity between them is sufficiently high, then the latter chunk is inferred. The similarity between chunks  $i$  and  $j$  is computed by using

$$s_{ci \sim cj} = \frac{n_{ci \cap cj}}{f(n_{cj})}, \quad (36.4)$$

where  $s_{ci \sim cj}$  is the similarity from  $i$  to chunk  $j$ ,  $n_{ci \cap cj}$  counts the number of features shared by chunks  $i$  and  $j$  (i.e., the feature overlap),  $n_{cj}$  counts the total number

of features in chunk  $j$ , and  $f(x)$  is a slightly super-linear, monotonically increasing, positive function (by default,  $f(x) = x^{1.1}$ ). Thus, similarity-based reasoning in CLARION is naturally accomplished using (1) top-down activation by chunk nodes of their corresponding bottom-level feature-based representations, (2) calculation of feature overlap between any two chunks (as in (36.4)), and (3) bottom-up activation of the top-level chunk nodes. This kind of similarity calculation is naturally accomplished in a multi-level cognitive architecture and represents a form of synergy between the explicit and implicit modules. Each round of reasoning in the **NACS** can be described by the following steps:

1. Propagate the activation of the activated features in the bottom level
2. Concurrently, fire all applicable associative rules in the top level
3. Integrate the outcomes of top and bottom-level processing
4. Update the activations in the top and bottom levels (e.g., similarity-based reasoning)
5. Go back to Step 1 (if another round of reasoning is requested by the **ACS**).

### 36.4.3 The Motivational and Meta-Cognitive Subsystems

The motivational subsystem (**MS**) is concerned with drives and their interactions [36.31], which lead to actions. It is concerned with why an agent does what it does. Simply saying that an agent chooses actions to maximize gains, rewards, reinforcements, or payoffs leaves open the question of what determines these things. The relevance of the **MS** to the **ACS** lies primarily in the fact that it provides the context in which the goal and the reinforcement of the **ACS** are set. It thereby influences the working of the **ACS**, and by extension, the working of the **NACS**.

Dual motivational representations are in place in CLARION. The explicit goals (such as *finding food*) of an agent may be generated based on internal drives (for example, *being hungry*; see [36.32] for details). Beyond low-level drives (concerning physiological needs), there are also higher-level drives. Some of them are primary, in the sense of being *hard wired*, while others are secondary (*derived*) drives acquired mostly in the process of satisfying primary drives.

The meta-cognitive subsystem (**MCS**) is closely tied to the **MS**. The **MCS** monitors, controls, and regulates cognitive processes for the sake of improving

cognitive performance [36.33, 34]. Control and regulation may be in the forms of setting goals for the **ACS**, setting essential parameters of the **ACS** and the **NACS**, interrupting and changing on-going processes in the **ACS** and the **NACS**, and so on. Control and regulation can also be carried out through setting reinforcement functions for the **ACS**. All of the above can be done on the basis of drive activations in the **MS**. The **MCS** is also made up of two levels: the top level (explicit) and the bottom level (implicit).

### 36.4.4 Simulation Example: Minefield Navigation

Sun et al. [36.7] empirically tested and simulated a complex minefield navigation task. In the empirical task, the subjects were seated in front of a computer monitor that displayed an instrument panel containing several gauges that provided current information on the status/location of a vehicle. The subjects used a joystick to control the direction and speed of the vehicle. In each trial, a random mine layout was generated, and the subjects had limited time to reach a target location without hitting a mine. Control subjects were trained for several consecutive days in this task. Sun and colleagues also tested three experimental conditions with the same amount of training but emphasized verbalization, over-verbalization, and dual-tasking (respectively). The human results show that learning was slower in the dual-task condition than in the single-task condition, and that a moderate amount of verbalization speeds up learning. However, the effect of verbalization is reversed in the over-verbalization condition; over-verbalization interfered with (slowed down) learning.

In the CLARION simulation, simplified (explicit) rules were represented in the form  $state \rightarrow action$  in the top level of the **ACS**. In the bottom level of the **ACS**, a backpropagation network was used to (implicitly) learn the input-output function using reinforcement learning. Reinforcement was received at the end of every trial. The bottom-level information was used to create and refine top-level rules (with bottom-up learning). The model started out with no specific a priori knowledge about the task (the same as a typical subject). The bottom level contained randomly initialized weights. The top level started empty and contained no a priori knowledge about the task (either in the form of instructions or rules). The interaction of the two levels was not determined a priori either: there was no fixed weight in combining outcomes from the two levels. The weights were automatically set based on relative perfor-

mance of the two levels on a periodic basis. The effects of the dual task and the various verbalization conditions were modeled using rule-learning thresholds so that more/less activities could occur at the top level. The CLARION simulation results closely matched the human results [36.7]. In addition, the human and sim-

ulated data were input into a common ANOVA and no statistically significant difference between human and simulated data was found in any of the conditions. Hence, CLARION did a good job of simulating detailed human data in the minefield navigation task. More details about this simulation can be found in [36.7].

## 36.5 Cognitive Architectures as Models of Multi-Agent Interaction

Most of the work in social simulation assumes rudimentary cognition on the part of agents. Agent models have frequently been custom-tailored to the task at hand, often with a restricted set of highly domain-specific rules. Although this approach may be adequate for achieving the limited objectives of some social simulations, it is overall unsatisfactory. For instance, it limits the realism, and hence applicability of social simulation, and more importantly it also precludes any possibility of resolving the theoretical question of the micro–macro link.

Cognitive models, especially cognitive architectures, may provide better grounding for understanding multi-agent interaction. This can be achieved by incorporating realistic constraints, capabilities, and tendencies of individual agents in terms of their psychological processes (and maybe even in terms of their physical embodiment) and their interactions with their environments (which include both physical and social environments). Cognitive architectures make it possible to investigate the interaction of cognition/motivation on the one hand and social institutions and processes on the other, through psychologically realistic agents. The results of the simulation may demonstrate significant interactions between cognitive-motivational factors and social-environmental factors. Thus, when trying to understand social processes and phenomena, it may be important to take the psychology of individuals into consideration given that detailed computational models of cognitive agents that incorporate a wide range of psychological functionalities have been developed in cognitive science.

For example, *Sun* and *Naveh* simulated an organizational classification decision-making task using the CLARION cognitive architecture [36.35]. In a classification decision-making task, agents gather information about problems, classify them, and then make further decisions based on the classification. In this case, the task is to determine whether a blip on a screen is a hostile aircraft, a flock of geese, or a civilian aircraft. In each case, there is a single object in the airspace. The

object has nine different attributes, each of which can take on one of three possible values (e.g., its speed can be low, medium, or high). An organization must determine the status of an observed object: whether it is friendly, neutral, or hostile. There are a total of 19 683 possible objects, and 100 problems are chosen randomly from this set.

Critically, no one single agent has access to all the information necessary to make a choice. Decisions are made by integrating separate decisions made by different agents, each of which is based on a different subset of information. In terms of organizational structures, there are two major types of interest: teams and hierarchies. In teams, decision-makers act autonomously, individual decisions are treated as votes, and the organization decision is the majority decision. In hierarchies, agents are organized in a chain of command, such that information is passed from subordinates to superiors, and the decision of a superior is based solely on the recommendations of his/her subordinates. In this task, only a two-level hierarchy with nine subordinates and one supervisor is considered.

In addition, organizations are distinguished by the structure of information accessible to each agent. There are two types of information access: distributed access, in which each agent sees a different subset of three attributes (no two agents see the same subset of three attributes), and blocked access, in which three agents see exactly the same subset of attributes. In both cases, each attribute is accessible to three agents.

The human experiments by *Carley* et al. [36.36] were done in a  $2 \times 2$  fashion (organization  $\times$  information access). The data showed that humans generally performed better in team situations, especially when distributed information access was in place. Moreover, distributed information access was generally better than blocked information access. The worst performance occurred when hierarchical organizational structure and blocked information access were used in conjunction.

The results of the CLARION simulations closely matched the patterns of the human data, with teams outperforming hierarchical structures, and distributed access being superior to blocked access. As in the human data, the effects of organization and information access were present, but more importantly the interaction of these two factors with length of training was reproduced. These interactions reflected the following trends: (1) the superiority of team and distributed information access at the start of the learning process and, (2) either the disappearance or reversal of these trends towards the end. These trends persisted robustly across a wide variety of settings of cognitive parameters, and did not critically depend on any one setting of these parameters. Also, as in humans, performance was not grossly skewed towards one condition or the other.

### 36.5.1 Extention

One advantage of using a more *cognitive* agent in social simulations is that we can address the question of what happens when cognitive parameters are varied. Because CLARION captures a wide range of cognitive processes, its parameters are generic (rather than task specific). Thus, one has the opportunity of studying social and organizational issues in the context of a general theory of cognition. Below we present some of the results observed (details can be found in [36.35]).

Varying the parameter controlling the probability of selecting implicit versus explicit processing in CLARION interacted with the length of training. Explicit rule learning was far more useful at the early stages of learning, when increased reliance on rules tended to boost performance (compared with performance toward the end of the learning process). This is because explicit rules are crisp guidelines that are based on past success, and as such, they provide a useful anchor at the uncertain early stages of learning. However, by the end of the learning process, they become no more reliable than highly trained networks. This corresponds

to findings in human cognition, where there are indications that rule-based learning is more widely used in the early stages of learning, but is later increasingly supplanted by similarity-based processes and skilled performance [36.37, 38]. Such trends may partially explain why hierarchies did not perform well initially; because a hierarchy's supervisor was burdened with a higher input dimensionality, it took a longer time to encode rules (which were, nevertheless, essential at the early stages of learning).

Another interesting result was the effect of varying the generalization threshold. The generalization threshold determines how readily an agent generalizes a successful rule. It was better to have a higher rule generalization threshold than a lower one (up to a point). That is, if one restricts the generalization of rules to those rules that have proven to be relatively successful, the result is a higher-quality rule set, which leads to better performance in the long run.

This CLARION simulation showed that some cognitive parameters (e.g., learning rate) had a monolithic, across-the-board effect under all conditions, while in other cases, complex interactions of factors were at work (see [36.35] for full details of the analysis). This illustrates the importance of limiting one's social simulation conclusions to the specific cognitive context in which human data were obtained (in contrast to the practice of some existing social simulations). By using CLARION, Sun and Naveh [36.35] were able to accurately capture organizational performance data and, moreover, to formulate deeper explanations for the results observed. In cognitive architectures, one can vary parameters and options that correspond to cognitive processes and test their effects on collective performance. In this way, cognitive architectures may be used to predict human performance in social/organizational settings and, furthermore, to help to improve collective performance by prescribing optimal or near-optimal cognitive abilities for individuals for specific collective tasks and/or organizational structures.

## 36.6 General Discussion

This chapter reviewed the most popular psychologically-oriented cognitive architectures with some example applications in human developmental learning, problem-solving, navigation, and cognitive social simulations. ACT\* (ACT-R's early version; [36.39]) and Soar [36.15] were some of the first cognitive architec-

tures available and have been around since the early 1980s, while CLARION was first proposed in the mid-1990s [36.30]. This chronology is crucial when exploring their learning capacity. ACT\* and Soar were developed before the connectionist revolution [36.40], and were, therefore, implemented using knowledge-

rich production systems [36.41]. In contrast, CLARION was proposed after the connectionist revolution and was implemented using neural networks. While some attempts have been made to implement **ACT-R** [36.42] and Soar [36.43] with neural networks, these architectures remain mostly knowledge-rich production systems grounded in the artificial intelligence tradition. One of the most important impacts of the connectionist revolution has been data-driven learning rules (e.g., backpropagation) that allows for autonomous learning. CLARION was created within this tradition, and every component in CLARION has been implemented using neural networks. For instance, explicit knowledge may be implemented using linear, two-layer neural networks [36.7, 23, 28, 29], while implicit knowledge has been implemented using nonlinear multilayer back-propagation networks in the **ACS** [36.7, 29] and recurrent associative memory networks in the **NACS** [36.23, 29]. This general philosophy has also been applied to modeling the **MS** and the **MCS** using linear (explicit) and nonlinear (implicit) neural networks [36.44]. As such, CLARION requires less pre-coded knowledge to achieve its goals, and can be considered more autonomous.

While the different cognitive architectures were motivated by different problems and took different implementation approaches, they share some theoretical similarities. For instance, Soar is somewhat similar to the top levels of CLARION. It contains production rules that fire in parallel and cycles until a goal is reached. In CLARION, top-level rules in the **NACS** fire in parallel in cycles (under the control of the **ACS**). However, CLARION includes a distinction between action-cen-

tered and non-action-centered knowledge. While this distinction has been added in Soar 9 [36.18], the additional distinction between explicit and implicit knowledge (one of the main assumptions in CLARION) was not. The inclusion of implicit knowledge in the bottom level of CLARION allows for an *automatic* representation of similarity-based reasoning, which is absent in Soar. While Soar can certainly account for similarity-based reasoning, adding an explicit (and ad hoc) representation of similarity can become cumbersome when a large number of items are involved.

**ACT-R** initially took a different approach. Work on the **ACT-R** cognitive architecture has clearly focused on psychological modeling from the very beginning and, as such, it includes more than one long-term memory store, distinguishing between procedural and declarative memories (similar to CLARION). In addition, **ACT-R** has a rudimentary representation of explicit and implicit memories: explicit memory is represented by symbolic structures (i.e., chunks and production rules), while implicit memory is represented by the activation of the structures. In contrast, the distinction between explicit and implicit memories in CLARION is one of the main focuses of the architecture, and a more detailed representation of implicit knowledge has allowed for a natural representation of similarity-based reasoning as well as natural simulations of many psychological data sets [36.7, 28, 29]. Yet, **ACT-R** memory structures have been adequate for simulating many data sets with over 30 years of research. Future work should be devoted to a detailed comparison of **ACT-R**, Soar, and CLARION using a common set of tasks to more accurately compare their modeling paradigms, capacities, and limits.

# Embodied Intelligence

Angelo Cangelosi, Josh Bongard, Martin H. Fischer, Stefano Nolfi

Embodied intelligence is the computational approach to the design and understanding of intelligent behavior in embodied and situated agents through the consideration of the strict coupling between the agent and its environment (situatedness), mediated by the constraints of the agent's own body, perceptual and motor system, and brain (embodiment). The emergence of the field of embodied intelligence is closely linked to parallel developments in computational intelligence and robotics, where the focus is on morphological computation and sensory–motor coordination in evolutionary robotics models, and in neuroscience and cognitive sciences where the focus is on embodied cognition and developmental robotics models of embodied symbol learning. This chapter provides a theoretical and technical overview of some principles of embodied intelligence, namely morphological computation, sensory–motor coordination, and developmental embodied cognition. It will also discuss some tutorial examples on the modeling of body/brain/environment adaptation for the evolution of morphological computational agents, evolutionary robotics model of navigation and object discrimination, and developmental robotics

## 37.1 Introduction to Embodied Intelligence

Organisms are not isolated entities which develop their sensory–motor and cognitive skills in isolation from their social and physical environment, and independently from their motor and sensory systems. On the contrary, behavioral and cognitive skills are dynamical properties that unfold in time and arise from a large number of interactions between the agents' nervous system, body, and environment [37.1–7]. Embodied intelligence is the computational approach to the design and understanding of intelligent behavior in embodied and situated agents through the consideration of

the strict coupling between the agent and its environment (situatedness), mediated by the constraints of the agent's own body, perceptual and motor system, and brain (embodiment).

Historically, the field of embodied intelligence has its origin from the development and use of bio-inspired computational intelligence methodologies in computer science and robotics, and the overcoming of the limitations of symbolic approaches typical of classical artificial intelligence methods. As argued in Brooks' [37.2] seminal paper on *Elephants don't play chess*, the study

of apparently simple behaviors, such as locomotion and motor control, permits an understanding of the embodied nature of intelligence, without the requirement to start from higher order abstract skills as those involved in chess playing algorithms. Moreover, the emergence of the field of embodied intelligence is closely linked to parallel developments in robotics, with the focus on morphological computation and sensory-motor coordination in evolutionary and developmental robotics models, and in neuroscience and cognitive sciences with the focus on embodied cognition (**EC**).

The phenomenon of *morphological computation* concerns the observation that a robot's (or animal's) *body plan* may perform computations: A body plan that allows the robot (or animal) to passively exploit interactions with its environment may perform computations that lead to successful behavior; in another body plan less well suited to the task at hand, those computations would have to be performed by the control policy [37.8–10]. If both the body plans and control policies of robots are evolved, evolutionary search may find robots that exhibit more morphological computation than an equally successful robot designed by hand (see more details in Sect. 37.2).

The principle of *sensory-motor coordination*, which concerns the relation between the characteristics of the agents' control policy and the behaviors emerging from agent/environmental interactions, has been demonstrated in numerous evolutionary robotics models [37.6]. Experiments have shown how adaptive agents can acquire an ability to coordinate their sensory and motor activity so as to self-select their forthcoming sensory experiences. This sensory-motor coordination can play several key functions such as enabling the agent to access the information necessary to make the appropriate behavioral decision, elaborating sensory information, and reducing the complexity of the agents' task to a manageable level. These two themes will be exemplified through the illustration of evolutionary robotics experiments in Sect. 37.3 in which the fine-grained characteristics of the agents' neural control system and body are subjected to variations (e.g. gene mutation) and in which variations are retained or discarded on the basis of their effects at the level of the

overall behavior exhibited by the agent in interaction with the environment.

In cognitive and neural sciences, the term *embodied cognition* (**EC**) [37.11, 12] is used to refer to systematic relationships between an organism's cognitive processes and its perceptual and response repertoire. Notwithstanding the many interpretations of this term [37.13], the broadest consensus of the proponents of **EC** is that our knowledge representations encompass the bodily activations that were present when we initially acquired this knowledge (for differentiations, [37.14]). This view helps us to understand the many findings of modality-specific biases induced by cognitive computations. Examples of **EC** in psychology and cognitive science can be sensory–motor (e.g., a systematic increase in comparison time with angular disparity between two views of the same object [37.15]), or conceptual (e.g., better recall of events that were experienced in the currently adopted body posture [37.16]), or emotional in nature (e.g., interpersonal warmth induced by a warm handheld object [37.17]). Such findings were hard to accommodate under the more traditional views where knowledge was presumed symbolic, amodal and abstract and thus dissociated from sensory input and motor output processes.

Embodied cognition experiments in psychology have inspired the design of developmental robotics models [37.18] which exploit the ontogenetic interaction between the developing (baby) robot and its social and physical environment to acquire both simple sensory–motor control strategies and higher order capabilities such as language and number learning (Sect. 37.4).

To provide the reader with both a theoretical and technical understanding of the principles of morphological computation, sensory–motor coordination and developmental **EC** the following three sections will review the progress in these fields, and analyze in detail some key studies as examples. The presentation of studies on the modeling of both sensory–motor tasks (such as locomotion, navigation, and object discrimination) and of higher order cognitive capabilities (such as linguistic and numerical cognition) demonstrates the impact of embodied intelligence in the design of a variety of perceptual, motor, and cognitive skills.

## 37.2 Morphological Computation for Body–Behavior Coadaptation

Embodied intelligence dictates that there are certain body plans and control policies that, when combined,

will produce some desired behavior. For example, imagine that the desired task is active categorical per-

ception (**ACP**) [37.19, 20]. **ACP** requires a learner to actively interact with objects in its environment to classify those objects. This stands in contrast to passive categorization whereby an agent observes objects from a distance – perhaps it is fed images of objects or views them through a camera – and labels the objects according to their perceived class. In order for an animal or robot to perform **ACP**, it must not only possess a control policy that produces as output the correct class for the object being manipulated, but also some manipulator with which to physically affect (and be affected by) the object.

One consequence of embodied intelligence is that certain pairings of *body* and *brain* produce the desired behavior, and others do not. Returning to the example of **ACP**, if a robot’s arm is too short to reach the objects then it obviously will not be able to categorize them. Imagine now a second robot that possesses an arm of the requisite length but can only bring the back of its hand into contact with the objects. Even if this robot’s control policy distinguishes between round and edged objects based on the patterned firing of touch sensors embedded in its palm, this robot will also not be able to perform **ACP**.

A further consequence of embodied intelligence is that some body plans may require a complex control policy to produce successful behavior, while another body plan may require a simpler control policy. This has been referred to as the morphology and control tradeoff in the literature [37.7]. Continuing the **ACP** example, consider a third robot that can bring its palm and fingers into contact with the objects, but only possesses a single binary touch sensor in its palm. In order to distinguish between round and edged objects, this robot will require a control policy that performs some complex signal processing on the time series data produced by this single sensor during manipulation. A fourth robot however, equipped with multiple tactile sensors embedded in its palm and fingers, may be able to categorize objects immediately after grasping them: Perhaps round objects produce characteristic static patterns of tactile signals that are markedly different from those patterns produced when grasping edged objects.

The morphology and control tradeoff however raises the question as to what is being traded. It has been argued that what is being traded is computation [37.7, 8]. If two robots succeed at a given task, and each robot is equipped with the simplest control policy that will allow that robot to succeed, but one control policy performs fewer computations than the other control policy, then the body plan of the robot

equipped with the simpler control policy must perform the *missing* computations required to succeed at the task.

This phenomenon of a robot’s (or animal’s) body plan performing computation has been termed *morphological computation* [37.8–10]. *Paul* [37.8] outlined a theoretical robot that uses its body to compute the XOR function. In another study [37.9] it was shown how the body of a vacuum cleaning robot could literally replace a portion of its artificial neural network controller, thus subsuming the computation normally performed by that part of the control policy into the robot’s body. *Pfeifer* and *Gomez* [37.21] describe a number of other robots that exhibit the phenomenon of morphological computation.

### 37.2.1 The Counterintuitive Nature of Morphological Computation

All of the robots outlined by *Pfeifer* and *Gomez* [37.21] were designed manually; in some cases the control policies were automatically optimized. If for each task there are a spectrum of robot body plan/control policy pairings that achieve the task, one might ask where along this spectrum the human-designed robots fall. That is, what mixtures of morphological computation and control computation do human designers tend to favor? The bulk of the artificial intelligence literature, since the field’s beginnings in the 1950s, seems to indicate that humans exhibit a cognitive chauvinism: we tend to favor control complexity over morphological complexity. Classical artificial intelligence dispensed with the body altogether: it was not until the 1980s that the role of morphology in intelligent behavior was explicitly stated [37.2]. As a more specific example, object manipulation was first addressed by creating rigid, articulated robot arms that required complex control policies to succeed [37.22]. Later, it was realized that soft manipulators could simplify the amount of control required for successful manipulation (e.g., [37.23]). Most recently, a class of robot manipulators known as *jamming grippers*’ was introduced [37.24]. In a jamming gripper, a robot arm is tipped with a bag of granular material such that when air is removed from the bag the grains undergo a phase transition into a *jammed*, solid-like state. The control policies for jamming grippers are much simpler than those required for rigid or even soft multifingered dexterous manipulators: at the limit, the controller must switch the manipulator between just two states (*grip* or *release*), regardless of the object.

Despite the fact that the technology for creating jamming grippers has existed for decades, it took a long time for this class of manipulators to be discovered. In other branches of robotics, one can discern a similar historical pattern: new classes of robot body plan were successively proposed that required less and less explicit control. In the field of legged locomotion for example, robots with *whegs* (wheel-leg hybrids) were shown to require less explicit control than robots with legs to enable travel over rough terrain [37.25].

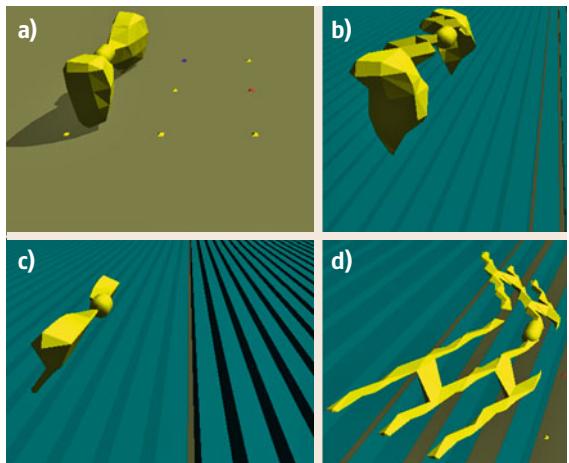

These observations suggest that robots with more morphological computation are less intuitive for humans to formulate and then design than robots with less morphological computation. However, there may be a benefit to creating robots that exhibit significant amounts of morphological computation. For example, hybrid dynamic walkers require very little control and are much more energy efficient compared to fully actuated legged robots [37.26]. It has been argued that tensegrity robots also require relatively little control compared to robots composed of serially linked rigid components, and this class of robot has several desirable properties such as the ability to absorb and recover from external perturbations [37.9].

So, if robots that exhibit morphological computation are desirable, yet it is difficult for humans to navigate in this part of the space of possible robots, can an automated search method be used to discover such robots?

### 37.2.2 Evolution and Morphological Computation

One of the advantages of using evolutionary algorithms to design robots, compared to machine learning methods, is that both the body plan and the control policy can be placed under evolutionary control [37.27]. Typically, machine learning methods optimize some of the parameters of a control policy with a fixed topology. However, if the body plans and control policies of robots are evolved, and there is sufficient variation within the population of evolving robots, search may discover multiple successful robots that exhibit varying degrees of morphological computation. Or, alternatively, if morphological computation confers a survival advantage within certain contexts, a phylogeny of robots may evolve that exhibit increasing amounts of morphological computation.

A recent pair of experiments illustrates how morphological computation may be explored. An evolutionary algorithm was employed to evolve the body plans

**Fig. 37.1a–d** A sample of four evolved robots with differing amounts of morphological complexity. **(a)** A simple-shaped robot that evolved to locomote over flat ground. **(b–d)** Three sample robots, more morphologically complex than the robot in **(a)**, that evolved in icy environments (after Auerbach and Bongard [37.28]). To view videos of these robots see [37.29]

and control policies of robots that must move in one of two environments. The first environment included nothing else other than a flat, high-friction ground plane (Fig. 37.1a). The second environment was composed of a number of low-friction bars that sit atop the high-friction ground plane (Fig. 37.1b–d). These bars can be thought of as ice distributed across a flat landscape. In order for robots to move across the icy terrain, they must evolve appendages that are able to reach down between the icy blocks, come into contact with the high-friction ground, and push or pull themselves forward.

It was found that robots evolved to travel over the ice had more complex shapes than those evolved to travel over flat ground (compare the robot in Fig. 37.1a to those in Fig. 37.1b–d) [37.28]. However, it was also found that the robots that travel over ice had fewer mechanical degrees of freedom (DOFs) than the robots evolved to travel over flat ground [37.30]. If a robot possesses fewer mechanical DOFs, one can conclude that it has a simpler control policy, because there are fewer motors to control. It seems that the robots evolved to travel over ice do so in the following manner: the complex shapes of their appendages cause the appendages to *reach* down into the crevices between the ice without explicit control; the simple control policy then simply sweeps the appendages back and

forth, horizontally, to in effect *skate* along the tops of the ice. In contrast, robots evolved to travel over flat ground must somehow push back, reach up, and pull forward – using several mechanical DOFs – to move forward.

One could conclude from these experiments that the robots evolved to travel over ice perform more morphological computation than those evolved to travel

over flat ground: the former robots have more complex bodies but simpler control policies than the latter robots, yet both successfully move in their environments. Much more work is required to generalize this result to different robots, behaviors, and environments, but this initial work suggests that evolutionary robotics may be a unique tool for studying the phenomenon of morphological computation.

## 37.3 Sensory–Motor Coordination in Evolving Robots

The actions performed by embodied and situated agents inevitably modify the agent–environmental relation and/or the environment. The type of stimuli that an agent will sense at the next time step at  $t+1$  crucially depends, for example, on whether the agent turns left or right at the current time  $t$ . Similarly, the stimuli that an agent will experience next at time  $t+1$  when standing next to an object depend on the effort with which it will push the object at time  $t$ . This implies that actions might play direct and indirect adaptive roles. Actions playing a direct role are, for example, foraging or predator escaping behaviors that directly impact on the agent’s own survival chances. Action playing indirect roles consists, for example, in wandering through the environment to spot interesting sensory information (e.g., the perception of a food area that might eventually afford foraging actions) or playing a fighting game with a conspecific that might enable the agent to acquire capacities that might later be exploited to deal with aggressive individuals. The possibility to self-select useful sensory stimuli through action is referred with the term sensory–motor coordination.

Together with morphological computation, sensory–motor coordination constitutes a fundamental property of embodied and situated agents and one of most important characteristic that can be used to differentiate these systems from alternative forms of intelligence. In the following sections, we illustrate three of the key roles that can be played by sensory–motor coordination:

- i) The discovery of parsimonious behavioral strategies
- ii) The access and generation of useful sensory information through action and active perception
- iii) The constraining and channeling of the learning process during evolution and development.

### 37.3.1 Enabling the Discovery of Simple Solutions

Sensory–motor coordination can be exploited to find solutions relying on more parsimonious control policies than alternative solutions not relying, or relying less, on this principle. An example is constituted by a set of experiments in which a Khepera robot [37.31] endowed with infrared and speed sensors, has been evolved for the ability to remain close to large cylindrical objects (food) while avoiding small cylindrical objects (dangers). From a passive perspective, that does not take into account the possibility to exploit sensory–motor coordination, the ability to discriminate between sensory stimuli experienced near small and large cylindrical objects requires a relatively complex control policy since the two classes of stimuli strongly overlap in the robot’s perceptual space [37.32]. On the other hand, robots evolved for the ability to perform this task tend to converge on a solution relying on a rather simple control policy: the robots begin to turn around objects as soon as they approach them and then discriminate the size of the object on the basis of the sensed differential speed of the left and right wheels during the execution of the object-circling behavior [37.33]. In other words, the execution of the object-circling behavior allows the robots to experience sensory stimuli on the wheel sensors that are well differentiated for small and large objects. This, in turn, allows them to solve the object discrimination problem with a rather simple but reliable control policy.

Another related experiment in which a Khepera robot provided solely with infrared sensors was adapted for finding and remaining close to a cylindrical object, while avoiding walls, demonstrates how sensory–motor coordination can be exploited to solve tasks that require the display of differentiated behavior in different

environmental circumstances, without discriminating the contexts requiring different responses [37.32, 34]. Indeed, evolved robots manage to avoid walls, find a cylindrical object, and remain near it simply by moving backward or forward when their frontal infrared sensors are activated or not, respectively, and by turning left or right when their right and left infrared sensors are activated, respectively (providing that the turning speed and the move forward speed is appropriately regulate on the basis of the sensors activation). Indeed, the execution of this simple control rule combined with the effects of the robot's actions lead to the exhibition of a move-forward behavior far from obstacles, an obstacle avoidance behavior near walls, and an oscillatory behavior near cylindrical objects (in which the robot remains near the object by alternating forward and backward and/or turn-left and turn-right movements). The differentiation of the behavior observed during the robot/wall and robot/cylinder interactions can be explained by considering that the execution of the same action produces different sensory effects in interaction with different objects. In particular, the execution of a turn-left action at time  $t$  elicited by the fact that the right infrared sensors are more activated than the left sensors near an object leads to the perception of: (i) a similar sensory stimulus eliciting a similar action at time  $t+1$ , ultimately producing an object avoidance behavior near a wall object, (ii) a different sensory stimulus (in which left infrared sensors can become more activated than the left infrared sensors) eliciting a turn-right action at time  $t+1$  ultimately producing an oscillatory behavior near the cylinder.

Examples of clever use of sensory–motor coordination abound in natural and artificial evolution. A paradigmatic example of the use of sensory–motor coordination in natural organisms are the navigation capabilities of flying insects that are based on the optic flow, i. e., the apparent motion of contrasting objects in the visual field caused by the relative motion of the agent [37.35]. Houseflies, for example, use this solution to navigate up to 700 body lengths per second in unknown 3D environment while using quite modest processing resources, i. e., about 0.001% of the number of neurons present in the human brain [37.36]. Examples in the evolutionary robotics literature include wheeled robots performing navigation tasks ([37.32], see below), artificial fingers and humanoid robotic arms evolved for the ability to discriminate between object varying in shapes [37.20, 37], and wheeled robots able to navigate visually by using a pan-tilt camera [37.38].

### 37.3.2 Accessing and Generating Information Through Action

A second fundamental role of sensory–motor coordination consists in accessing and/or generating useful sensory information through action. Differently from experimental settings in which stimuli are brought to the passive agent by the experimenter, in ecological conditions agents need to access relevant information through action. For example, infants access the visual information necessary to recognize the 3D structure of an object by rotating it in the hand and by keeping it at close distance so to minimize visual occlusions [37.39]. The use of sensory–motor coordination for this purpose is usually named *active perception* [37.37, 40, 41].

Interestingly, action can be exploited not only to access sensory information but also to generate it. To understand this aspect, we should consider that through their action agents can elaborate the information they access through their sensory system over time and store the result of the elaboration in their body state and/or in their posture or location. A well-known example of this phenomenon is constituted by depth perception as a result of convergence, i. e., the simultaneous inward movement of both eyes toward each other, to maintain a single binocular percept of a selected object. The execution of this behavior produces a kinesthetic sensation in the eye muscles that reliably correlates with the object's depth.

The careful reader might have recognized that the robot's behavioral discrimination strategies to perceive larger and smaller cylindrical objects, described in the previous section, exploit the same active perception mechanism. For a robot provided with infrared and wheel-speed sensors, the perception of object size necessarily requires a capacity to integrate the information provided by several stimuli. The elaboration of this information however is not realized internally, within the robot's nervous system, but rather externally through the exhibition of the object-circling behavior. It is this behavior that generates the corresponding kinesthetic sensation on the wheel sensors that is then used by the robot to decide to remain or leave, depending on the circumstances.

Examples of clever strategies able to elaborate the required information through action and active perception abound in evolutionary robotics experiments. By carrying out an experiment in which a robot needed to reach two foraging areas located in the northeast and southwest side of a rectangular environment surrounded by walls, *Nolfi* [37.34] observed that the evolved robots

developed a clever strategy that allows them to compute the relative length of the two sides of the environment and to navigate toward the two right corners on the basis of a simple control policy. The strategy consists in leaving the first encountered corner with an angle of about 45° with respect to the two sides, moving straight, and then eventually following the left side of the next encountered wall ([37.34] for details). Another clever exploitation of sensory–motor coordination was observed in an experiment involving two cooperating robots that helped each other to navigate toward circular target areas [37.42]. Evolved robots discovered and displayed a behavior solution that allowed them to inform each other on the relative location of the center of their target navigation area despite their sensory system being unable to detect their relative position within the area [37.42].

### 37.3.3 Channeling the Course of the Learning Process

A third fundamental role of sensory–motor coordination consists in channeling the course of the forthcoming adaptive process.

The sensory states experienced during learning crucially determine the course and the outcome of the learning process [37.43]. This implies that the actions displayed by an agent, that co-determine the agent’s forthcoming sensory states, ultimately affect how the agent changes ontogenetically. In other words, the behavior exhibited by an agent at a certain stage of its

development constraints and channels the course of the agent’s developmental process.

Indeed, evolutionary robotics experiments indicate how the evolution of plastic agents (agents that vary their characteristics while they interact with the environment [37.44]) lead to qualitatively different results with respect to the evolution of nonplastic individuals. The traits evolved in the case of nonplastic individuals are selected directly for enabling the agent to display the required capabilities. The traits evolved in the case of plastic individuals, instead, are selected primarily for enabling the agents to acquire the required capabilities through an ontogenetic adaptation process. This implies that, in this case, the selected traits do not enable the agent to master their adaptive task (agents tend to display rather poor performance at the beginning of their lifetime) but rather to acquire the required capacities through ontogenetic adaptation.

More generally, the behavioral strategies adopted by agents at a certain stage of their developmental process can crucially constrain the course of the adaptive process. For example, agents learning to reach and grasp objects might temporarily reduce the complexity of the task to be mastered by freezing (i. e., locking) selected DOFs and by then unfreezing them when their capacity reaches a level that allows them to master the task in its full complexity [37.45, 46]. This type of process can enable exploratory learning by encompassing variation and selection of either the general strategy displayed by the agent or the specific way in which the currently selected strategy is realized.

## 37.4 Developmental Robotics for Higher Order Embodied Cognitive Capabilities

### 37.4.1 Embodied Cognition and Developmental Robots

The previous sections have demonstrated the fundamental role of embodiment and of the agent–environment coupling in the design of adaptive agents and robots capable to perform sensory–motor tasks such as navigation and object discrimination. However, embodiment also plays an important role in higher order cognitive capabilities [37.12], such as object categorization and representation, language learning, and processing, and even the acquisition of abstract concepts such as numbers. In this section, we will consider some of the key psychological and neuroscience ev-

idence of EC and its contribution in the design of linguistic and numerical skills in cognitive robots.

Intelligent behavior has traditionally been modeled as a result of activation patterns across distributed knowledge representations, such as hierarchical networks of interrelated propositional (symbolic) nodes that represent objects in the world and their attributes as abstract, amodal (nonembodied) entities [37.47]. For example, the response *bird* to a flying object with feathers and wings would result from perceiving its features and retrieving its name from memory on the basis of a matching process. Such traditional views were attractive for a number of reasons: They followed the predominant philosophical tradition of logical concep-

tual knowledge organization, according to which all objects are members of categories and category membership can be determined in an all-or-none fashion via defining features. Also, such hierarchical knowledge networks were consistent with cognitive performance in simple tasks such as speeded property verification, which were thought to tap into the retrieval of knowledge. For example, verifying the statement *a bird has feathers* was thought to be easier than verifying the statement *a bird is alive* because the feature *feathers* was presumably stored in memory as defining the category *bird*, while the feature *alive* applies to all animals and was therefore represented at a superordinate level of knowledge, hence requiring more time to retrieve after having just processed *bird* [37.47]. Finally, it was convenient to computationally model such networks by likening the human mind to an information processing device with systematic input, storage, retrieval, and output mechanisms. Thus, knowledge was considered as an abstract commodity independent of the physical device within which it was implemented.

More recent work called into question several of these assumptions about the workings of the human mind. For example, graded category memberships and prototypicality effects in categorization tasks pointed to disparities between the normative logical knowledge organization and the psychological reality of knowledge retrieval [37.48]. Computational modeling of cognitive processes has revealed alternative, distributed representational networks for computing intelligent responses in perceptual, conceptual, and motor tasks that avoid the neurophysiologically implausible assumption of localized storage of specific knowledge [37.49]. Most importantly, though, traditional propositional knowledge networks were limited to explaining the meaning of any given concept in terms of an activation pattern across other conceptual nodes, thus effectively defining the meaning of one symbol in terms of arbitrary other symbols. This process never referred to a concrete experience or event and essentially made the process of connecting internal and external referents arbitrary. In other words, traditional knowledge representations never make contact with specific sensory and motor modalities that is essential to imbue meaning to the activation pattern in a network. This limitation is known as the grounding problem [37.50] and points to a fundamental flaw in traditional attempts to model human knowledge representations.

A second reason for abandoning traditional amodal models of knowledge representation is the fact that these models cannot account for patterns of sensory

and motor excitation that occur whenever we activate our knowledge. Already at the time when symbol manipulation approaches to intelligent behavior had their heyday there was powerful evidence for a mandatory link between intelligent thought and sensory-motor experience: When matching two images of the same object, the time we need to recognize that it is the same object is linearly related to the angular disparity between the two views [37.15]. This result suggests that the mental comparison process simulates the physical object rotation we would perform if the two images were manipulable in our hands. In recent years, there has been both more behavioral and also neuroscientific evidence of an involvement of sensory-motor processes in intelligent thought, leading to the influential notion of action simulation as an obligatory component of intelligent thought (for review, [37.51]).

To summarize, the idea that sensory and motor processes are an integral part of our knowledge is driven by both theoretical and empirical considerations. On the theoretical side, the EC stance addresses the grounding problem, a fundamental limitation of classical views of knowledge representation. Empirically, it is tough for traditional amodal conceptualizations of knowledge to address systematic patterns of sensory and motor biases that accompany knowledge activation.

Amongst the latest development in robotics and computational intelligence, the field of developmental robotics has specifically focused on the essential role of EC in the ontogenetic development of cognitive capabilities. Developmental robotics (also known as epigenetic robotics and as the field of autonomous mental development) is the interdisciplinary approach to the autonomous design of behavioral and cognitive capabilities in artificial agents (robots) that takes direct inspiration from the developmental principles and mechanisms observed in natural cognitive systems (children) [37.18, 52–54]. In particular, the key principle of developmental robotics is that the robot, using a set of intrinsic developmental principles regulating the real-time interaction between its body, brain, and environment, can autonomously acquire an increasingly complex set of sensorimotor and mental capabilities. Existing models in developmental robotics have covered the full range of sensory-motor and cognitive capabilities, from intrinsic motivation and motor control to social learning, language and reasoning with abstract knowledge ([37.18] for a full overview).

To demonstrate the benefits of combining EC with developmental robotics in the modeling of embodied intelligence, the two domains of the action bases of

language and of the relationship between space and numerical cognition have been chosen. In Sect. 37.4.2, we will look at seminal examples of the embodied bases of language in psycholinguistics, neuroscience, and developmental psychology, and the corresponding developmental robotics models. Section 37.4.3 will consider EC evidence on the link between spatial and numerical cognition, and a developmental robotics model of embodied language learning.

### 37.4.2 Embodied Language Learning

In experimental psychology and psycholinguistics, an influential demonstration of action simulation as part of language comprehension was first carried out by *Glenberg and Kaschak* [37.55]. They asked healthy adults to move their right index finger from a button in their mid-sagittal plane either away from or toward their body to indicate whether a visually presented statement was meaningful or not. Sentences like *Open the drawer* led to faster initiation of movements toward than away from the body, while sentences like *Close the drawer* led to faster initiation of movements away from than toward the body. Thus, there was a congruency effect between the implied spatial direction of the linguistic description and the movement direction of the reader's motor response. This motor congruency effect in language comprehension has been replicated and extended (for review, [37.56]). It suggests that higher level cognitive feats (such as language comprehension) are ultimately making use of lower level (sensory–motor) capacities of the agent, as predicted by an embodied account of intelligence.

In parallel, growing cognitive neuroscience evidence has shown that the cortical areas of the brain specialized for motor processing are also involved in language processing tasks; thus supporting the EC view that action and language are strictly integrated [37.57, 58]. For example, *Hauk et al.* [37.59] carried out brain imaging experiments where participants read words referring to face, arm, or leg actions (e.g., *lick*, *pick*, *kick*). Results support the embodied view of language, as the linguistic task of reading a word differentially activated parts of the premotor area that were directly adjacent, or overlapped, with region activated by actual movement of the tongue, the fingers, or the feet, respectively.

The embodied nature of language has also been shown in developmental psychology studies, as in *Tomasello's* [37.60] constructivist theory of language acquisition and in *Smith and Samuelson's* [37.61] study on embodiment biases in early word learning. For ex-

ample, *Smith and Samuelson* [37.61] investigated the role of embodiment factors such as posture and spatial representations during the learning of first words. They demonstrated the importance of the changes in postures involved in the interaction with objects located in different parts (left and right) of the child's peripersonal space. Experimental data with 18-month old children show that infants can learn new names also in the absence of the referent objects, when the new label is said whilst the child looks at the same left/right location where the object has previously appeared. This specific study was the inspiration of a developmental robotics study on the role of posture in the acquisition of object names with the iCub baby robot [37.62].

The iCub is an open source robotic platform developed as a benchmark experimental tool for cognitive and developmental robotics research [37.63]. It has a total of 53 DOF, with a high number of DOF (32) in the arms and hands to study object manipulation and the role of fine motor skills in cognitive development. This facilitates the replication of the experimental setup of *Smith and Samuelson's* study [37.61]. In the iCub experiments, a human tutor shows two novel objects respectively in the left and right location of a table put in front of the robot. Initially the robot moves to look at each object and learns to categorize it according to its visual features, such as shape and color. Subsequently the tutor hides both objects, directs the robot's attention toward the right side where the first object was shown and says a new word: *Modi*. In the test phase both objects are presented simultaneously in the centre of the table, and the robot is asked *Find the modi*. The robot must then look and point at the object that was presented in the right location. Four different experiments were carried out, as in Smith and Samuelson's child study. Two experiments differ with regards to the frequency of the left/right locations used to show each objects: the Default Condition when each object always appears in the same location, and the Switch Condition when the position of the two objects is varied to weaken the object/location spatial association. In the other two experimental conditions, the object is named whilst in sight, so to compare the relative weighting of the embodiment spatial constraints and the time constraint.

The robot's behavior is controlled by a modular neural network consisting of a series of pretrained Kohonen self-organizing maps (SOMs), connected through Hebbian learning weights that are trained online during the experiment [37.64]. The first SOM is

a *color map* as it is used to categorize objects according to their color (average RGB (red-green-blue) color of the foveal area). The second map, the *auditory map*, is used to represent the words heard by the robot, as the result of the automatic speech recognition system. The other **SOM** is the *body-hub map*, and this is the key component of the robot's neural system that implements the role of embodiment. The body-hub **SOM** has four inputs, each being the angle of a single joint. In the experiments detailed here only 2 degrees from the head (up/down and left/right motors), and 2 degrees from the eyes (up/down and left/right motors) are used. Embodiment is operationalized here as the posture of eye and head position when the robot has to look to the left and to the right of the scene.

During each experiment, the connection weight linking the color map and the auditory map to the body-hub map are adjusted in real time using a Hebbian learning rule. These Hebbian associative connections are only modified from the current active body posture node. As the maps are linked together in real time, strong connections between objects typically encountered in particular spatial locations, and hence in similar body postures, build up.

To replicate the four experimental conditions of *Smith* and *Samuelson* [37.61], 20 different robots were used in each condition, with new random weights for the **SOM** and Hebbian connections. Results from the four conditions show a very high match between the robot's data and the child experiment results, closely replicating the variations in the four conditions. For example, in the Default Condition 83% of the trials resulted in the robots selecting the spatially linked objects, whilst in the Switch condition, where the space/object association was weakened, the robots' choices were practically due to chance at 55%. *Smith* and *Samuelson* [37.61] reported 71% of children selected the spatially linked object, versus 45% in the Switch condition.

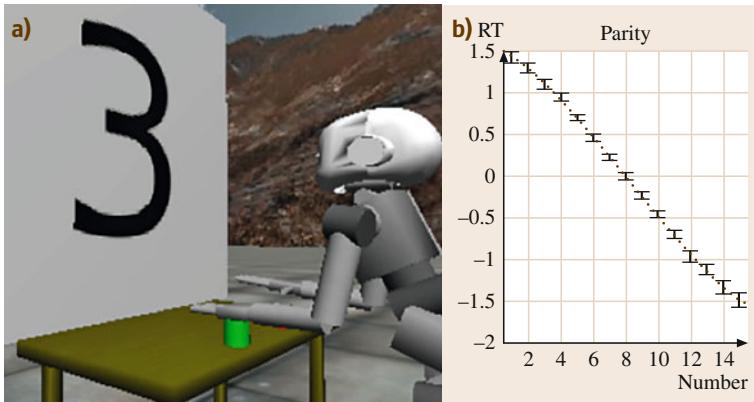

This model demonstrates that it is possible to build an embodied cognitive system that develops linguistic and sensorimotor capabilities through interaction with the world, closely resembling the embodiment strategies observed in children's acquisition early word learning. Other cognitive robotics models have also been developed which exploit the principle of embodiment in robots' language learning, as in models of compositionality in action and language [37.65–68], in models of the cultural evolution of construction grammar [37.69, 70], and the modeling of the grounding of abstract words [37.71].

### 37.4.3 Number and Space

Number concepts have long been considered as prototypical examples of abstract and amodal concepts because their acquisition would require generalizing across a large range of instances to discover the invariant cardinality meaning of words such as *two* and *four* [37.72]. Mental arithmetic would therefore appropriately be modeled as abstract symbol manipulation, such as incrementing a counter or retrieving factual knowledge [37.73]. But evidence for an inescapable reference back from abstract number concepts to the sensori-motor experiences during concept acquisition has been present for a long time. Specifically, *Moyer* and *Landauer* [37.74] showed that the speed of deciding which of two visually presented digits represents the larger number depends on their numerical distance, with faster decisions for larger distances. Thus, even in the presence of abstract symbols we seem to refer to analog representations, as if comparing sensory impressions of small and large object compilations.

More recent studies provided further evidence that sensory-motor experiences have a strong impact on the availability of number knowledge. This embodiment signature can be documented by measuring the speed of classifying single digits as odd or even with lateralized response buttons. The typical finding is that small numbers (1, 2) are classified faster with left responses and large numbers (8, 9) are classified faster with right responses [37.76]. This spatial-numerical association response codes, or **SNARC**s effect, has been replicated across several tasks and extended to other effectors (for review [37.77]), including even attention shifts to the left or right side induced by small or large numbers, respectively [37.78].

Importantly, **SNARC** depends on one's sensory-motor experiences, such as directional scanning and finger counting habits, as well as current task demands. For example, the initial acquisition of number concepts in childhood occurs almost universally through finger counting and this learning process leaves a residue in the number knowledge of adults. Those who start counting on their left hand, thereby associating small numbers with left space, have a stronger **SNARC** than those who start counting on their right hand [37.79]. Similarly, reading direction modulates the strength of **SNARC**. In the original report by *Dehaene* et al. [37.76], it was noticed that adults from a right-to-left reading culture presented with weaker or even reversed **SNARC**. The notion of a spill-over of directional reading habits into the domain of num-

**Fig. 37.2a,b** (a) iCub simulation model of the **SNARC** (spatial–numerical association response code) effect; (b) **SNARC** effect results, with the difference in reaction times (right minus left hand) is plotted against number magnitude (after [37.75])

ber knowledge was further supported by developmental studies showing that it takes around 3 years of schooling before the **SNARC** emerges [37.80]. However, more recent work has found **SNARC** even in preschoolers (for review [37.81]), thus lending credibility to the role of embodied practices such as finger counting in the formation of **SNARC**.

In a recent series of experiments with Russian–Hebrew bilinguals, Shaki et al. [37.82–84] (for review [37.85]) documented that both one’s habitual reading direction and the most recent, task-specific scanning direction determine the strength of one’s **SNARC**. These findings make clear that **SNARC** is a compound effect where embodied and situated (task-specific) factors add different weights to the overall **SNARC**.

**SNARC** and other biases extend into more complex numerical tasks such as mental arithmetic. For example, the association of larger numbers with right space is also present during addition (the operational momentum or **OM** effect). Regardless of whether symbolic digits or nonsymbolic dot patterns are added together, participants tend to over-estimate the sum, and this bias also influences spatial behavior [37.86]. More generally, intelligent behavior such as mental arithmetic seems to reflect component processes (distance effect, **SNARC** effect, **OM** effect) that are grounded in sensorimotor experiences.

The strong link between spatial cognition and number knowledge permits the modeling of the embodiment processes in the acquisition of number in robots. This has been the case with the recent developmental model developed by Rucinski et al. [37.75, 87] to model the **SNARC** effect and the contribution of pointing gestures in number acquisition. In the first study [37.75], a simulation model of the iCub is used. The robot is first trained to develop a body schema of the upper

body through motor babbling of its arms. The iCub is subsequently trained to learn to recognize numbers by associating quantities of objects with numerical symbols as 1 and 2. In the **SNARC** test case, the robot has to perform a psychological-like experiment and press a left or right button to make judgments on number comparison and parity judgment (Fig. 37.2b).

The robot’s cognitive architecture is based on a modular neural network controller with two main components, following inspiration from a connectionist model of numerical cognition [37.88] and the TRoPI-CALS cognitive architecture of Caligioire et al. [37.89, 90]. The two main components of the neural control system are: (i) *ventral* pathway network, responsible for processing of the identity of objects as well as task-dependent decision making and language processing; and (ii) *dorsal* pathway network, involved in processing of spatial information about locations and shapes of objects and processing for the robot’s action.

The *ventral* pathway is modeled, following Chen and Verguts [37.88], with a symbolic input which encodes the alphanumerical number symbols of numbers from 1 to 15, a mental number line encoding the number meaning (quantity), a decision layer for the number comparison and parity judgment tasks, and a response layer, with two neurons for left/right hand response selection. The *dorsal* pathway is composed of a number of **SOMs** which code for spatial locations of objects in the robot peripersonal space. One map is associated with gaze direction, and two maps respectively for each of the robot’s left and right arms. The input to the gaze map arrives from the 3-dimensional proprioceptive vector representing the robot gaze direction (azimuth, elevation and vergence). The input to each arm position map consists of a 7-dimensional proprioceptive vector representing the position of the relevant arm joints. This

dorsal pathway constitutes the core component of the model where the embodied properties of the model are directly implemented as the robot's own sensorimotor maps.

To model the developmental learning processes involved in number knowledge acquisition, a series of training phases are implemented. For the embodiment part, the robot is first trained to perform a process equivalent to motor babbling, to develop the gaze and arm space maps. With motor babbling the robot builds its internal visual and motor space representations (**SOMs**) by performing random reaching movements to touch a toy in its peripersonal space, whilst following its hand's position. Transformations between the visual spatial map for gaze and the maps of reachable left and right spaces are implemented as connections between the maps, which are learned using the classical Hebbian rule. At each trial of motor babbling, gaze and appropriate arm are directed toward the same point and resulting co-activations in already developed spatial maps is used to establish links between them.

The next developmental training establishes the links between number words (modeled as activations in the ventral input layer) and the number meaning (activations in the mental number line hidden layer). Subsequently the robot is taught to count. This stage models the cultural biases that result in the internal association of *small* numbers with the left side of space and *large* numbers with the right side. As an example of these biases, we considered a tendency of children to count objects from left to right, which is related to the fact that European culture is characterized by left-to-right reading direction [37.91]. In order to model the process of learning to count, the robot was exposed to an appropriate sequence of number words (fed to the ventral input layer of the model network), while at the same time the robot's gaze was directed toward a specific location in space (via the input to the gaze visual map). These spatial locations were generated in such a way that their horizontal coordinates correlated with number magnitude (small numbers presented on the left, large numbers on the right) with a certain amount of Gaussian noise. During this stage, Hebbian learning established links between number word and stimuli location in the visual field.

Finally, the model is trained to perform number reasoning tasks, such as number comparison and parity judgment, which corresponds to establishing appropriate links between the mental number line hidden layer and neurons in the decision layer. Specifically, one

experiment focuses on the modeling of the **SNARC** effect. The robot's reaction time (i.e., amount of activity needed to exceed a response threshold in one of the two response nodes) in parity judgment and number comparison tasks were recorded to calculate the difference between right hand and left hand RTs for the same number. When difference values are plotted against number magnitudes the **SNARC** effect manifests itself in a negative slope as in Fig. 37.2. As the connections between visual and motor maps form a gradient from left to right, the links to the left arm map become weaker, while those to the right become stronger. Thus, when a small number is presented, internal connections lead to stronger automatic activation of the representations linked with the left arm than that of the right arm, thus causing the **SNARC** effect.

This model of space and number knowledge was also extended to include a more active interaction with the environment during the number learning process. This is linked to the fact that gestures such as pointing at the object being counted, or the actual touching of the objects enumerated, has been shown to improve the overall counting performance in children [37.92]. In the subsequent model by Rucinski et al. [37.87], a simpler neural control architecture was used based on the Elman recurrent network to allow sequential number counting and the representation of gestures as proprioceptive states for the pointing gestures. The robot has to learn to produce a sequence of number words (from 1 to 10) with the length of the sequence equivalent to the number of objects present in the scene. Visual input to the model is a one-dimensional saliency map, which can be considered a simple model of a retina. In input, the additional proprioceptive signal was obtained from a pointing gesture performed by the iCub humanoid robot and is used to implement the gestural input to the model in the pointing condition. The output nodes encode the phonetic representation of the 10 numbers.

During the experiment, the robot is first trained to recite a sequence of number words. Then, in order to assess the impact of the proprioceptive information connected with the pointing gesture, the training is divided into two conditions: (i) training to count the number of objects shown to the visual input in the absence of the proprioceptive gesture signal, and (ii) counting through pointing, via the activation of the gesture proprioceptive input. Results show that such a simple recurrent architecture benefits from the input of the proprioceptive gesturing signal, with improved counting accuracy. In particular, the model reproduces

the quantitative effects of gestures on the counted set size, replicating child psychology data reported in [37.92].

Overall, such a developmental robotics model clearly shows that the modeling of embodiment phenomena, such as the use of spatial representation in number judgments, and of the pointing gestures for

number learning, can allow us to understand the acquisition of abstract concepts in humans as well as artificial agents and robots. This further demonstrates the benefit of the embodied intelligence approach to model a range of behavioral and cognitive phenomena from simple sensory–motor tasks to higher order linguistic and abstract cognition tasks.

## 37.5 Conclusion

This chapter has provided an overview of the three key principles of embodied intelligence, namely morphological computation, sensory–motor coordination, and EC, and of the experimental approaches and models from evolutionary robotics and developmental robotics. The wide range of behavioral and cognitive capabilities modeled through evolutionary and developmental experiments (e.g., locomotion in different environments, navigation and object discrimination, posture in early word learning and space and number integration) demonstrates the impact of embodied intelligence in the design of a variety of perceptual, motor and cognitive skills, including the potential to model the embodied basis of abstract knowledge as in numerical cognition.

The current progress of both evolutionary and developmental models of embodied intelligence, although showing significant scientific and technological advances in the design of embodied and situated agents, still has a series of open challenges and issues. These issues are informing ongoing work in the various fields of embodied intelligence.

One open challenge in morphological computation concerns how best to automatically design the body plans of robots so that they can best exploit this phenomenon. In parallel to this, much work remains to be done to understand what advantages morphological computation confers on a robot. For one, it is likely that a robot with a simpler control policy will be more robust to unanticipated situations: for example the jamming gripper is able to grasp multiple objects with the same control strategy; a rigid hand requires different control strategies for different objects. Secondly, a robot that performs more morphological computation may be more easily transferred from the simulation in which it was evolved to a physical machine: with a simpler control policy there is less that can go wrong when experiencing the different sensor signals and motor feedback generated by operation in the physical world.

Evolving robots provides a unique opportunity for developing rigorous methods for measuring whether and how much morphological computation a robot performs. For instance, if evolutionary algorithms can be designed that produce robots with similar abilities yet different levels of control and morphological complexity, and it is found that in most cases reduced control complexity implies greater morphological complexity, this would provide evidence for the evolution of morphological computation.

The emerging field of soft robotics [37.93] provides much opportunity for exploring the various aspects of morphological computation because the space of all possible soft robot body plans – with large variations in shape and continuous admixtures of hard and soft materials – is much larger than the space of rigid linkages traditionally employed in *classical* robots.

The design issue, i. e., the question of how systems able to exploit coordinated action and perception processes can be designed, represents an open challenge for sensory–motor coordination as well. As illustrated above, adaptive techniques in which the fine-grained characteristics that determine how agents react to current and previous sensory states are varied randomly and in which variations are retained or discarded on the basis of their effects at the level of the overall behavior exhibited by the agent/s interacting with their environment constitutes an effective method. However, this method might not scale up well with the number of parameters to be adapted. The question of how sensory–motor coordination capabilities can be acquired through the use of other learning techniques that relays on shorter term feedbacks represents an open issue. An interesting research direction, in that respect, consists in the hypothesis that the development of sensory–motor coordination can be induced through the use of task independent criteria such as information theoretic measures [37.94, 95].

Other important research directions concerns the theoretical elaboration of the different roles that morphological computation and sensory–motor coordination can play and the clarification of the relationship between processes occurring as a result of the agent/environmental interactions and processes occurring inside the agents’ nervous systems

In developmental robotics models of EC the issues of open-ended, cumulative learning and of the scaling up of the sensory–motor and cognitive repertoires still requires significant efforts and novel methodological and theoretical approaches. Another issue, which combines both evolutionary and developmental approaches, is the interaction of phylogenetic and ontogenetic phenomena in the body/environment/brain adaptation.

Human development is characterized by cumulative, open-ended learning. This refers to the fact that learning and development do not start and stop at specific stages, but rather this is a life-long learning experience. Moreover, the skills acquired in various developmental stages are accumulated and integrated to support the further acquisition of more complex capabilities. One consequence of cumulative, open-ended learning is cognitive bootstrapping. For example in language development, the phenomenon of the vocabulary spurt exist, in which the knowledge and experience from the slow learning of the first 50–100 words causes a redefinition of the word learning strategy, and to syntactic bootstrapping, where children rely on syntactic cues and word context in verb learning to determine the meaning of new verbs [37.96]. Although some computational intelligence models of the vocabulary spurt exist [37.97], robotic experiments on language learning have been restricted to smaller lexicons, not reaching the critical threshold to allow extensive modeling of the bootstrapping of the agent’s lexicon and grammar knowledge. These current limitations are also linked to the general issue of the scaling up of the robot’s motor and cognitive capabilities and of cross-modal learning. Most of the current cognitive robotics models typically focus on the separate acquisition of only one task or modality (perception, or phonetics, or semantics etc.), often with limited repertoires rarely reaching 10 or slightly more learned actions or words. Thus a truly online, cross-modal, cumulative, open-ended developmental robotics model remains a fundamental challenge to the field.

Another key challenge for future research is the modeling of the interaction of the different timescales of adaptation in embodied intelligence, that is between phylogenetic (evolutionary) factors and ontogenetic (development, learning, maturation) phenomena. For example, maturation refers to changes in the anatomy and physiology of both the child’s brain and the body, especially during the first years of life. Maturational phenomena related to the brain include the decrease of brain plasticity during early development, whilst maturation in the body is more evident due to the significant morphological growth changes a child goes through from birth to adulthood (see *Thelen and Smith*’s analysis of crawling and walking [37.98]). The ontogenetic changes due to maturation and learning have important implications for the interaction of development with phylogenetic changes due to evolution. Body morphology and brain plasticity variations can be in fact explained as evolutionary adaptations of the species to changing environmental context as with heterochronic changes [37.99]. For example, *Elman* et al. [37.43] discuss how genetic and heterochronic mechanisms provide an alternative explanation of the nature/nurture debate, where genetic phenomena produce architectural constraints of the organism’s brain and body, which subsequently control and affects the results of learning interaction. Following this, *Cangelosi* [37.100] has tested the effects of heterochronic changes in the evolution of neural network architectures for simulated robotic agents.

The interaction between ontogenetic and phylogenetic factors has been investigated through evolutionary robotics models. For example, *Hinton* and *Nolan* [37.101] and *Nolfi* et al. [37.102] have developed evolutionary computational models explaining the effects of learning in evolution. The modeling of the evolution of varying body and brain morphologies in response to phylogenetic and ontogenetic requirements is also the goal of the *evo-devo* field of computational intelligence [37.7, 103–105]. These evolutionary/ontogenetic interaction models have, however, mostly focused on simple sensory–motor tasks such as navigation and foraging. Future work combining evolutionary and developmental robotics models can better provide theoretical and technological understanding of the contribution of different adaptation time scales and mechanisms in embodied intelligence.

# Neuromorph

## 38. Neuromorphic Engineering

Giacomo Indiveri

Neuromorphic engineering is a relatively young field that attempts to build physical realizations of biologically realistic models of neural systems using electronic circuits implemented in very large scale integration technology. While originally focusing on models of the sensory periphery implemented using mainly analog circuits, the field has grown and expanded to include the modeling of neural processing systems that incorporate the computational role of the body, that model learning and cognitive processes, and that implement large distributed spiking neural networks using a variety of design techniques and technologies. This emerging field is characterized by its multidisciplinary nature and its focus on the physics of computation, driving innovations in theoretical neuroscience, device physics, electrical engineering, and computer science.

### 38.1 The Origins

Models of neural information processing systems that link the type of information processing that takes place in the brain with theories of computation and computer science date back to the origins of computer science itself [38.1, 2]. The theory of computation based on abstract neural networks models was developed already in the 1950s [38.3, 4], and the development of artificial neural networks implemented on digital computers was very popular throughout the 1980s and the early 1990s [38.5–8]. Similarly, the history of implementing electronic models of neural circuits extends back to the construction of perceptrons in the late 1950s [38.3] and retinas in the early 1970s [38.9]. However, the modern wave of research utilizing very large scale integration technology and emphasizing the nonlinear current characteristics of the transistor to study and implement neural computation began only in the mid-1980s, with the collaboration that sprung up be-

tween scientists such as Max Delbrück, John Hopfield, Carver Mead, and Richard Feynman [38.10]. Inspired by graded synaptic transmission in the retina, Mead sought to use the graded (analog) properties of transistors, rather than simply operating them as on–off (digital) switches, to build circuits that emulate biological neural systems. He developed *neuromorphic* circuits that shared many common physical properties with proteic channels in neurons, and that consequently required far fewer transistors than digital approaches to emulating neural systems [38.11]. Neuromorphic engineering is the research field that was born out of this activity and which carries on that legacy: it takes inspiration from biology, physics, mathematics, computer science, and engineering to design artificial neural systems for carrying out robust and efficient computation using low power, massively parallel analog very large scale integration (**VLSI**) circuits, that operate with the same

*physics of computation* present in the brain [38.12]. Indeed, this young research field was born both out of the *Physics of Computation* course taught at Caltech by Carver Mead, John Hopfield, and Richard Feynman and with Mead's textbook *Analog Very Large Scale Integration and Neural Systems* [38.11]. Prominent in the early expansion of the field were scientists and engineers such as Christof Koch, Terry Sejnowski, Rodney Douglas, Andreas Andreou, Paul Mueller, Jan van der Spiegel, and Eric Vittoz, training a generation of cross-disciplinary students. Examples of successes in neuromorphic engineering range from the first biologically realistic silicon neuron [38.13], or realistic silicon models of the mammalian retina [38.14], to more recent silicon cochlea devices potentially useful for cochlear implants [38.15], or complex distributed multichip architectures for implementing event-driven autonomous behaving systems [38.16].

It is now a well-established field [38.17], with two flagship workshops (the Telluride Neuromorphic Engineering [38.18] and Capo Caccia Cognitive Neuromorphic Engineering [38.19] workshops) that are

currently still held every year. Neuromorphic circuits are now being investigated by many academic and industrial research groups worldwide to develop a new generation of computing technologies that use the same organizing principles of the biological nervous system [38.15, 20, 21]. Research in this field represents *frontier* research as it opens new technological and scientific horizons: in addition to basic science questions on the fundamental principles of computation used by the cortical circuits, neuromorphic engineering addresses issues in computer-science, and electrical engineering which go well beyond established frontiers of knowledge. A major effort is now being invested for understanding how these neuromorphic computational principles can be implemented using massively parallel arrays of basic computing elements (or *cores*), and how they can be exploited to create a new generation of computing technologies that takes advantage of future (nano)technologies and scaled **VLSI** processes, while coping with the problems of low-power dissipation, device unreliability, inhomogeneity, fault tolerance, etc.

## 38.2 Neural and Neuromorphic Computing

Neural computing (or neurocomputing) is concerned with the implementation of artificial neural networks for solving practical problems. Similarly, hardware implementations of artificial neural networks (neurocomputers) adopt mainly statistics and signal processing methods to solve the problem they are designed to tackle. These algorithms and systems are not necessarily tied to detailed models of neural or cortical processing. Neuromorphic computing on the other hand aims to reproduce the principles of neural computation by emulating as faithfully as possible the detailed biophysics of the nervous system in hardware. In this respect, one major characteristic of these systems is their use of *spikes* for representing and processing signals. This is not an end in itself: spiking neural networks represent a promising computational paradigm for solving complex pattern recognition and sensory processing tasks that are difficult to tackle using standard machine vision and machine learning techniques [38.22, 23]. Much research has been dedicated to software simulations of spiking neural networks [38.24], and a wide range of solutions have been proposed for solving real-world and engineering problems [38.25, 26]. Similarly, there are projects that focus on software

simulations of large-scale spiking neural networks for exploring the computational properties of models of cortical circuits [38.27, 28]. Recently, several research projects have been established worldwide to develop large-scale hardware implementations of spiking neural systems using **VLSI** technologies, mainly for allowing neuroscientists to carry out simulations and virtual experiments in real time or even faster than real-time scales [38.29–31]. Although dealing with hardware implementations of neural systems, either with custom **VLSI** devices or with dedicated computer architectures, these projects represent the conventional neurocomputing approaches, rather than neuromorphic-computing ones. Indeed, these systems are mainly concerned with fast and large simulations of spiking neural networks. They are optimized for speed and precision, at the cost of size and power consumption (which ranges from megawatts to kilowatts, depending on which approach is followed). An example of an alternative large-scale spiking neural network implementation that follows the original neuromorphic engineering principles (i. e., that exploits the characteristics of **VLSI** technology to directly emulate the biophysics and the connectivity of cortical circuits) is represented by the *Neurogrid* sys-

tem [38.32]. This system comprises an array of 16 **VLSI** chips, each integrating mixed analog neuromorphic neuron and synapse circuits with digital asynchronous event routing logic. The chips are assembled on a  $16.5 \times 19 \text{ cm}^2$  printed circuit board, and the whole system can model over one million neurons connected by billions of synapses in real time, and using only about  $\approx 3\text{W}$  of power [38.32].

Irrespective of the approach followed, these projects have two common goals: On one hand they aim to advance our understanding of neural processing in

the brain by developing models and physically building them using electronic circuits, and on the other they aim to exploit this understanding for developing a new generation of radically different non-von Neumann computing technologies that are inspired by neural and cortical circuits. In this interdisciplinary journey neuroscience findings will influence theoretical developments, and these will determine specifications and constraints for developing new neuromorphic circuits and systems that can implement them optimally.

### 38.3 The Importance of Fundamental Neuroscience

The neocortex is a remarkable computational device [38.33]. It is the neuronal structure in the brain that most expresses biology's ability to implement perception and cognition. Anatomical and neurophysiological studies have shown that the mammalian cortex with its laminar organization and regular microscopic structure has a surprisingly uniform architecture [38.34]. Since the original work of *Gilbert* and *Wiesel* [38.35] on the neural circuits of visual cortex it has been argued that this basic architecture, and its underlying computational principles computational principles can be understood in terms of the laminar distribution of relatively few classes of excitatory and inhibitory neurons [38.34]. Based on these slow, unreliable and inhomogeneous computing elements, the cortex easily outperform today's most powerful computers in a wide variety of computational tasks such as vision, audition, or motor control. Indeed, despite the remarkable progress in information and communication technology and the vast amount of resources dedicated to information and communication technology research and development, today's most fastest and largest computers are still not able to match neural systems, when it comes to carrying out robust computations in real-world tasks. The reasons for this performance gap are not yet fully understood, but it is clear that one fundamental difference between the two types of computing systems lies in the style of computation. Rather than using Boolean logic, precise digital representations, and clocked operations, nervous systems carry out robust and reliable computation using hybrid analog/digital unreliable components; they emphasize distributed, event driven, collective, and massively parallel mechanisms, and make extensive use of adaptation, self-organization and learning. Specifically, the patchy organization of the neurons in

the cortex suggests a computational machine where populations of neurons perform collective computation in individual clusters, transmit the results of this computation to neighboring clusters, and set the local context of the cluster by means of feedback connections from/to other relevant cortical areas. This overall graphical architecture resembles graphical processing models that perform Bayesian inference [38.36, 37]. However, the theoretical knowledge for designing and analyzing these models is limited mainly to graphs without loops, while the cortex is characterized by massive recurrent (loopy) connectivity schemes. Recent studies exploring loopy graphical models related to cortical architectures started to emerge [38.33, 38], but issues of convergence and accuracy remain unresolved, hardware implementations in a cortical architectures composed of spiking neurons have not been addressed yet.

Understanding the fundamental computational principles used by the cortex, how they are exploited for processing, and how to implement them in hardware, will allow us to develop radically novel computing paradigms and to construct a new generation of information and communication technology that combine the strengths of silicon technology with the performance of brains. Indeed fundamental research in neuroscience has already made substantial progress in uncovering these principles, and information and communication technologies have advanced to a point where it is possible to integrate almost as many transistors in a **VLSI** system as neurons in a brain. From the theoretical standpoint of view, it has been demonstrated that any Turing machine, and hence any conceivable digital computation, can be implemented by a noise-free network of spiking neurons [38.39]. It has also been

shown that networks of spiking neurons can carry out a wide variety of complex state-dependent computations, even in the presence of noise [38.40–44]. However, apart from isolated results, a general insight into which computations can be carried out in a robust manner by networks of unreliable spiking elements is still missing. Current proposals in state-of-the-art computational and theoretical neuroscience research represent mainly approximate functional models and are implemented as abstract artificial neural networks [38.45, 46]. It is less clear how these functions are realized by the actual networks of neocortex [38.34], how these networks are interconnected locally, and how percep-

tual and cognitive computations can be supported by them.

Both additional neurophysiological studies on neuron types and quantitative descriptions of local and inter-areal connectivity patterns are required to determine the specifications for developing the neuromorphic **VLSI** analogs of the cortical circuits studied, and additional computational neuroscience and neuromorphic engineering studies are required to understand what level of detail to use in implementing spiking neural networks, and what formal methodology to use for synthesizing and programming these non-von Neumann computational architectures.

## 38.4 Temporal Dynamics in Neuromorphic Architectures

Neuromorphic spiking neural network architectures typically comprise massively parallel arrays of simple processing elements with memory and computation co-localized (Fig. 38.1). Given their architectural constraints, these neural processing systems cannot process signals using the same strategies used by the conventional von Neumann computing architectures, such as digital signal processor or central processing unit, that time-domain multiplex small numbers of highly complex processors at high clock rates and operate by transferring the partial results of the computation from and to external memory banks. The synapses and neurons in these architectures have to process input spikes and produce output responses as the input signals arrive, in real time, at the rate of the incoming data. It is not possible to virtualize time and transfer partial results in memory banks outside the architecture core, at higher rates. Rather it is necessary to employ resources that compute with time constants that are well matched to those of the signals they are designed to process. Therefore, to interact with the environment and process signals with biological timescales efficiently, hardware neuromorphic systems need to be able to compute using biologically realistic time constants. In this way, they are well matched to the signals they process, and are inherently synchronized with the real world events.

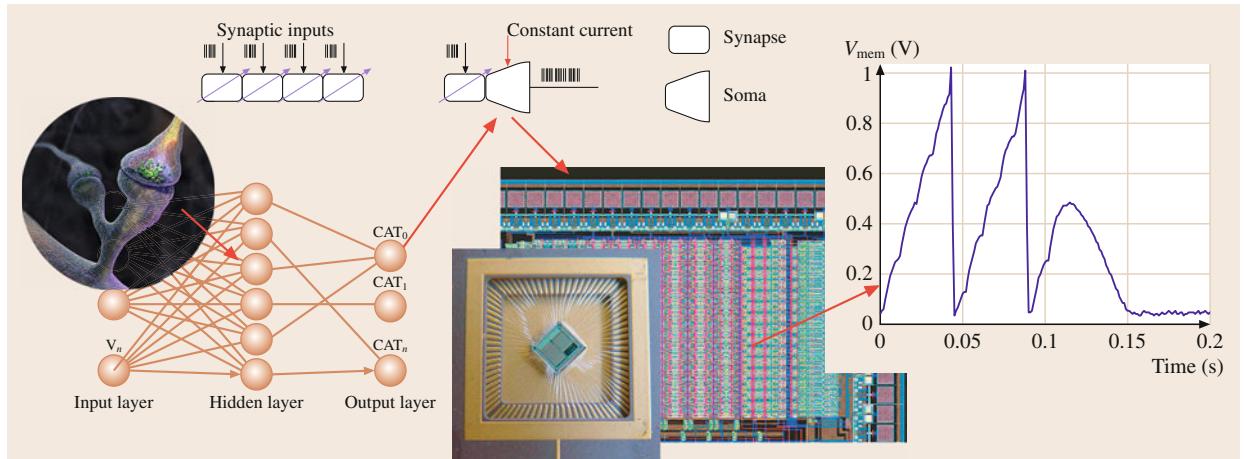

This constraint is not easy to satisfy using analog **VLSI** technology. Standard analog circuit design techniques either lead to bulky and silicon-area expensive solutions [38.47] or fail to meet this condition, resorting to modeling neural dynamics at *accelerated* unrealistic timescales [38.48–50].

One elegant solution to this problem is to use current-mode design techniques [38.51] and log-domain circuits operated in the weak-inversion regime [38.52]. When metal oxide semiconductor field effect transistors are operated in this regime, the main mechanism of carrier transport is that of diffusion, as it is for ions flowing through proteic channels across neuron membranes. In general, neuromorphic **VLSI** circuits operate in this domain (also known as the *subthreshold* regime), and this is why they share many common physical properties with proteic channels in neurons [38.52]. For example, metal oxide semiconductor field effect transistor have an exponential relationship between gate-to-source voltage and drain current, and produce currents that range from femto- to nanoampere resolution. In this domain, it is therefore possible to integrate relatively small capacitors in **VLSI** circuits, to implement temporal filters that are both compact and have biologically realistic time constants, ranging from tens to hundreds of milliseconds.

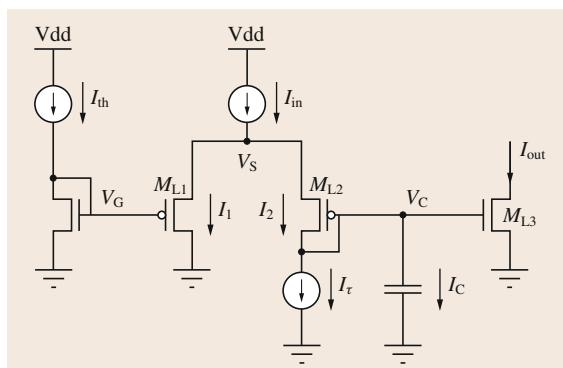

A very compact subthreshold log-domain circuit that can reproduce biologically plausible temporal dynamics is the differential pair integrator circuit [38.53], shown in Fig. 38.2. It can be shown, by log-domain circuit analysis techniques [38.54, 55] that the response of this circuit is governed by the following first-order differential equation

$$\tau \left( 1 + \frac{I_{\text{th}}}{I_{\text{out}}} \right) \frac{d}{dt} I_{\text{out}} + I_{\text{out}} = \frac{I_{\text{th}} I_{\text{in}}}{I_{\tau}} - I_{\text{th}}, \quad (38.1)$$

where the time constant  $\tau \triangleq C U_{\text{T}} / \kappa I_{\tau}$ , the term  $U_{\text{T}}$  represents the thermal voltage and  $\kappa$  the subthreshold slope factor [38.52].

**Fig. 38.1** Neuromorphic spiking neural network architectures: detailed biophysical models of cortical circuits are derived from neuroscience experiments; neural networks models are designed, with realistic spiking neurons and dynamic synapses; these are mapped into analog circuits, and integrated in large numbers on VLSI chips. Input spikes are integrated by synaptic circuits, which drive their target postsynaptic neurons, which in turn integrate all synaptic inputs and generate action potentials. Spikes of multiple neurons are transmitted off chip using asynchronous digital circuits, to eventually control in real-time autonomous behaving systems

**Fig. 38.2** Schematic diagram of neuromorphic integrator circuit. Input currents are integrated in time to produce output currents with large time constants, and with a tunable gain factor

Although this first-order *nonlinear* differential equation cannot be solved analytically, for sufficiently large input currents ( $I_{in} \gg I_\tau$ ) the term  $-I_{th}$  on the right-hand side of (38.1) becomes negligible, and eventually when the condition  $I_{out} \gg I_{th}$  is met, the equation can be well approximated by

$$\tau \frac{d}{dt} I_{out} + I_{out} = \frac{I_{in} I_{th}}{I_\tau}. \quad (38.2)$$

Under the reasonable assumptions of nonnegligible input currents, this circuit implements therefore a compact linear integrator with time constants that can be set to range from microseconds to hundreds of milliseconds. It is a circuit that can be used to build neuromorphic sensory systems that interact with the environment [38.56], and most importantly, is a circuit that reproduces faithfully the dynamics of synaptic transmission observed in biological synapses [38.57].

## 38.5 Synapse and Neuron Circuits

Synapses are fundamental elements for computation and information transfer in both real and artificial neural systems. They play a crucial role in neural coding and learning algorithms, as well as in neuromorphic neural network architectures. While modeling the nonlinear properties and the dynamics of real synapses

can be extremely onerous for software simulations in terms of computational power, memory requirements, and simulation time, neuromorphic synapse circuits can faithfully reproduce synaptic dynamics using integrators such as the differential pair integrator shown in Fig. 38.2. The same differential pair integrator cir-

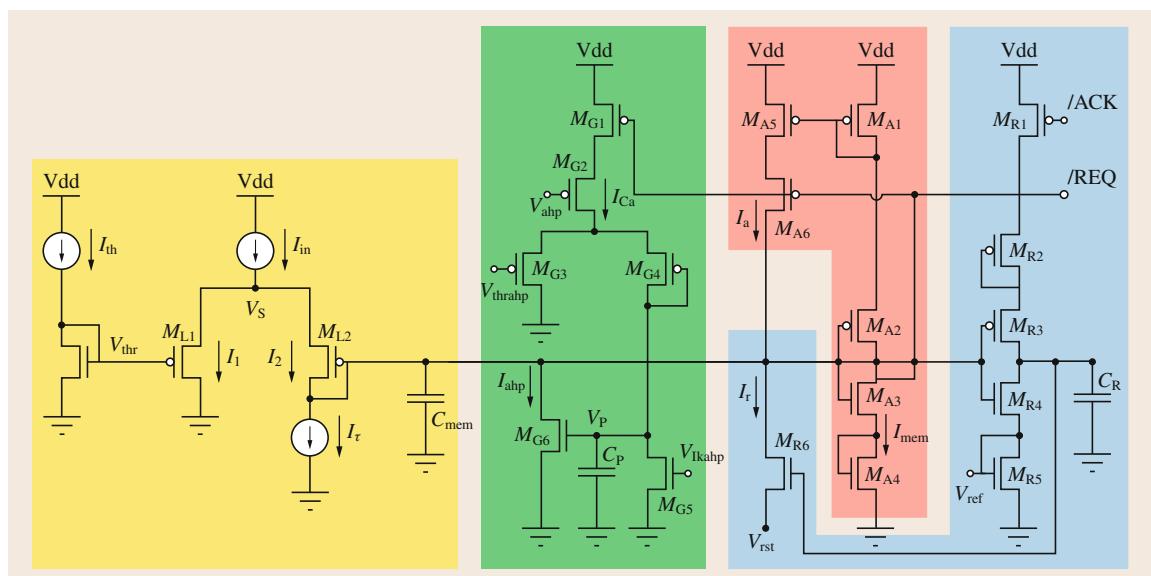

cuit can be used to model the passive leak and conductance behavior in silicon neurons. An example of a silicon neuron circuit that incorporated the differential pair integrator is shown in Fig. 38.3. This circuit implements an *adaptive exponential integrate-and-fire neuron* model [38.58]. In addition to the conductance-based behavior, it implements a spike-frequency adaptation mechanism, a positive feedback mechanism that models the effect of sodium activation and inactivation channels, and a reset mechanism with a free parameter that can be used to set the neuron's reset potential. The neuron's input differential pair integrator integrates the input current until it approaches the neuron's threshold voltage. As the positive feedback circuit gets activated, it induces an exponential rise in the variable that represents the model neuron membrane potential, which in the circuit of Fig. 38.3 is the current  $I_{\text{mem}}$ . This quickly causes the neuron to produce an action potential and make a request for transmitting a spike (i.e., the  $\text{REQ}$  signal of Fig. 38.3 is activated). Once the digital request signal is acknowledged, the membrane capacitance  $C_{\text{mem}}$  is reset to the neuron's tunable reset potential  $V_{\text{rst}}$ . These types of neuron circuits have been shown to be extremely low power, consuming about 7 pJ per

spike [38.59]. In addition, the circuit is extremely compact compared to alternative designs [38.58], while still being able to reproduce realistic dynamics.

As synapse and neuron circuits integrate their corresponding input signals in parallel, the neural network emulation time does not depend on the number of elements involved, and the network response always happen in real time. These circuits can be therefore used to develop low-power large-scale hardware neural architectures, for signal processing and general purpose computing [38.58]

### 38.5.1 Spike-Based Learning Circuits

As large-scale very large scale integration (VLSI) networks of spiking neurons are becoming realizable, the development of robust spike-based learning methods, algorithms, and circuits has become crucial. Spike-based learning mechanisms enable the hardware neural systems they are embedded in to adapt to the statistics of their input signals, to learn and classify complex sequences of spatiotemporal patterns, and eventually to implement general purpose state-dependent computing paradigms. Biologically plausible spike-driven

**Fig. 38.3** Schematic diagrams of a conductance-based integrate-and-fire neuron. An input differential pair integrator low-pass filter ( $M_{L1-3}$ ) implements the neuron leak conductance. A noninverting amplifier with current-mode positive feedback ( $M_{A1-6}$ ) produces address events at extremely low-power operation. A reset block ( $M_{R1-6}$ ) resets the neuron to the reset voltage  $V_{\text{rst}}$  and keeps it reset for a refractory period, set by the  $V_{\text{ref}}$  bias voltage. An additional differential pair integrator low-pass filter ( $M_{G1-6}$ ) integrates the output events in a negative feedback loop, to implement a *spike-frequency adaptation* mechanism

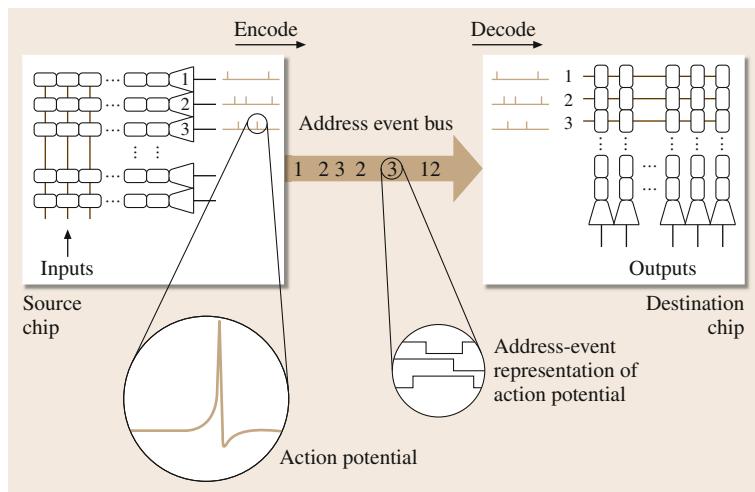

synaptic plasticity mechanisms have been thoroughly investigated in recent years. It has been shown, for example, how spike-timing dependent plasticity (**STDP**) can be used to learn to encode temporal patterns of spikes [38.42, 60, 61]. In spike-timing dependent plasticity the relative timing of pre- and postsynaptic spikes determine how to update the efficacy of a synapse. Plasticity mechanisms based on the timing of the spikes map very effectively onto silicon neuromorphic devices, and so a wide range of spike-timing dependent plasticity models have been implemented in **VLSI** [38.62–67]. It is therefore possible to build

large-scale neural systems that can carry out signal processing and neural computation, and include adaptation and learning. These types of systems are, by their very own nature, modular and scalable. It is possible to develop very large scale systems by designing basic neural processing *cores*, and by interconnecting them together [38.68]. However, to interconnect multiple neural network chips among each other, or to provide sensory inputs to them, or to interface them to conventional computers or robotic platforms, it is necessary to develop efficient spike-based communication protocols and interfaces.

## 38.6 Spike-Based Multichip Neuromorphic Systems

In addition to using spikes for signal efficient processing and computations, neuromorphic systems can use spiking representations also for efficient communication. The use of asynchronous spike- or event-based representations in electronic systems can be energy efficient and fault tolerant, making them ideal for building modular systems and creating complex hierarchies of computation. In recent years, a new class of neuromorphic multichip systems started to emerge [38.69–71]. These systems typically comprise one or more neuromorphic sensors, interfaced to general-purpose neural network chips comprising spiking silicon neurons and dynamic synapses. The strategy used to transmit signals across chip boundaries in these types of systems is based on asynchronous *address-events*: output events are represented by the addresses of the neurons that spiked, and transmitted in real time on a digital bus

(Fig. 38.4). The communication protocol used by these systems is commonly referred to as address event representation [38.72, 73]. The analog nature of the **AER** (address event representation) signals being transmitted is encoded in the mean frequency of the neurons spikes (spike rates) and in their precise timing. Both types of representations are still an active topic of research in neuroscience, and can be investigated in real time with these hardware systems. Once on a digital bus, the address events can be translated, converted or remapped to multiple destinations using the conventional logic and memory elements. Digital address event representation infrastructures allow us to construct large multichip networks with arbitrary connectivity, and to seamlessly reconfigure the network topology. Although digital, the asynchronous real-time nature of the **AER** protocol poses significant technological challenges that are still

**Fig. 38.4** Asynchronous communication scheme between two chips: when a neuron on the source chip generates an action potential, its address is placed on a common digital bus. The receiving chip decodes the address events and routes them to the appropriate synapses

being actively investigated by the electrical engineering community [38.74]. But by using analog processing in the neuromorphic *cores* and asynchronous digital communication outside them, neuromorphic systems can exploit the best of both worlds, and implement compact

low-power brain inspired neural processing systems that can interact with the environment in real time, and represent an alternative (complementary) computing technology to the more common and the conventional **VLSI** computing architectures.

## 38.7 State-Dependent Computation in Neuromorphic Systems

General-purpose cortical-like computing architectures can be interfaced to real-time autonomous behaving systems to process sensory signals and carry out event-driven state-dependent computation in real time. However, while the circuit design techniques and technologies for implementing these neuromorphic systems are becoming well established, formal methodologies for *programming* them, to execute specific procedures and solve user defined tasks, do not exist yet. A first step toward this goal is the definition of methods and procedures for implementing state-dependent computation in networks of spiking neurons. In general, state-dependent computation in autonomous behaving systems has been a challenging research field since the advent of digital computers. Recent theoretical findings and technological developments show promising results in this domain [38.16, 43, 44, 75, 76]. But the computational tasks that these systems are currently able to perform remain rather simple, compared to what can be achieved by humans, mammals, and many other animal species. We know, for instance, that nervous systems can exhibit context-dependent behavior, can execute *programs* consisting of series of flexible iterations, and can conditionally branch to alternative behaviors. A general understanding of how to configure artificial neural systems to achieve this sophistication of processing, including also adaptation, autonomous learning, interpretation of ambiguous input signals, symbolic manipulation, inference, and other characteristics that we could regard as effective cognition is still missing. But progress is being made in this direction by studying the computa-

tional properties of spiking neural networks configured as *attractors* or winner-take-all networks [38.33, 44, 77]. When properly configured, these architectures produce persistent activities, which can be regarded as computational states. Both software and **VLSI** event-driven soft-winner-take-all architectures are being developed to couple spike-based computational models among each other, using the asynchronous communication infrastructure, and use them to investigate their computational properties as neural finite-state machines in autonomous behaving robotic platforms [38.44, 78].

The theoretical, modeling, and **VLSI** design interdisciplinary activities is carried out with tight interactions, in an effort to understand:

1. How to use the analog, unreliable, and low-precision silicon neurons and synapse circuits operated in the weak-inversion regime [38.52] to carry out reliable and robust signal processing and pattern recognition tasks;
2. How to compose networks of such elements and how to embody them in real-time behaving systems for implementing sets of prespecified desired functionalities and behaviors; and
3. How to formalize these theories and techniques to develop a systematic methodology for configuring these networks and systems to achieve arbitrary state-dependent computations, similar to what is currently done using high-level programming languages such as Java or C++ for conventional digital architectures.

## 38.8 Conclusions

In this chapter, we presented an overview of the neuromorphic engineering field, focusing on very large scale integration implementations of spiking neural networks and on multineuron chips that comprise synapses and neurons with biophysically realistic dynamics, nonlinear properties, and spike-based plasticity mechanisms. We argued that the multineuron chips built using these

silicon neurons and synaptic circuits can be used to implement an alternative brain inspired computational paradigm that is complementary to the conventional ones based on von Neumann architectures.

Indeed, the field of neuromorphic engineering has been very successful in developing a new generation of computing technologies implemented with design prin-

ciples based on those of the nervous systems, and which exploit the physics of computation used in biological neural systems. It is now possible to design and implement complex large-scale artificial neural systems with elaborate computational properties, such as spike-based plasticity and soft winner-take-all behavior, or even complete artificial sensory-motor systems, able to robustly process signals in real time using neuromorphic **VLSI** technology.

Within this context, neuromorphic **VLSI** technology can be extremely useful for exploring neural processing strategies in real time. While there are clear advantages of this technology, for example, in terms of power budget and size requirements, there are also restrictions and limitations imposed by the hardware implementations that limit their possible range of applications. These constraints include for example limited resolution in the state variables or bounded parameters (e.g., bounded synaptic weights that cannot grow indefinitely or become negative). Also the presence of noise and inhomogeneities in all circuit components, place severe limitations on the precision and reliability of the computations performed. However, most, if not all, the limitations that neuromorphic hardware implementations face, (e.g., in maintaining stability, in achieving robust computation using unreliable components, etc.)

are often the same one faced by real neural systems. So these limitations are useful for reducing the space of possible artificial neural models that explain or reproduce the properties of real cortical circuits. While in principle these *features* could be simulated also in software (e.g., by adding a noise term to each state variable, or restricting the resolution of variables to 3, 4, or 6 bits instead of using the floating point representations), they are seldom taken into account. So in addition to representing a technology useful for implementing hardware neural processing systems and solving practical applications, neuromorphic circuits can be used as an additional tool for studying and understanding basic neuroscience.

As **VLSI** technology is widespread and readily accessible, it is possible to easily learn (and train new generations of students) to design neuromorphic **VLSI** neural networks for building hardware models of neural systems and sensory-motor systems. Understanding how to build real-time behaving neuromorphic systems that can work in real-world scenarios, will allow us to both gain a better understanding of the principles of neural coding in the nervous system, and develop a new generation of computing technologies that extend and complement current digital computing devices, circuits, and architectures.

# Neuroengineering

## 39. Neuroengineering

Damien Coyle, Ronen Sosnik

Neuroengineering of sensorimotor rhythm-based brain-computer interface (**BCI**) systems is the process of using engineering techniques to understand, repair, replace, enhance, or otherwise exploit the properties of neural systems, engaged in the representation, planning, and execution of volitional movements, for the restoration and augmentation of human function via direct interactions between the nervous system and devices.

This chapter reviews information that is fundamental for the complete and comprehensive understanding of this complex interdisciplinary research field, namely an overview of the motor system, an overview of recent findings in neuroimaging and electrophysiology studies of the motor cortical anatomy and networks, and the engineering approaches used to analyze motor cortical signals and translate them into control signals that computer programs and devices can interpret.

Specifically, the anatomy and physiology of the human motor system, focusing on the brain areas and spinal elements involved in the generation of volitional movements is reviewed. The stage is then set for introducing human prototypical motion attributes, sensorimotor learning, and several computational models suggested to explain psychophysical motor phenomena based on the current knowledge in the field of neurophysiology.

An introduction to invasive and non-invasive neural recording techniques, including functional and structural magnetic resonance imaging (**fMRI** and **sMRI**), electrocorticography (**ECoG**), electroencephalography (**EEG**), intracortical single unit activity (**SU**) and multiple unit extracellular recordings, and magnetoencephalography (**MEG**) is integrated with coverage aimed at elucidating what is known about sensory motor oscillations and brain anatomy, which are used to generate control signals for brain actuated devices and al-

ternative communication in **BCI**. Emphasis is on latest findings in these topics and on highlighting what information is accessible at each of the different scales and the levels of activity that are discernible or utilizable for the effective control of devices using intentional activation sensorimotor neurons and/or modulation of sensorimotor rhythms and oscillations.

The nature, advantages, and drawbacks of various approaches and their suggested functions as the neural correlates of various spatiotemporal motion attributes are reviewed. Sections dealing with signal analysis techniques, translation algorithms, and adaption to the brain's non-stationary dynamics present the reader with a wide-ranging review of the mathematical and statistical techniques commonly used to extract and classify the bulk of neural information recorded by the various recording techniques and the challenges that are posed for deploying **BCI** systems for their intended uses, be it alternative communication and control, assistive technologies, neurorehabilitation, neurorestoration or replacement, or recreation and entertainment, among other applications. Lastly, a discussion is presented on the future of the field, highlighting newly emerging research directions and their potential ability to enhance our understanding of the human brain and specifically the human motor system and ultimately how that knowledge may lead to more advanced and intelligent computational systems.

## 39.1 Overview – Neuroengineering in General

Neuroengineering is defined as the interdisciplinary field of engineering and computational approaches to problems in basic and clinical neurosciences. Thus, education and research in neuroengineering encompasses the fields of engineering, mathematics, and computer science on the one hand, and molecular, cellular, and systems neurosciences on the other. Prominent goals in the field include restoration and augmentation of human functions via direct interactions between the nervous system and artificial devices. Much current research is focused on understanding the coding and processing of information in the sensory and motor systems, quantifying how this processing is altered in the pathological state, and how it can be manipulated through interactions with artificial devices, including brain–computer interfaces (BCIs) and neuroprostheses.

Although there are many topics that can be covered under neuroengineering umbrella, this chapter does not aim to cover them all. Focus is on providing a com-

prehensive overview of state-of-the-art in technologies and knowledge surrounding the human motor system. The motor system is extremely complex in terms of the functions it performs and the structure underlying the control it provides; however, there is an ever-increasing body of knowledge on how it works and is controlled. This has been facilitated by studies of animal models, computational models, electrophysiology, and neuroimaging of humans. Another important development that is extending the boundaries of our knowledge about the motor system is the development of brain–computer interface (BCI) technologies that involve intentional modulation of sensorimotor activity through executed as well as imagined movement (motor imagery). BCI research not only opens up a framework for non-muscular communication between humans and computers/machines but offers experimental paradigms for understanding the neuroscience of motor control, testing hypotheses, and gaining detailed insight into

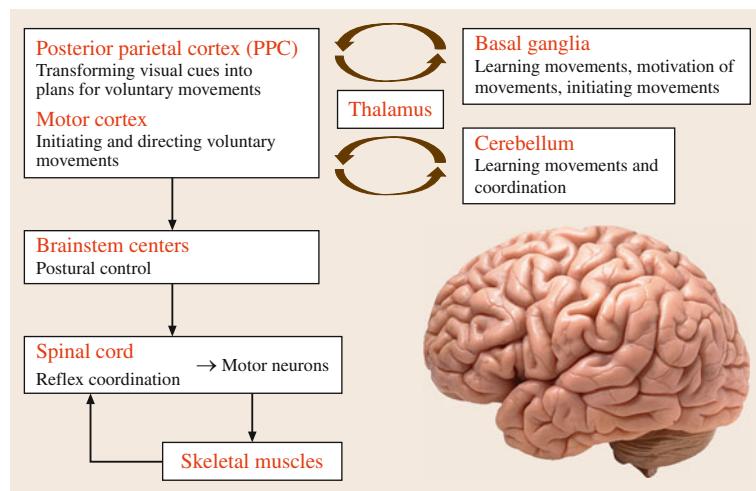

motor control from the activity of a single neuron, a small population of neurons, networks of neurons, and the spatial and spectral relationship across multiple brain regions and networks. This knowledge will undoubtedly lead to better diagnostics for motor-related pathologies, better BCIs for assistance and alternative non-muscular communication applications for the physically impaired, better rehabilitation for those capable of regaining lost motor function, and a better understanding of the brain as a whole.

Relevantly, for the context and scope of this handbook, BCI research will contribute to better gaining a better insight of information processing in the brain, resulting in better, more intelligent computational approaches to developing, truly intelligent systems – systems that perceive, reason, and act autonomously.

The motor system is often considered to be at the heart of human intelligence. From the *motor chauvinist's point of view the entire purpose of the brain is to produce movement* [39.1]. This assertion is based on the following observations about movement:

1. Interaction with the world is only achieved through movement.
2. All communication is mediated via the motor system including speech, sign language, gesture, and writing.
3. All sensory and cognitive processes can be considered inputs that determine future motor outputs.

Neuroscientists and researchers focusing on other areas and functions of the brain may refute this suggestion given the fact that many regions related to general intelligence are located throughout the brain and that a single *intelligence center* is unlikely. No single neuroanatomical structure determines general intelligence, and different types of brain designs can produce equivalent intellectual performance [39.3]. Nevertheless, there is no doubt that the motor system is critical to the advancement of human level intelligence and, therefore, in the context of computational intelligence, this chapter focuses on reviewing studies and methodologies that elucidate some of the aspects that we know about sensorimotor systems and how these can be studied. Although the aim of the chapter is not to provide an exhaustive review of the available extensive literature, it does aim to provide insights into key findings using some of the state-of-the-art experimental and methodological approaches deployed in neuroscience and neuroengineering, whilst at the same time reviewing methodology that may lead to the development of practical BCIs. BCIs have revealed new ways of studying how the brain learns and adapts, which in turn have helped improve BCI designs and better computational intelligence for adapting the signal processing to the adaptation regime of the brain. One of the key findings in BCI research is that it can trigger plastic changes in different brain areas, suggesting that the brain has even greater flexibility than previously thought [39.4]. These findings can only serve to improve our understanding of how the brain, the most sophisticated and complex organism in the known universe, functions, undoubtedly leading to better computational systems.

**Fig. 39.1** Major components of the motor system (after [39.2], courtesy of Shadmehr)

### 39.1.1 The Human Motor System

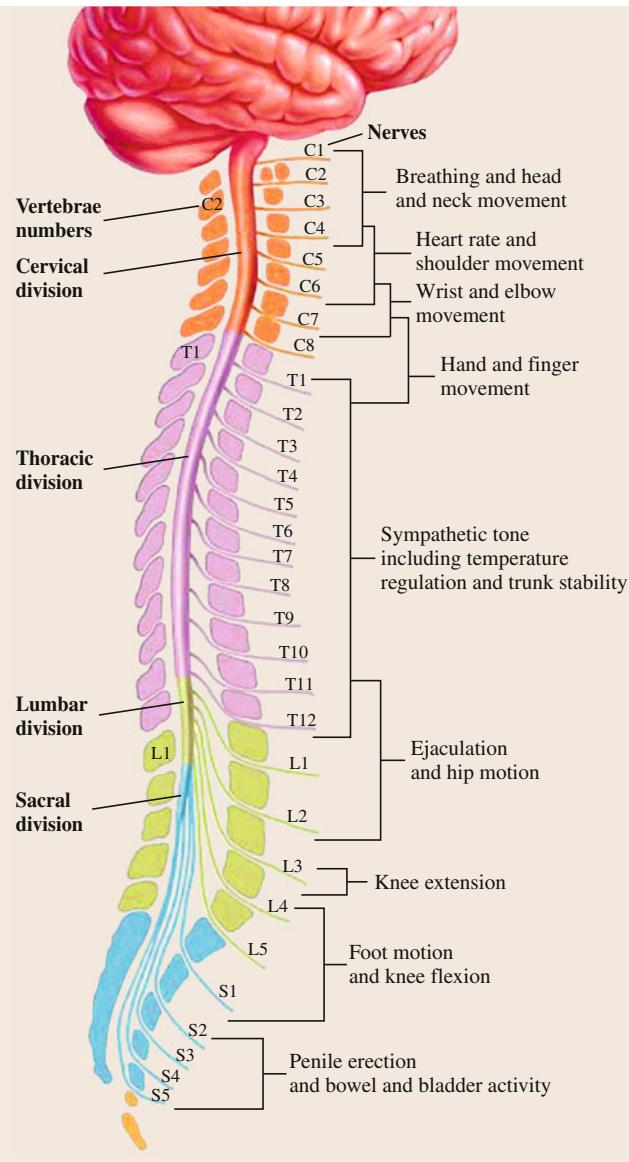

The human motor system produces action. It controls goal-directed movement by selecting the targets of action, generating a motor plan and coordinating the generation of forces needed to achieve those objectives. Genes encode a great deal of the information required by the motor system – especially for actions involving

locomotion, orientation, exploration, ingestion, defence, aggression, and reproduction – but every individual must learn and remember a great deal of motor information during his or her lifetime. Some of that information rises to conscious awareness, but much of it does not. Here we will focus on the motor system of humans, drawing on information from primates and other mammals, as necessary.

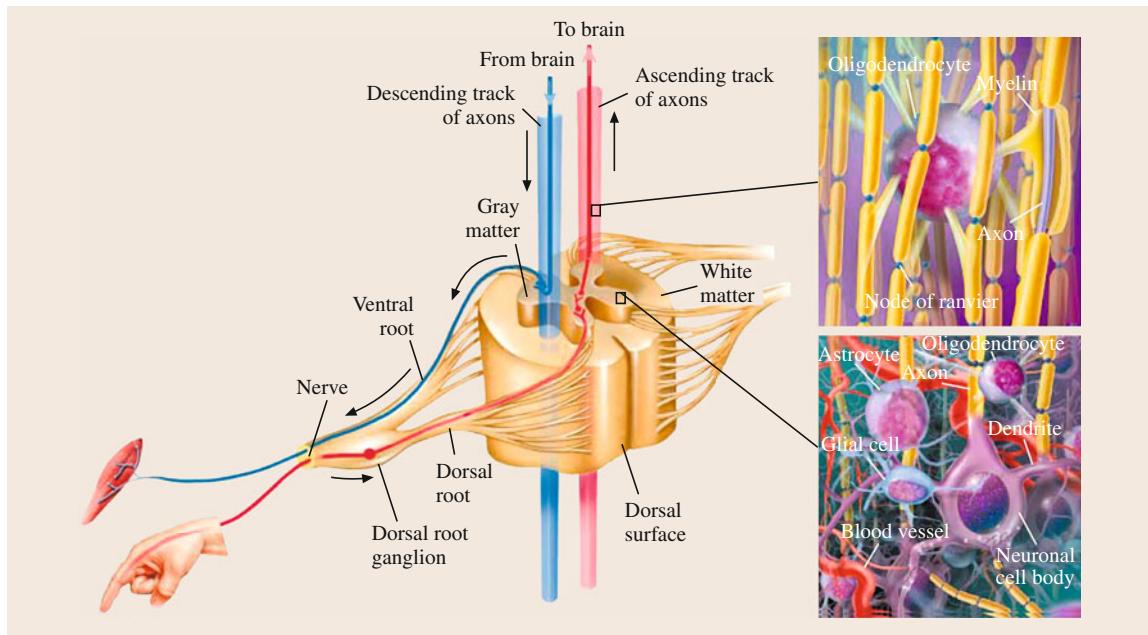

#### Major Components of the Motor System

The central nervous system that vertebrates have evolved comprises six major components: the spinal cord, medulla, pons, midbrain, diencephalon and telencephalon, the last five of which compose the brain. In a different grouping, the hindbrain (medulla and pons), the midbrain, and the forebrain (telencephalon plus diencephalon) constitute the brain. Taken together, the midbrain and hindbrain make up the brainstem. All levels of the central nervous system participate in motor control. However, let us take the simple act of reaching to pick up a cup of coffee to illustrate the function of the various components of the motor system (Fig. 39.1):

- The *parietal cortex*: Processes visual information and proprioceptive information to compute location of the cup with respect to the hand. Sends this information to the motor cortex.
- The *motor cortex*: Using the information regarding the location of the cup with respect to the hand, it computes forces that are necessary to move the arm. This computation results in commands that are sent to the brainstem and the spinal cord.
- The *brainstem motor center*: Sends commands to the spinal cord that will maintain the body's balance during the reaching movement.
- The *spinal cord*: Motor neurons send the commands received from the motor cortex and the brainstem to the muscles. During the movement, sensory information from the limb is acquired and transmitted back to the cortex. Reflex pathways ensure stability of the limb.
- The *cerebellum*: This center is important for coordination of multi-joint movements, learning of movements, and maintenance of postural stability.
- The *basal ganglia*: This center is important for learning of movements, stability of movements, initiation of movements, emotional, and motivational aspects of movements.
- The *thalamus*: May be thought of as a kind of switchboard of information. It acts as a relay between a variety of subcortical areas and the cerebral

**Fig. 39.2** Divisions of the spinal cord (after [39.5], courtesy of Shadmehr and McDonald)

**Fig. 39.3** A spinal segment (after [39.5], courtesy of Shadmehr and McDonald)

cortex, although recent studies suggest that thalamic function is more selective. The neuronal information processes necessary for motor control are proposed as a network involving the thalamus as a subcortical motor center. The nature of the interconnected tissues of the cerebellum to the multiple motor cortices suggests that the thalamus fulfills a key function in providing the specific channels from the basal ganglia and cerebellum to the cortical motor areas.

The spinal cord comprises four major divisions. From rostral to caudal, these are called: cervical, thoracic, lumbar, and sacral (Fig. 39.2). Cervix is the Latin word for neck. The cervical spinal segments intervene between the pectoral (or shoulder) girdle and the skull. Thorax means chest (or breast plate). Lumbar refers to the loins. Sacral, the most intriguing name of all refers to some sort of sacred bone.

In mammals, the cervical spinal cord has 8 segments; the thoracic spinal cord has 12, and the lumbar and sacral cords both have 5. The parts of the spinal cord that receive inputs from and control the muscles of the arms (more generally, forelimbs) and legs (more generally, hind limbs) show enlargements associated with an increasing number and size of neurons and fibers: the cervical enlargement for the arms and the

lumbar enlargement for the legs. Each segment is labeled and numbered according to its order, from rostral to caudal, within each general region of spinal cord. Thus, the first cervical segment is abbreviated C1 and together the eight cervical segments can be designated as C1–C8.

In each spinal segment, one finds a ring of white matter (WM) surrounding a central core of gray matter (GM) (Fig. 39.3). White matter is so called because the high concentration of myelin in the fiber pathways gives it a lighter, shiny appearance relative to regions with many cell bodies. The spinal gray matter bulges at the dorsal and ventral surfaces to form the dorsal horn and ventral horn, respectively.

The cord has two major systems of neurons: descending and ascending. In the descending group, the neurons control both smooth muscles of the internal organs and the striated muscles attached to our bones. The descending pathway begins in the brain, which sends electrical signals to specific segments in the cord. Motor neurons in those segments then convey the impulses towards their destinations outside the cord.

The ascending group is the sensory pathways, sending sensory signals received from the limbs and muscles and our organs to specific segments of the cord and to the brain. These signals originate with special-

ized transducer cells, such as cells in the skin that detect pressure. The cell bodies of the neurons are in a gray, butterfly-shaped region of the cord (gray matter). The ascending and descending axon fibers

travel in a surrounding area known as the white matter. It is called white matter because the axons are wrapped in myelin, a white electrically insulating material.

## 39.2 Human Motor Control

Motor control is a complex process that involves the brain, muscles, limbs, and often external objects. It underlies motion, balance, stability, coordination, and our interaction with others and technology. The general mission of the human motor control research field is to understand the physiology of normal human voluntary movement and the pathophysiology of different movement disorders. Some of the opening questions include: how do we select our actions of the many actions possible? How are these behaviors sequenced for appropriate order and timing between them? How does perception integrate with motor control? And how are perceptual-motor skills acquired? In the following section the basic aspects of motor control – motor planning and motor execution are presented.

### 39.2.1 Motion Planning and Execution in Humans

Human goal-directed arm movements are fast, accurate, and can compensate for various dynamic loads exerted by the environment. These movements exhibit remarkable invariant properties, although a motor goal can be achieved using different combinations of elementary movements.

Models of goal-directed human arm movements can be divided into two major groups: feedback and feed-forward. Feedback schemes for motion planning assume that the motion is generated through a feedback control law, whereas feed-forward schemes of trajectory formation propose that the movement is planned in advance and then executed. While a comprehensive model of human arm movements should include feed-forward as well as feedback control mechanisms, pure feedback control mechanisms cannot account for the fast and smooth movements performed by adult humans. Although none of the existing models are able to account for all the characteristics of human motion, there is compelling evidence that mechanisms for feed-forward motion planning exist within the central nervous system (**CNS**). A further supporting argument for the existence of a pre-planned trajectory is that visu-

ally directed movements are characterized by relatively long reaction times (**RT**) of 200–500 ms [39.6], which are supposed to reflect the time needed to plan an adequate movement. A partial knowledge of either the amplitude or the direction of the upcoming movement can significantly reduce the **RT**.

#### 39.2.2 Coordinate Systems Used to Acquire a New Internal Model

In reaching for objects around us, neural processing transforms visuospatial information about target location into motor commands to specify muscle forces and joint motions that are involved in moving the hand to the desired location [39.7]. In planar reaching movements, extent and direction have different variable errors, suggesting that the **CNS** plans the movement amplitude and direction independently and that the hand paths are initially planned in vectorial coordinates without taking into account joint motions. In this framework, the movement vector is specified as an extent and direction from the initial hand position. Kinematic accuracy depends on learning a scaling factor from errors in extent and reference axes from errors in direction, and the learning of new reference axes shows limited generalization [39.8]. Altogether, these findings suggest that motor planning takes place in extrinsic, hand-centered, visually perceived coordinates. Finally however, vectorial information needs to be converted into muscle forces for the desired movement to be produced. This transformation needs to take into account the biomechanical properties of the moving arm, notably the interaction torques produced at all the joints by the motion of all limb segments. For multi-joint arms, there are significant inertial dynamic interactions between the moving skeletal segments, and several muscles pull across more than one joint. Clearly, these complexities raise complicated control problems since one needs to overcome or solve the inverse dynamics problem. The capacity to anticipate the dynamic effects is understood to depend on learning an internal model of muscu-

loskeletal dynamics and other forces acting on the limb.

The equilibrium trajectory hypothesis for multi-joint arm motions [39.9] circumvented the complex dynamic problem mentioned above by using the spring-like properties of muscles and stating that multi-joint arm movements are generated by gradually shifting the hand equilibrium positions defined by the neuromuscular activity. The magnitude of the force exerted on the arm, at any time, depends on the difference between the actual and equilibrium hand positions and the stiffness and viscosity about the equilibrium position.

Neuropsychological studies indicate that for M1 (primary motor) region, the representations that mediate motor behavior are distributed, often in a graded manner, across extensive, overlapping cortical regions, so that different memory systems can underlie different coordinate systems, which are used at different hierarchical levels.

### 39.2.3 Spatial Accuracy and Reproducibility

Our ability to generate accurate and appropriate motor behavior relies on tailoring our motor commands to the prevailing movement context. This context embodies parameters of both our own motor system, such as the level of muscle fatigue, and the outside world, such as the weight of a bottle to be lifted. As the consequence of a given motor command depends on the current context, the CNS has to estimate this context so that the motor commands can be appropriately adjusted to attain accurate control. A current context can be estimated by integrating two sources of information: sensory feedback and knowledge about how the context

is likely to have changed from the previous estimate. In the absence of sensory feedback about the context, the CNS is able to extrapolate the likely evolution of the context without requiring awareness that the context is changing [39.10].

Although the CNS tries to maximize our motion accuracy, systematic directional errors are still found. These errors may result from a number of sources. One cause for not being accurate is a visual distortion, which could be the outcome of fatigue of the eyes or inherent optical distortion. A second cause could be imperfect control processes due to the noise in the neuromuscular system or blood flow pulsations, which cause our movements to be jerky. A third cause could be that each movement we utilize, consciously or unconsciously, may involve different motor plans, which result in slightly different trajectories and endpoint accuracies.

In a simple aiming movement, the task is to minimize the final error, as measured by the variance about the target. The endpoint variability has an ellipsoid shape with two main axes perpendicular one to another. This finding led to the vectorial planning hypotheses stating that planning of visually guided reaches is accomplished by independent specification of extent and direction [39.8]. It was later suggested that the aim of the optimal control strategy is to minimize the volume of the ellipsoid, thereby being as accurate as possible. Non-smooth movements require increased motor commands, which generate increased noise; smoothness thereby leads to increased end-point accuracy but is not a goal in its own. Although the end-point-error cost function specifies the optimal movement, how one approaches this optimum for novel, unrehearsed movements is an open question.

## 39.3 Modeling the Motor System – Internal Motor Models

An internal model is a postulated neural process that simulates the response of the motor system in order to estimate the outcome of a motor command. The internal model theory of motor control argues that the motor system is controlled by the constant interactions of the *plant* and the *controller*. The plant is the body part being controlled, while the internal model itself is considered part of the controller. Information from the controller, such as information from the CNS, feedback information, and the efference copy, is sent to the plant which moves accordingly.

Internal models can be controlled through either feed-forward or feedback control. Feed-forward control computes its input into a system using only the current state and its model of the system. It does not use feedback, so it cannot correct for errors in its control. In feedback control, some of the output of the system can be fed back into the system's input, and the system is then able to make adjustments or compensate for errors from its desired output. Two primary types of internal models have been proposed: forward models and inverse models. In simulations, models can be

combined together to solve more complex movement tasks.

The following section elaborates on the two internal models, introduces the concept of optimization principles and its use in modeling human motor behavior, presenting a well-established motor control model for 2-D volitional hand movement.

### 39.3.1 Forward Models, Inverse Models, and Combined Models

In their simplest form, forward models take the input of a motor command to the *plant* and output a predicted position of the body. The motor command input to the forward model can be an efference copy. The output from that forward model, the predicted position of the body, is then compared with the actual position of the body. The actual and predicted position of the body may differ due to noise introduced into the system by either internal (e.g., body sensors are not perfect, sensory noise) or external (e.g., unpredictable forces from outside the body) sources. If the actual and predicted body positions differ, the difference can be fed back as an input into the entire system again so that an adjusted set of motor commands can be formed to create a more accurate movement.

Inverse models use the desired and actual position of the body as inputs to estimate the necessary motor commands that would transform the current position into the desired one. For example, in an arm reaching task, the desired position (or a trajectory of consecutive positions) of the arm is input into the postulated inverse model, and the inverse model generates the motor commands needed to control the arm and bring it into this desired configuration.

Theoretical work has shown that in models of motor control, when inverse models are used in combination with a forward model, the efference copy of the motor command output from the inverse model can be used as an input to a forward model for further predictions. For example if, in addition to reaching with the arm, the hand must be controlled to grab an object, an efference copy of the arm motor command can be input into a forward model to estimate the arm's predicted trajectory. With this information, the controller can then generate the appropriate motor command telling the hand to grab the object. It has been proposed that if they exist, this combination of inverse and forward models would allow the CNS to take a desired action (reach with the arm), accurately control the reach, and then accurately control the hand to grip an object.

### 39.3.2 Adaptive Control Theory

With the assumption that new models can be acquired and pre-existing models can be updated, the efference copy is important for the adaptive control of a movement task. Throughout the duration of a motor task, an efference copy is fed into a forward model known as a dynamics predictor whose output allows prediction of the motor output. When applying adaptive control theory techniques to motor control, the efference copy is used in indirect control schemes as the input to the reference model.

### 39.3.3 Optimization Principles

Optimization theory is a valuable integrative and predictive tool for studying the interaction between the many complex factors, which result in the generation of goal-directed motor behavior. It provides a convenient way to formulate a model of the underlying neural computations without requiring specific details on the way those computations are carried out. The components of optimization problems are: a task goal (defined mathematically by a performance criterion or a cost function), a system to be controlled (a set of system variables that are available for modulation), and an algorithm capable of finding an analytical or a numerical solution. By rephrasing the learning problem within the framework of an optimization problem, one is forced to make explicit, quantitative hypotheses about the goals of motor actions and to articulate how these goals relate to observable behavior.

As indicated in the last section, goal-directed arm movements exhibit remarkable invariant properties despite the fact that a given point in space can be reached through an infinite number of spatial, articular, and muscle combinations. In order to account for this observation it is necessary to postulate the existence of a *regulator*, i.e., a functional constraint, to reduce the number of degrees of freedom available to perform the task. Most of the regulators proposed during the last decade refer to a general hypothesis that the nervous system tries to minimize some cost related to the movement performance. Nelson [39.11] first formulated this idea in an operative way by proposing to use mathematical cost functions to estimate the energy or other costs consumed during a movement. This approach was further developed by several investigators who proposed different criteria such as, for instance, minimum muscular energy, minimum effort, minimum torque, minimum work, or minimum variance. A model that is indis-

putably one of the most mentioned in the literature and that has proven to be very powerful in describing multi-joint movements is the minimum jerk model described in the next section.

### 39.3.4 Kinematic Features of Human Hand Movements and the Minimum Jerk Hypothesis

Human point-to-point arm movements that are restricted in the horizontal plane tend to be straight, smooth, with single-peaked, bell-shaped velocity profiles and are invariant with respect to rotation, translation, and spatial or temporal scaling. Motor adaptation studies in which unexpected static loads or velocity-dependent force fields were applied during horizontal reaching movements further supported the hypothesis that arm trajectories follow a kinematic plan formulated in an extrinsic Cartesian task-space. The morphological invariance of the movement in Cartesian space supported the hypothesis that the hand trajectory in task-space is the primary variable computed during movement planning. It is assumed that following the planning process, the CNS performs non-linear inverse kinematics computations, which convert time sequences of hand position into time sequences of joint positions.

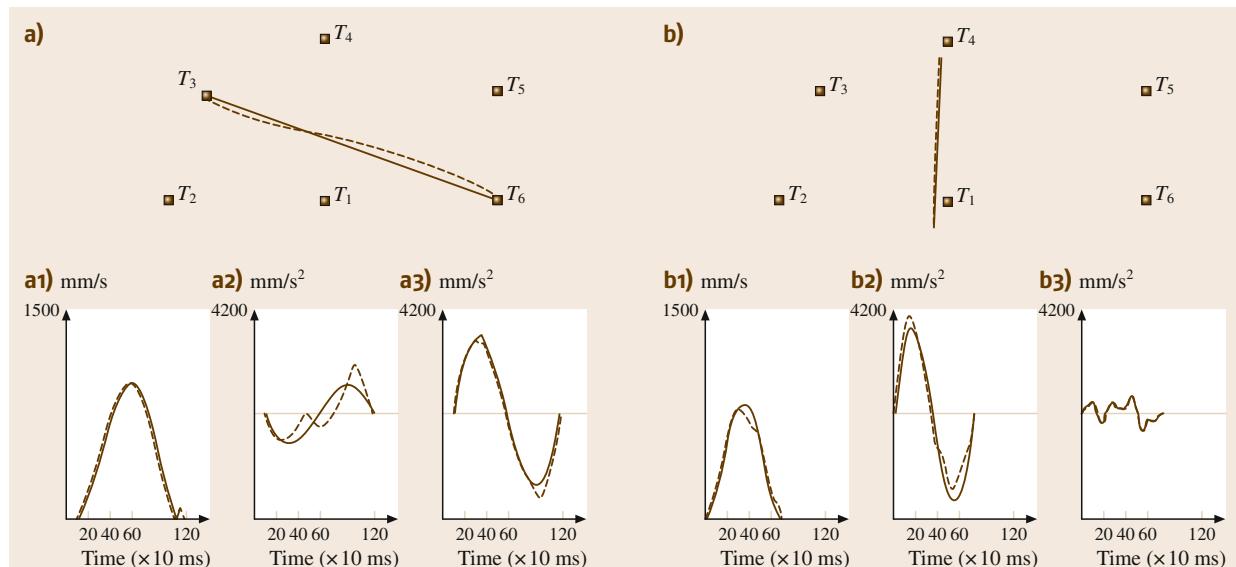

The kinematic features of one-joint goal directed movements were successfully modeled by the minimum jerk hypothesis [39.13] and were later extended for planar hand motion [39.12]. The minimum jerk model states that the time integral of the squared magnitude of the first derivative of the Cartesian hand acceleration (jerk) is minimized,

$$C = \int_0^T \left( \frac{d^3 r}{dt^3} \right)^2 dt, \quad (39.1)$$

where  $r(t) = (x(t), y(t))$  are the Cartesian coordinates of the hand and  $T$  is the movement duration. The solution of this variational problem, assuming zero velocity and zero acceleration at the initial and final hand locations  $r_i, r_f$ , is given by

$$r(t) = r_i + \left( 10 \left( \frac{t}{T} \right)^3 - 15 \left( \frac{t}{T} \right)^4 + 6 \left( \frac{t}{T} \right)^5 \right) \times (r_f - r_i). \quad (39.2)$$

The experimental setup and the comparison between experimental data and the minimum-jerk model prediction for hand paths, tangential velocities, and acceleration components between different targets are depicted in Fig. 39.4.

**Fig. 39.4a,b** Overlapped predicted (solid lines) and measured (dashed lines) hand paths ( $a_1, b_1$ ), speeds ( $a_2, b_2$ ), and acceleration components along the y-axis ( $a_3, b_3$ ) and along the x-axis (d) for two unconstrained point-to-point movements. **(a)** A movement between targets 3 and 6. **(b)** A movement between targets 1 and 4 (after [39.12], courtesy of Flash)

### 39.3.5 The Minimum Jerk Model, The Target Switching Paradigm, and Writing-like Sequence Movements

The stereotyped kinematic patterns of planar reaching movements are not the expression of a pre-wired or inborn motor pattern, but the result of learning during ontogenesis. When infants start to reach, their reaching is characterized by multiple accelerations and decelerations of the hand, while experienced infants reach with much straighter hand paths and with a single smooth acceleration and deceleration of the hand. It is possible to decompose a large proportion of infant reaches into an underlying sequence of sub-movements that resemble simple movements of adults. It is now believed that the CNS uses small, smooth sub-movements, commonly known as *motion primitives*, which are smoothly concatenated in time and space, in order to construct more complicated trajectories. Motor primitives can be considered neural control modules that can be flexibly combined to generate a large repertoire of behaviors. A primitive may represent the temporal profile of a particular muscle activity (*low level*, dynamic intrinsic primitive) or a geometrical shape in visually perceived Cartesian coordinates (*high level*, kinematic extrinsic primitive [39.14, 15]). The overall motor output will be the sum of all primitives, weighted by the level of activations of each module. A behavior for which the motor system has many primitives will be easy to learn, whereas a behavior that cannot be approximated by any set of primitives would be impossible to learn [39.16].

The biological plausibility of the *primitives' modules* model was demonstrated in studies on spinalized frogs and rats that showed that the pre-motor circuits within the spinal cord are organized into a set of discrete modules [39.17]. Each module, when activated, induces a specific force field, and the simultaneous activation of multiple modules leads to the vectorial combination

of the corresponding fields. Other evidence for the existence of primitive sub-movements came from works on hemiplegic stroke patients, which showed that the patients' first movements were clearly segmented and exhibited a remarkably invariant speed vs. time profile.

The concept of superposition was further elaborated and modeled for target switching experiments [39.18]. It was found that arm trajectory modification in a double target displacement paradigm involves the vectorial summation of two independent plans, each coding for a maximally smooth point-to-point trajectory. The first plan is the initial unmodified plan for moving between the initial hand position and the first target location. The second plan is a time-shifted trajectory plan that starts and ends at rest and has the same amplitude and kinematic form as a simple point-to-point movement between the first and second target locations.

The minimum jerk model is also a powerful model for predicting the generated trajectory when subjects are instructed to generate continuous movements from one target to another through an intermediate target. It was also shown that, using the minimum jerk model, human handwriting properties can be faithfully reconstructed while specifying the velocities and the positions at via-points, taken at maximum curvature locations.

Understanding primitives may only be achieved by investigating the neural correlates of sensorimotor learning and control. We already know a lot about the neural correlates of motor imagery and execution as highlighted in Sects. 39.6 and 39.7, which may provide a good starting point to investigate motion primitives, but we will have to go beyond basic correlates to understand the time-dependent, non-linear relationship among various neural correlates of motor learning and control. This will involve new experimental paradigms and computational methods. The following section overviews investigations into sensorimotor learning.

## 39.4 Sensorimotor Learning

Motion planning strategies may also change with learning. If a task is performed for the first time the only strategy the CNS might follow is to develop a plan, which allows the execution of the task without taking into account the *computational cost*. A repetitive performance might result in a change in the coding of the movement and produce a more optimal behavior – at

a lower computational cost. Thus, practice – the track for perfection, allows the performance of many tasks to improve, throughout life, with repetitions.

Even in adulthood simple tasks such as reaching towards a target or rapidly and accurately tapping a short sequence of finger movements, which appear when mastered to be effortlessly performed, often require ex-

tensive training before skilled performance develops. A performance gains asymptotes after a long training period and is usually kept intact for years to come. Many studies have focused on different aspects of motor learning: time scale in motor learning and development, task and effector specificity, effect of attention, and intention and explicit vs. implicit motor learning. These topics are discussed in the next section in the context of motor sequence learning.

### 39.4.1 Explicit Versus Implicit Motor Learning

When considering sequence learning one needs to distinguish between explicit and implicit learning. Explicit learning is frequently assumed to be similar to the processes which operate during conscious problem solving, and includes: conscious attempts to construct a representation of the task; directed search of memory for similar or analogous task relevant information; and conscious attempts to derive and test hypotheses related to the structure of the task. This type of learning has been distinguished from alternative models of learning, termed *implicit* learning. The term *implicit* learning denotes learning phenomena in which more or less complex structures are reflected in behavior, although the learners are unable to verbally describe these structures. Numerous studies have examined implicit learning of serial-order information using the serial reaction time (**SRT**) task. In this task, learning is revealed as a decrease in reaction times for stimuli presented when needed to repeat a sequence versus those presented in a random order.

There is a vast literature debating what is really learned in the **SRT** task. The description of a given sequence structure is from a theoretical point of view not trivial because a given structure typically has several different structural components. Implicit learning may depend on each of these structural components. In sequence learning tasks these components may pertain to: frequency-based, statistical structures (i.e., redundancy), relational structures, and temporal and spatial patterns. A literature review shows that all of these components influence on the rate in which a sequence is learned.

Neuropsychological research suggests that implicit sequence learning in the **SRT** task is spared in patients with organic amnesia, so implicit **SRT** learning does not appear to depend on the medial temporal and diencephalic brain regions that are critical for explicit memory. Conversely, patients with Huntington or Parkinson diseases have consistently shown **SRT** im-

pairments, so the basal ganglia seem to be critically involved in **SRT** learning. Recent studies indicate that the anterior striatum affects learning of new sequences while the posterior striatum is engaged in recalling a well-learned sequence. In the following section the discussion is restricted to explicit motor learning.

### 39.4.2 Time Phases in Motor Learning

It is reasonable to assume that a gain in a motor performance reflects a change in brain processing which is triggered by practice. The verity that many skills, when acquired, are retained over long time intervals suggests that training can induce long-lasting neural changes. Previous results from neuroimaging studies in which performance was modified over time have shown that different learning stages can be defined by altered brain activations patterns. As an effect of repetition or practice, several studies report that specific brain areas showed an increase in the magnitude or extent of activation. Motor skill learning (e.g., sequential finger opposition tasks) requires prolonged training times and has two distinct phases, analogous to those subserving perceptual skill learning: an initial, fast improvement phase (*fast learning*) in which the extent of activation in the **M1** area decreases (habituation-like response) and a slowly evolving, post training incremental performance gain (*slow learning*), in which the activation in **M1** increases compared to control conditions [39.19].

### 39.4.3 Effector Dependency

Another fascinating enigma in the realm of motor learning is whether the representation of procedural memory in the brain changes throughout training and whether different neural correlates underlie the different learning stages. A study conducted on monkeys, in which a sequence of ten button presses is learned by trial and error, has shown that the time course of improvement of two performance measures: key press errors and reaction-time (**RT**), was different [39.20]. The key press errors reached an asymptote within a shorter period of training compared to the **RTs**, which continued to decrease throughout a longer time period. This finding suggested that the acquisition of sequence knowledge (as measured by key press errors) may take place quickly but long-term motor sequence learning (as measured by **RT**) may take longer to be established, thus different aspects of the task are learned in different time scales. Further studies on monkeys and humans demonstrated that although effector-dependent and indepen-

dent learning occur simultaneously, effector-dependent representation might take longer to establish than effector-independent representation.

#### 39.4.4 Coarticulation

After a motor sequence is extensively trained, most of the subjects undergo implicit or explicit anticipation, which results in a coarticulation – the spatial and temporal overlap of adjacent articulatory activities. It is well known that as we learn to speak, our speech becomes smooth and fluent. Coarticulation in speech production is a phenomenon in which the articulator movements for a given speech sound vary systematically with the surrounding sounds and their associated movements. Several models have tried to predict the movements of fleshy tissue points on the tongue, lips, and jaw during speech production. Coarticulation has also been studied in the hand motor sequence. It was shown that pianists could anticipate a couple of notes before playing, which resulted in hand and finger kinematic divergence (assuming an anticipatory position) prior to the depression of the last common note. Such a divergence implies an anticipatory modification of sequential movements of the hand, akin to the phenomenon of coarticulation in speech. Moreover, studies on fluent finger spelling has shown that rather than simply an interaction whereby a preceding movement affects the one following, the anticipated movement in a sequence could systematically affect the one preceding it.

#### 39.4.5 Movement Cuing

Another important aspect of motor sequence performance is the type of movement cuing, external or internal. As internally cued movements are initiated at subject's will, they have, by definition, predictable timing. Externally triggered movements are performed in response to

*go* signals; hence, they have unpredictable timing (unless the timing of the *go* signal is not random and follows some temporal pattern that can be learned implicitly or explicitly). Studies on movement cuing in animals and patients with movement disorders have showed that the basal ganglia are presumably internal-cue generators and that they are preferentially connected with the supplementary motor area (**SMA**), an area that is concerned more with internal than with external motor initiation. In normal subjects the type of movement cuing influences movement execution and performance. It has also been shown that teaching Parkinson disease (**PD**) patients, who are impaired with respect to tasks involving the spontaneous generation of appropriate strategies, to initiate movements concurrently with external cue improved their motor performance.

The preceding sections have provided a brief overview of the extensive literature available on understanding the motor system from an experimental psychophysics and model-based perspective. A focus on general high level modeling is critical to understanding motor control; however, the problem is being tackled from other perspectives, namely understanding the details of neuro and electrophysiology of brain regions and neural pathways involved in controlling motor function. In the context of developing brain-computer interfaces there have been significant efforts focused on understanding small network populations and structural, functional, and electrophysiological correlates of motor functions using epidural and subdural recordings, as well as non-invasively recorded electroencephalography (**EEG**), magnetoencephalography (**MEG**), and magnetic resonance imaging-based (**MRI**) technologies. Understanding the differences between imagined movement and motor execution, as well as the effects of movement feedback and no feedback have shed light on motor functioning. The following sections provide a snapshot of some recent findings.

### 39.5 MRI and the Motor System – Structure and Function

A new key phase of research is beginning to investigate how functional networks relate to structural networks, with emphasis on how distributed brain areas communicate with each other [39.21]. Structural methods have been powerful in indicating when and where changes occur in both gray and white matter with learning and recovery [39.22] and disease [39.23]. Here we review some of the findings in sensorimotor systems with an

emphasis on elucidating regions engaged in motor execution and motor imagery (imagined movement), and motor sequence learning.

Even with identical practice, no two individuals are able to reach the same level of performance on a motor skill – nor do they follow the same trajectory of improvement as they learn [39.24]. These differences are related to brain structure and function, but individual

differences in structure have rarely been explored. Studies have shown individual differences in white matter (**WM**) supporting visuospatial attention, motor cortical connectivity through the Corpus callosum, and connectivity between the motor regions of the cerebellum and motor cortex. Steele et al. [39.24] studied the structural characteristics of the brain regions that are functionally engaged in motor sequence performance along with the fiber pathways involved. Using diffusion tensor imaging (**DTI**), probabilistic tractography, and voxel-based morphometry they aimed to determine the structural correlates of skilled motor performance. **DTI** is used to assess white matter integrity and perform probabilistic tractography.

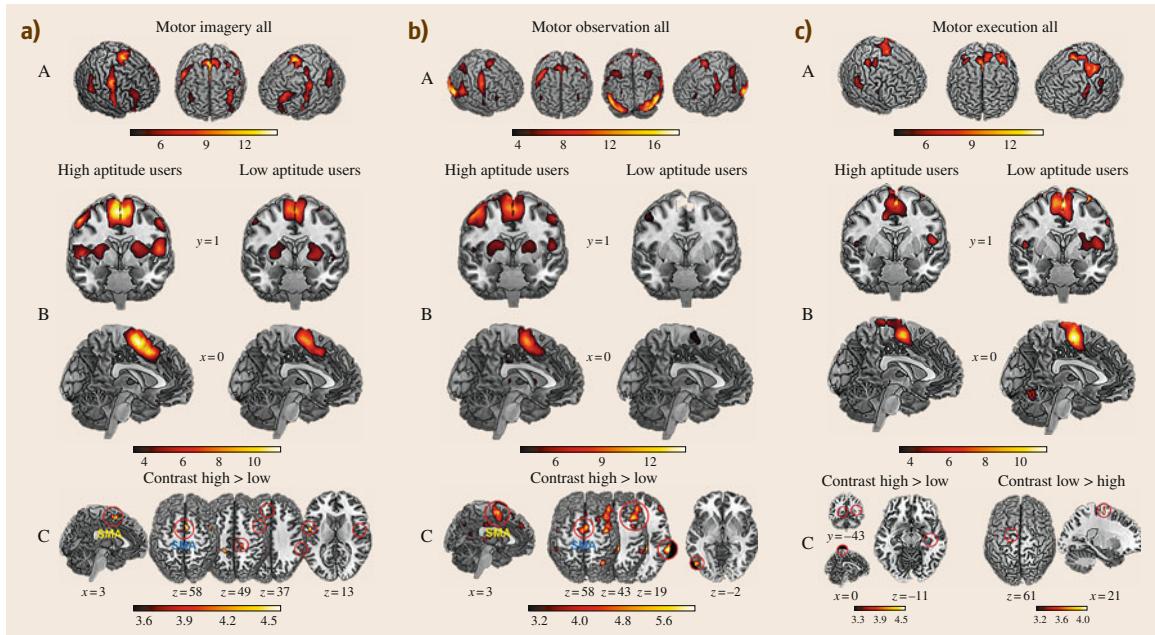

Fractional anisotropy (**FA**) is affected by **WM** properties, including axon myelination, diameter, and packing density. Differences in these properties may lead to individual differences in performance through pre-existing differences or training-induced changes in axon conduction velocity and synaptic synchronization, or density of innervation [39.24, 25]. Greater fiber integrity along the superior longitudinal fasciculus (**SLF**) would be consistent with the idea that greater myelination observed in relation to performance may underlie enhancements in synchronized activity between task-relevant regions.

Voxel-based morphometry is used to assess gray matter (**GM**) volume. Individual differences in **GM** volume may be influenced by multiple factors such as neuronal and glial cell density, synaptic density, vascular architecture, and cortical thickness [39.26].

The majority of structural studies of individual differences find that better performance is associated with higher **FA** or greater **GM** volume. Individual differences in structural measures reflect differences in the microstructural organization of tissue related to task performance. A greater **FA**, an index of fiber integrity, may represent a greater ability for neurons in connected regions to communicate. Steele et al. [39.24] found enhanced synchronization performance on a temporal motor sequence task related to greater fiber integrity of the **SLF**, where the rate of improvement on synchronization was positively correlated with **GM** volume in cerebellar lobules HVI and V-regions that showed training-related decreases in activity in the same sample. The synchronization performance on the task was negatively correlated with **FA** in **WM** underlying the bilateral sensorimotor cortex, in particular within the bilateral corticospinal tract (**CST**), such that participants with greater final synchronization performance on the tasks had lower **FA** in these clusters.

The results provide clear evidence of the importance of structure in learning skilled tasks and that a larger corticospinal tract does not necessarily mean better performance. Enhanced fiber integrity in the **SLF** may result in reduced **FA** in regions where it crosses the **CST** and, therefore, there is a trade-off between the two in the region of the **CST-SLF** fiber crossing, which enables better performance for some motor imagery and **BCI** participants – and is consistent with the idea of enhanced communication/synchronization between regions that are functionally important for this task. The causes of inter-individual variability in brain structure are not fully understood, but are likely to include pre-existing genetic contributions and contributions from learning and the environment [39.24]. Ullén et al. [39.27] attempted to address this by investigating whether millisecond variability in a simple, automatic timing task, isochronous finger tapping, correlates with intellectual performance and, using voxel-based morphometry, whether these two tasks share neuroanatomical substrates. Volumes of overlapping right prefrontal **WM** regions were found to be correlated with both stability of tapping and intelligence. These results suggest a bottom-up explanation where extensive pre-frontal connectivity underlies individual differences in both variables as opposed to top-down mechanisms such as attentional control and cognitive strategies.

Sensorimotor rhythm modulation is the most popular **BCI** control strategy, yet little is known about the structural and functional differences that separate motor areas related to motor output from higher-order motor control areas or about the functional neural correlates of high-order control areas during voluntary motor control. **EEG** and **fMRI** studies have shown the extent of motor regions that are active along with the temporal sequence of activations across different motor areas during a motor task and across different subjects [39.28, 29]. Ball et al. [39.28] have shown that all subjects in an **EEG/fMRI** study involving finger flexion had highly activated primary motor cortex areas along with activation of the frontal medial wall motor areas. They also showed that some subjects had anterior type activations as opposed to posterior activation for others, with some showing activity starting in the anterior cingulate motor area (**CMA**) and then shifting to the intermediate supplementary motor areas. The time sequence of these activations was noted where it was shown that  $\approx 120$  ms before movement onset there was a drop in source strength in conjunction with an immediate increase of source strength in the **M1** area. Those who showed more posterior activations

**Fig. 39.5a–c** Brain activation motor imagery (a) motor observation task (b) and motor execution task (c) showing mean activation of all participants (A), high aptitude users and low aptitude users individually (B), and the contrast of high aptitude users low aptitude users (C). The figure illustrates the maximum contrast between low aptitude and high aptitude BCI users (after [39.29], courtesy of Halder)

were restricted to the posterior **SMA**. Some subjects showed activation of the inferior parietal lobe (**IPL**) during early movement onset. In all subjects showing activation of higher-order motor areas (anterior **CMA**, intermediate **SMA**, **IPL**), these areas became active before the executive motor areas (**M1** and posterior **SMA**). A number of these areas are related to attentional processing, others to triggering and others to executing. Understanding the sequence of these events for each individual in the context of rehabilitation and more advanced brain and neural computer interfacing will be important.

The neural mechanisms of brain–computer interface control were investigated by [39.29] in an **fMRI** study. It was shown that up to 30 different motor sites are significantly activated during motor execution, motor observation, and motor imagery and that the number of activated voxels during motor observation was significantly correlated with accuracy in an **EEG** sensorimotor rhythm-based (**SMR**) **BCI** task (see Sect. 39.7.1 for further details on **SMR**). Significantly higher activations of the supplementary motor areas for motor imagery and motor observation tasks were observed for high aptitude **BCI** users (see Fig. 39.5 for

an illustration [39.29]). The results demonstrate that acquisition of the sensorimotor program reflected in **SMR-BCI** control (Sect. 39.7.1) is tightly related to the recall of such sensorimotor programs during observation of movements and unrelated to the actual execution of these movement sequences.

Using such knowledge about sensorimotor control will be critical in understanding and developing successful learning and control models for robotic devices and **BCIs**, and fully closing the sensorimotor learning loop to enable finer manipulation abilities using **BCIs** and for retraining or enabling better relearning of motor actions after cortical damage. Understanding the neuroanatomy involved in motor execution/imagery/observation may also provide a means of enhancing our knowledge of motion primitives and their neural correlates as discussed in Sect. 39.4. **MRI** and **fMRI**, however, only provide part of the picture, at the level of large networks of neurons, and on relatively large time scales. Invasive electrophysiology, however, can target specific neuronal networks at millisecond time resolution. The following section highlights some of the most recent findings from motor cortical surface potentials investigations.

## 39.6 Electrocorticographic Motor Cortical Surface Potentials

The electroencephalogram ([EEG](#)) is derived from the action potentials of millions of neurons firing electrical pulses simultaneously. The human brain has more than 100 000 000 000 ( $10^{11}$ ) neurons and thousands of spikes (electrical pulses) are emitted each millisecond. [EEG](#) reflects the aggregate activity of millions of individual neurons recorded with electrodes positioned in a standardized pattern on the scalp. Brainwaves are categorized into a number of different frequency bands including delta (1–4 Hz), theta (5–8 Hz), alpha (8–12 Hz), mu (8–12 Hz), beta (13–30 Hz), and gamma (> 30 Hz). Each of these brain rhythms can be associated with various brain processes and behavioral states, however, knowledge of exactly where brainwaves are generated in the brain, and if/how they communicate information, is very limited. By studying brain rhythms and oscillations we attempt to answer these questions and have realized that brain rhythms underpin almost every aspect of information processing in the brain, including memory, attention, and even our intelligence. We also observe that abnormal brain oscillations may underlie the problems experienced in diseases such as epilepsy or Alzheimer's disease and we know that certain changes in brain rhythms and oscillations are good indicators of brain pathology associated with these diseases. If we know more about the function of brainwaves we may be able to develop better diagnosis and treatments of these diseases. It may also lead to better computational tools and better bio-inspired processing tools to develop artificial cognitive systems.

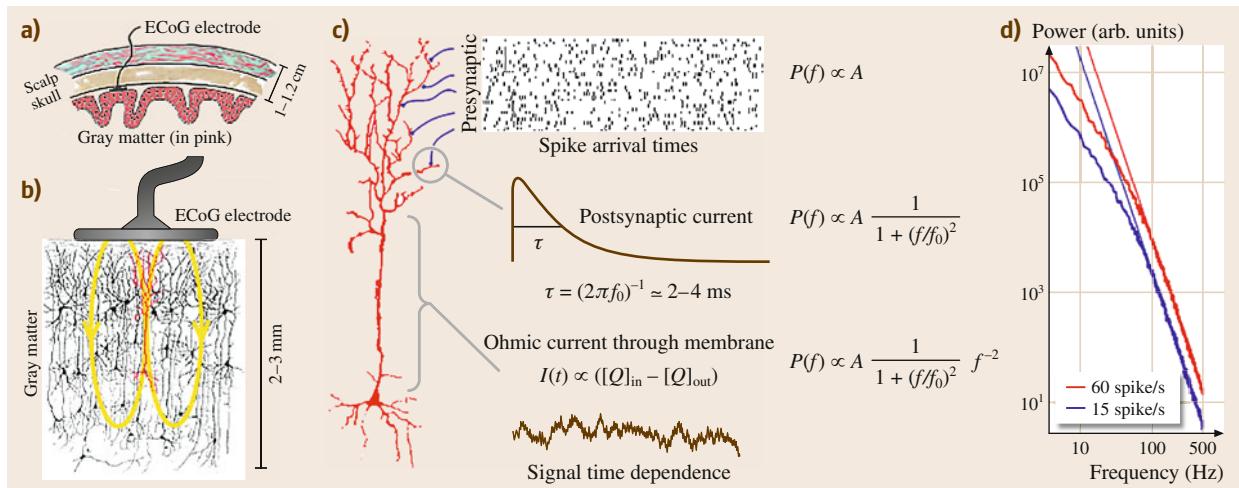

Brain rhythmic activity can be recorded non-invasively from the scalp as [EEG](#) or intracranially from the surface of the cortex as cortical [EEG](#) or the electrocorticogram ([EEG](#) is described in Sect. 39.7).

Elecrocorticography ([ECoG](#)), involving the clinical placement of electrode arrays on the brain surface (usually above the dura) enables the recording of, similar to [EEG](#), large-scale field potentials that are primarily derived from the aggregate synaptic potential from large neuronal populations, whereby synaptic current produces a change in the local electric field. [ECoG](#) can characterize local cortical potentials with high spatiotemporal precision ( $0.5 \text{ cm}^2$  in [ECoG](#) compared to  $1 \text{ cm}^2$  in [EEG](#)) and high amplitudes ( $10\text{--}200 \mu\text{V}$  in [ECoG](#) compared to  $10\text{--}100 \mu\text{V}$  in [EEG](#)). Furthermore, the [ECoG](#) spectral content can reach 300 Hz (compared to 60 Hz in [EEG](#)) due to the closer vicinity of the electrodes to the electric source (the non-homogenous,

anisotropic brain volume and tissues act as a low-pass filter). Independent individual finger movement dynamics can be resolved at the 20 ms time scale, which has been shown not to be possible with [EEG](#) (but has recently been demonstrated using [MEG](#) [39.30] as described in Sect. 39.7). Here we review some of the latest findings of [ECoG](#) studies involving human sensorimotor systems.

The power spectral density ([PSD](#)) of the cortical potential can reveal properties within neuronal populations. Peaks in the [PSD](#) indicate activity that is synchronized across a neuronal population, for example, movement decreases the lateral frontoparietal alpha (8–12 Hz) and beta rhythm (12–30 Hz) amplitudes with limited spatial specificity whereas high gamma changes, which are spatially more focused, are also observable during motor control. *Miller et al.* [39.31], however, observed through a range of studies investigating local gamma band-specific cortical processing, a lack of distinct peaks in the cortical potential [PSD](#) beyond 60 Hz and hypothesized the existence of broadband changes across all frequencies that were obscured at low frequencies by covariate fluctuations in  $\theta$  (4–7 Hz),  $\alpha$  (8–12 Hz), and  $\beta$  (13–30 Hz) band oscillations. They demonstrated that there is a phenomenon that obeys a broadband, power-law form extending across the entire frequency range. Even with local brain activity in the gamma band there is an increase in power across all frequencies, and the power law shape is conserved. This suggests that there are phenomena with no special timescale where the neuronal population beneath does not oscillate synchronously but may simply reflect a change in the population mean firing rate. *Miller et al.* [39.31] postulated that the power-law scaling during high  $\gamma$  activity is a reflection of changes in asynchronous activity and not necessarily synchronous, rhythmic, action potential activity changes, as is often hypothesized.

These findings suggest a fundamentally different approach to the way we consider the cortical potential spectrum: power-law scaling reflects asynchronous, averaged input to the local neural population, whereas changes in characteristic brain rhythms reflect synchronized populations that coherently oscillate across large cortical regions. *Miller et al.* [39.31] also augment the findings by demonstrating power-law scaling in simulated cortical potentials using small-scale, simplified integrate and fire neuronal models, an example of which is shown in Fig. 39.6.

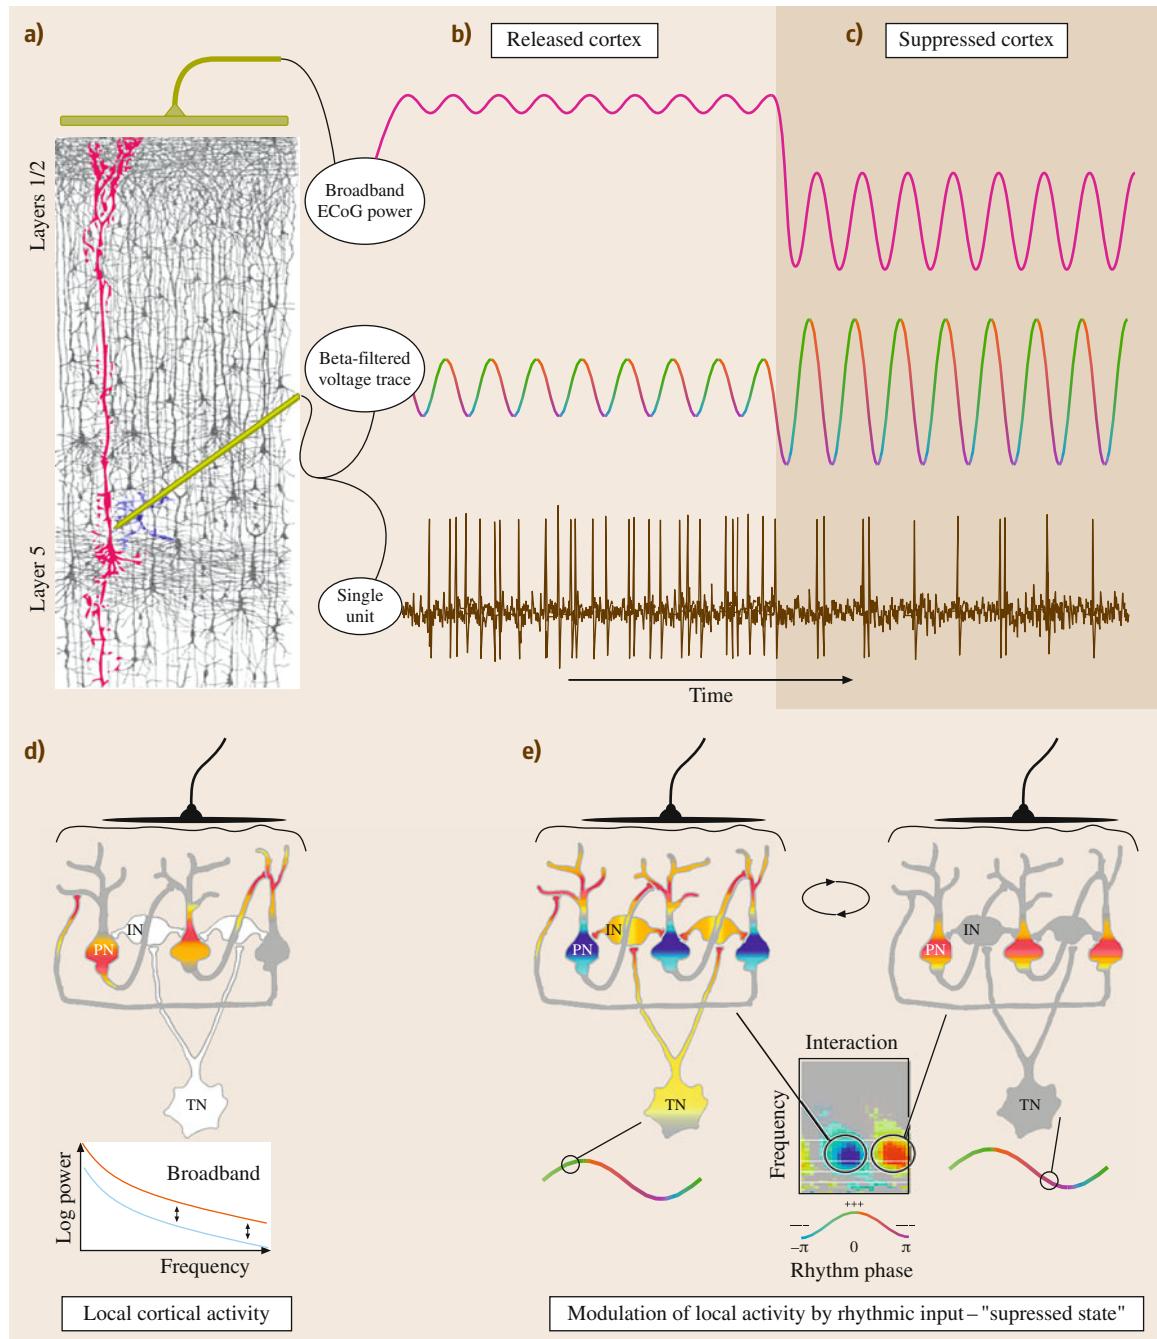

**Fig. 39.6a-d** An illustration of how the power-law phenomena in the cortical potential might be generated based on a simulation study (see [39.31] for details). Panel (d) shows the PSD of this signal and has a knee 70 Hz, with a power law of  $P \approx 1/f^4$ , which would normally be observed in **ECoG PSD**. The change in the spectra with increasing mean spike rate of synaptic input strongly resembles the change observed experimentally over motor cortex during activity, as demonstrated in [39.31] (after [39.31] with permission from *Miller*)

Knowledge of this power-law scaling in the brain surface electric potential was subsequently exploited in a number of further studies investigating differences in motor cortical processing during imagined and executed movements [39.32] and the role of rhythms and oscillations in sensorimotor activations [39.33].

As outlined, motor imagery to produce volitional neural signals to control external devices and for rehabilitation is one of the most popular approaches employed in brain-computer interfaces. As highlighted in the previous section neuroimaging using hemodynamic markers (positron emission tomography (**PET**) and **fMRI**) and extra cerebral magnetic and electric field studies (**MEG** and **EEG**) have shown that motor imagery activates many of the same neocortical areas as those involved in planning and execution of movements. *Miller* et al. [39.32] studied the execution-imagery similarities with electrocorticographic cortical surface potentials in eight human subjects during overt action and kinaesthetic imagery of the same movement to determine what and where are the neuronal substrates that underlie motor imagery-based learning and the congruence of cortical electrophysiologic change associated with motor movement and motor imagery. The results show that the spatial distribution of activation significantly overlaps between hand and tongue movement in the lower frequency bands (**LFB**) but not in the higher frequency bands (**HFB**), whereas during

**Fig. 39.7a-e** An illustration of modes of neural activity with cortical beta rhythm states. **(a)** Modulation of broadband amplitude by underlying rhythm can be thought of as population-averaged spike-field interaction. **(b)** Released cortex demonstrates a small amount of broadband power coupling to underlying rhythm phase, and the underlying spiking from pyramidal neurons is high in rate and only weakly coupled to the underlying rhythm phase. **(c)** Suppressed cortex demonstrates less broadband power but with higher modulation by the underlying rhythm, while underlying single unit spiking is low in rate but tightly coupled to the rhythm phase. **(d)** A simplified heuristic for how rhythms might influence cortical computation: During active computation, pyramidal neurons (**PN**) engage in asynchronous activity, where mutual excitation has a sophisticated spatio-temporal pattern. Averaged across the population, the **ECoG** signal shows broadband increase, with negligible beta. **(e)** During resting state, cortical neurons, via synchronized interneuron (**IN**) input, are entrained with the beta rhythm, which also involves extracortical circuits symbolized by the input from a synchronizing neuron in the thalamus (**TN**). The modulation of local activity with rhythms is revealed in the **ECoG** by significant broadband modulation with the phase of low frequency rhythms (after [39.33], courtesy of *Miller*; see [39.33] for further details) ►

kinaesthetic imagination of the same movement task the magnitude of spectral changes were smaller (26% less

calculated across the electrode array) even though the spatially broad decrease in power in the LFB and the focal increase in HFB power were similar for movement and imagery.

During an imagery-based learning task involving real-time feedback of the magnitude of cortical activation of a particular electrode, in the form of cursor movement on screen, the spatial distribution of HFB ac-

tivity was quantitatively conserved in each case, but the magnitude of the imagery associated spectral change increased significantly and, in many cases, exceeded that observed during actual movement. The spatially broad desynchronization in LFB is consistent with EEG-based imagery, which uses  $\alpha/\beta$  desynchronization as a means of cursor control in BCIs [39.19]; however, the results demonstrate that this phenomena reflects an aspect of cortical processing that is fundamentally non-specific. LFB desynchronization may reflect altered feedback between cortical and subcortical structure with a timescale of interaction that corresponds to the peak frequency in the PSD as opposed to local, somatotopically distinct, population-scale computation. Miller et al. [39.32] speculate that the significant LFB power difference during movement and imagery might be a correlate of a partial release of cortex by subcortical structures (partial decoherence of a synchronized corticothalamic circuit) as opposed to a complete release during actual movement or after motor imagery feedback.

The HFB change is reflective of a broadband PSD increase that is obscured at lower frequencies by the motor associated  $\alpha/\beta$  rhythms but which has been specifically correlated with local population firing rate and is observed in a number of spatially overlapping areas, including primary motor cortical areas for both movement and imagery. These findings have been used for much speculation about the neural substrates and electrophysiology of movement control. The results clearly demonstrate the congruence in large-scale activation between motor imagery and overt movement, and imagery-based feedback and the overlapping activation in distributed circuits during movement and imagery, the clear role of the primary motor cortex during motor imagery, and the role of feedback in the augmentation of widespread neuronal activity during motor imagery. Electrocorticographic evidence of the relevance of the role of primary motor areas during motor imagery to complement EEG and neuroimaging showing primary motor activation during imagery/movement such as those outlined in the previous section was also an outcome of the study. The dramatic augmentation given by feedback, particularly in primary motor cortex is significant, particularly in the context of BCI training, because it demonstrates a dynamic restructuring of neuronal dynamics across a whole population in the motor cortex on very short time scales ( $< 10$  min) [39.32]. This augmentation and restructuring can, indeed, result in improved motor imager performance over time but leads to the necessity to co-adapt the BCI signal pro-

cessing to cope with associated non-stationary drifts in the resulting oscillations of cortical potentials (a topic to which we return in Sect. 39.9).

Human motor behaviors such as reaching, reading, and speaking are executed and controlled by somatomotor regions of the cerebral cortex, which are located immediately anterior and posterior to the central sulcus [39.33]. Electrical oscillations in the lower beta band (12–20 Hz) have been shown to have an inverse relationship to motor production and imagery, decreasing during movement initiation and production and rebounding (synchronization) following movement cessation and during imagery continuation in the peri-central somatomotor and somatosensory cortex.

Investigations have been conducted to determine whether beta rhythms play an active role in the computations taking place in somatomotor cortex or whether it is epiphenomenon of cortical state changes influenced by the other cortical or subcortical processes [39.33]. There is strong correlation between the firing time of individual neurons in the primary motor cortex and the phase of the beta rhythms in the local field potential [39.34]. Miller et al. [39.33] have acquired ECoG evidence of the role of beta rhythms in the organization of the somatomotor function by analyzing the broadband spectral power on fast time scales (tens of milliseconds) during rest (visual fixation) and finger flexion. The results show that cortical activity has a robust entrainment on the phase of the beta rhythms, which is predominant in peri-central motor areas whereby broadband spectral changes vary with the phase of underlying motor beta rhythm. This relationship between beta rhythms and local neuronal activity is a property of the *idling* brain (present during resting and selectively diminished during movement). Specifically, Miller et al. [39.33] propose that the predominant pattern for the beta range shows a tendency for brain activity, as measured by broadband power, to increase just prior to the surface negative phase and decrease just prior to the surface positive phase of the beta rhythm, which they refer to as rhythmic entrainment. The predominant phase couplings for  $\theta/\alpha/\beta$  ranges are found to be different and have different spatial localizations.

Miller et al. [39.33] proposed a *suppression through synchronization hypothesis*, whereby diffuse cortical inputs originating from subcortical areas might functionally suppress large regions of the cortex, the advantage of which is to enable selective engagement of task-relevant and task-irrelevant brain circuits and for dynamical reallocation of metabolic resources. This shifting entrainment suggests that the  $\beta$ -rhythm is not

simply a background process that is suppressed during movement, but rather that the beta rhythm plays an active and important role in motor processing. In recent years, there has been a growing focus on coupling be-

tween neuronal firing and rhythmic brain activity, and this study provides substantial evidence and methodology to support the important role of brain rhythms in neuronal functioning.

## 39.7 MEG and EEG – Extra Cerebral Magnetic and Electric Fields of the Motor System

The previous section highlighted a number of the most recent examples of **ECoG**-based studies that are shedding more light on the way in which the motor system processes information and is activated during imagery and movement. As electrocorticography is a highly invasive procedure involving surgery, a key question that has been addressed is whether the spectral findings and spatial specificity of **ECoG** will ever be possible using non-invasive extracerebrally acquired **EEG**, or whether **ECoG** findings can be used to develop better **EEG**-based processing methodologies to extract **ECoG** information. At the International **BCI** meeting in 2010 a workshop addressed the critical questions around the state-of-the-art **BCI** signal processing, in particular, *should future **BCI** research emphasize a shift from scalp-recorded **EEG** to **ECoG**, and how are the signals from the two modalities related?* [39.35].

There is still much debate around the future of **EEG** for **BCI** due to its limited spatial resolution and various noise-related issues, whereas **ECoG** shows much promise in addressing both of these issues. However, **ECoG** requires surgical implantation and the long-term effectiveness remains to be verified in humans. A step toward answering this question is to better understand the relationship between **EEG** and **ECoG**. In a workshop summary the question was addressed by comparing and contrasting the contribution of population synchronized (rhythmic) and asynchronous changes in the **EEG** and **ECoG** potential measurements [39.35]. The beta rhythm is robust in extracerebral **EEG** recordings, spatially synchronous across the pre and postcentral gyri, so this coherent rhythm is augmented with respect to background spatial averaging. The different states of the surface rhythms may represent switching between the stable modes observed in on-going surface oscillations.

In contrast, the broadband spectral change that accompanies movement is asynchronous at the local level and unrelated across cortical regions, so it is distorted or diminished by spatial averaging. *Krusienski et al. [39.35]* compared the contribution of popula-

tion synchronized (rhythmic) and asynchronous (broadband,  $1/f$ ) changes in the **EEG** and **ECoG** potential measurements using a number of simplifications and approximations. These approximations suggest that synchronized cortical oscillations may be differently reflected at the **EEG** scale than the **ECoG** scale. *Krusienski et al. [39.35]* show that to have the same contribution to **EEG** that a single cortical column has on **ECoG**, the spatial extent of cortical activity would have to span nearly the full width of a gyrus, and nearly a centimeter longitudinally. Based upon **ECoG** measurements of the  $1/f$  change in the visual cortex, the findings confirm the possibility of detecting  $1/f$  change in **EEG** during visual input directly over the occipital pole as an event-related potential. In the pre-central motor cortex, the movement of several digits in concert can produce a widespread change, which is dramatic enough to be measured in the **EEG**; however, based on these findings, the detection of single finger digit movement in **EEG** is not possible. This finding has been supported in other recent studies, a number of which involved magnetoencephalography (**MEG**). As with **EEG**, the magnetoencephalogram (**MEG**) is recorded non-invasively; however **MEG** is a record of magnetic fields, measured outside the head, produced by electrical activity within the brain, whereas **EEG** is a measure of the electrical potentials. Synchronized neuronal currents, produced primarily by the intracellular electrical currents within the dendrites of pyramidal cells in the cortex, induce weak magnetic fields. Neuronal networks of 50 000 or more active neurons are needed to produce a detectable signal using **MEG**. **MEG** has a number of advantages over **EEG**, most notably its spatial specificity as the magnetic flux detected at the surface of the head with **MEG** penetrates the skull and tissues without significant distortion, unlike the secondary volume currents detected outside the head with **EEG** [39.36]. **MEG**, however, is also less practical, requiring significant shielding from environmental electric magnetic interference and is not a wearable or mobile technology like **EEG** and, therefore, cannot be used for bedside record-

ings in a clinical setting or mobile **BCI** applications. **MEG** has been used in a range of clinical applications (cf. [39.36] for a review) and for research. Below we describe a number of studies with focus on motor cortical investigations in the context of developing brain–computer interfaces.

*Quandt* et al. [39.30] have investigated single trial brain activity in **MEG** and **EEG** recordings elicited by finger movement on one hand. The muscle mass involved in finger movement is smaller than in limb or hand movement, and neuronal discharges of motor cortex neurons are correspondingly smaller in finger movement than in arm or wrist movements. This makes detection of finger movement more difficult from non-invasive recordings. Using **MEG** *Kauhanen* et al. [39.37, 38] showed that left and right-hand index finger movement can be discriminated and that single trial brain activity recorded non-invasively can be used to decode finger movement; however, there are significant obstacles in non-invasive recordings in terms of the substantial overlapping activations in **M1** when decoding individual finger movements on the same hand. *Miller* et al. [39.39] and *Wang* et al. [39.40] have shown that real-time representation of individual finger movements is possible using **ECoG**; however, finger movement discrimination from extracerebral neural recordings has only recently been shown to be possible. *Quandt* et al. [39.30] found using simultaneously recorded **EEG** and **MEG** that finger discrimination on the same hand is possible with **MEG** but **EEG** is not sufficient for robust classification. The lower spatial resolution of scalp signal **EEG** is due to the spatial blurring at the interface of tissues with different conductance. The issue cannot be overcome by increasing the density of **EEG** electrodes. It is speculated that the strong curvature of the cortical sheet in the finger knob (an omega-shaped knob of the central sulcus) contributes to the high decoding accuracy of **MEG**, whereby orientation change in the active tissue may change spatial patterns of magnetic flux measured in sensor space, but potentials caused by the same processes are not detectable at the scalp. Using different approaches four fingers on the same hand could be decoded with circa 57% accuracy using **MEG** and across all cases **MEG** performs better than **EEG** ( $p < 0.005$ ), whilst **EEG** often only produced accuracies slightly above the upper confidence interval for guessing.

Analysis of the oscillations from **MEG** correspond to **ECoG** studies where the power of the lower oscillations ( $< 60\text{ Hz}$ ) decreases around the movement, whereas power in the high gamma band increases

and that the effects in the high gamma band are more spatially focused than in the lower frequency bands [39.30]. Interestingly, the discrimination accuracy from the band power of the most informative frequency band between 6 and 11 Hz was clearly inferior to the accuracy derived from the time-series data, indicating that slow movement-related neural activation modulations are most informative about which finger of a hand moves, and the inferior accuracy given by the band power is likely to be due to the lack of phase information contained in band-power features [39.30] (time embedding, temporal sequence information and exploiting phase information in discriminating motor signals are revisited in Sect. 39.9).

The above are just a few examples of what has been shown not to be possible to characterize sufficiently in **EEG**. The following section provides an overview of the known sensorimotor phenomena detectable from **EEG** and some of the most recent advances in decoding hand/arm movements non-invasively.

### 39.7.1 Sensorimotor Rhythms and Other Surrounding Oscillations

There are a number of rhythms and potentials that have been strongly linked with motor control, many of which have been exploited in **EEG**-based non-invasive **BCI** devices. As outlined previously, the sensorimotor area (**SMA**) generates a variety of rhythms that have specific functional and topographic properties. To reiterate, distinct rhythms are generated by hand movements over the post central somatosensory cortex. The  $\mu$  (8–12 Hz) and  $\beta$  (13–30 Hz) bands are altered during sensorimotor processing [39.41–43]. Attenuation of the spectral power in these bands indicates an event-related desynchronization (**ERD**), whilst an increase in power indicates event-related synchronization (**ERS**). **ERD** of the  $\mu$  and  $\beta$  bands are commonly associated with activated sensorimotor areas and **ERS** in the  $\mu$  band is associated with idle or resting sensorimotor areas. **ERD/ERS** has been studied widely for many cognitive studies and provides very distinctive lateralized **EEG** pattern differences, which form the basis of left hand vs. right hand or foot MI-based **BCIs** [39.44, 45]. However, as outlined above, later studies have shown the actual rhythmic activity generated by the sensorimotor system can be much more detailed. The  $\alpha$  or  $\mu$  component of the **SMR** also has a phase-coupled second peak in the beta band. Both the alpha and beta peaks can become independent at the offset of a movement, after which the beta band rebounds faster and

with higher amplitude than the alpha band. Desynchronization of the beta band during a motor task can occur in different frequency bands than the subsequent resynchronization (rebound) after the motor task [39.41]. As previously outlined, many studies have shown that neural networks similar to those of executed movement are activated during imagery and observation of movement and thus similar sensorimotor rhythmic activity can be observed during motor imagery and execution.

Gamma oscillations of the electromagnetic field of the brain are known to be involved in a variety of cognitive processes and are believed to be fundamental for information processing within the brain. Gamma oscillations have been shown to be correlated with other brain rhythms at different frequencies and a recent study has shown the causal influences of gamma oscillation on sensorimotor rhythms (**SMR**) in healthy subjects using magnetoencephalography [39.46]. It has been shown that the modulation of sensorimotor rhythms is positively correlated with the power of frontal and occipital gamma oscillations, negatively correlated with the power of centro-parietal gamma oscillations and that simple causal structure can be attributed to a causal relationship or influence of gamma oscillations on the **SMR**. The behavioral correlate of the topographic alterations of gamma power, a shift of gamma power from centro-parietal to frontal and occipital regions, remains elusive, although increased gamma power over frontal areas has been associated with selective attention in auditory paradigms. Grosse-Wentrup et al. [39.46] postulated that neurofeedback of gamma activity may be used to enhance **BCI** performance to help low aptitude **BCI** users, i. e., those who appear incapable of **BCI** control using **SMR**.

### 39.7.2 Movement-Related Potentials

Signals observed during and before the onset of movement signify motor planning and preparation. For example, the *bereitschafts potential* or **BP** (from German, *readiness potential*), also called the pre-motor potential or readiness potential (**RP**), is a measure of activity in the motor cortex of the brain leading up to voluntary muscle movement [39.47, 48]. The **BP** is a manifestation of cortical contribution to the pre-motor planning of volitional movement. Krauledat et al. [39.49, 50] report on experiments carried out using the lateralized readiness potential (**LRP**) (i. e., *Bereitschafts potential*) for brain–computer interfaces. Before accomplishing motor tasks a negative readiness potential which reflects the preparation can be observed. They showed

it is possible to distinguish the pre-movement potentials from finger tapping experiments, even before the movement occurs or the onset of the movement, thus potentially improving accuracy and reducing latency in the **BCI** system. The **BP** is ten to a hundred times smaller than the  $\alpha$ -rhythm of the **EEG** and it can only be identified by averaging across trials and has two components: an early component referred to as **BP1** (sometime **NS1**) lasting from about  $-1.2$  to  $-0.5$  s before movement onset (negative slope (**NS**) of early **BP**) and a late component (**BP2** or **NS2**) from  $-0.5$  to shortly before 0 s (steeper negative slope of late **BP**) [39.48, 51, 52]. A pre-movement positivity can be observed along with a motor-potential which starts about 50 to 60 ms before the onset of movement and has its maximum over the contralateral precentral hand area.

### 39.7.3 Decoding Hand Movements from **EEG**

Movement-related cortical potentials (**MRCP**) have been used as control signals for **BCIs** [39.53]. **MRCP** and **SMR** have distinct changes during execution or imagination of voluntary movements. **MRCP** is considered a slow cortical potential where the surface negativity which develops 2 s before the movement onset is the *Bereitschaftspotential* referred to above. Gu et al. [39.53] studied **MRCP** and **SMRs** in the context of discriminating the movement type and speed from the same limb based on the hypothesis that if the imagined movements are related to the same limb, the control could be more natural than associating commands to movements of different limbs for **BCIs**. They focused on fast slow wrist rotation and extension and they found that average **MRCPs** rebounded more strongly when fast-speed movements were imagined compared with slow-speed movements; however, the rebound rate of **MRCP** was not substantially different between movement types. The peak negativity was more pronounced in the frontal (Fz) and central region (C1) than in the occipital region (Pz). The rebound rate of **MRCP** was greater in the central region (C1) when compared to the occipital region (Pz). **MRCP** and **SMR** are independent of each other as they originate from different brain sources and they occupy different frequency bands [39.52–54]. This renders them useful for multi-dimensional control in **BCIs**.

In accordance with the analysis of averaged **MRCPs**, the single-trial classification rate between two movements performed at the same speed was lower than when combining movements at different speeds. Gu et al. [39.53] suggest that selecting different speeds

rather than different movements when these are executed at the same joint may be best for **BCI** applications. However, the task pair that was optimal in terms of classification accuracy is subject-dependent, and thus a subject-specific evaluation of the task pair should be conducted. The study by *Gu* et al. [39.53] is important as it is one of a limited number of studies that focus on discriminating different movements of the same limb as opposed to moving different limbs from **EEG**, which is much more common practice in **BCI** designs. However, *Lakany* and *Conway* [39.55] investigated the difference between imagined and executed wrist movements in 20 different directions using machine learning and found that the accuracy of discriminating wrist movement imagination is much less than for actual movement; however, they later found [39.56] time-frequency **EEG** features modulated by force direction in arm isometric exertions to four different directions in the horizontal plane can give better directional discrimination information and that *t-f* features from the planning and execution phase may be most appropriate.

Although a limited number of works demonstrating **EEG**-based **2-D** and **3-D** continuous control of a cursor through biofeedback have been reported [39.57, 58] along with a few studies of classification of the direction/speed of **2-D** hand/wrist movements outlined above, there are very few studies that have demonstrated continuous decoding of hand kinematics from **EEG**. Classification of different motor imagery tasks on single trial basis is more commonly reported. The signal-to-noise ratio, the bandwidth, and the information content of electroencephalography are generally thought to be insufficient to extract detailed information about natural, multi-joint movements of the upper limb. However, evidence from a study by *Bradberry* et al. [39.59] investigating whether the kinematics of natural hand movements are decodable from **EEG** challenges this assumption. They continuously extract hand velocity from signals collected during a three-dimensional (**3-D**) center-out reaching task and found that a linear **EEG** decoding model could reconstruct **3-D** hand-velocity profiles reasonably well and that sensor CP3, which lies roughly above the primary sensori-

motor cortex contralateral to the reaching hand, made the greatest contribution. Using a time-lagged approach they found that **EEG** data from 60 ms in the past supplied the most information with 16.0% of the total contribution suggesting a linear decoding method such as the one used [39.59] rely on a sub-seconds history of neural data to reconstruct hand kinematics. Using a source localization technique they found that the primary sensorimotor cortex (pre-central gyrus and post-central gyrus) was indeed a major contributor along with the inferior parietal lobule (**IPL**), all of which have been found to be activated during motor execution and imagery in other investigations [39.12, 13, 16]. *Bradberry* et al. [39.59] also found that the movement variability is negatively correlated with decoding accuracy, suggesting two reasons; 1) increased movement variability could degrade decoding accuracy due to less similar pairs of **EEG**-kinematic exemplars, i.e., less movement variability results in reduced intra-class variability for training, and 2) subjects differ in their ability to perform the task without practice (motor learning is important for improving predictions of movement). Hence, the strengths of a priori neural representations of the required movements vary until learned or practiced, and these differences could directly relate to the accuracy with which the representations can be extracted. This study provides important evidence that decodable information about detailed, complex hand movements can be derived from the brain non-invasively using **EEG**; however, it remains to be determined whether these findings are consistent when using the same methodology in an imagined **3-D** center-out task.

Although we know a lot about brain structure associated with sensorimotor activity, as well as the rhythms and potentials surrounding this activity, we have not yet systematically linked the neural correlates of these to specific motion primitives or motor control models. Modeling, using biological plausible neural models, the findings in relation to motor cortical structure, function, and dynamics along with linkage to the underlying motor psychophysics and advanced signal processing in **BCI** may help advance our knowledge on motion primitives, sensorimotor learning, and control.

## 39.8 Extracellular Recording – Decoding Hand Movements from Spikes and Local Field Potential

Although **fMRI**, **MEG**, and **EEG** offer low risk, non-surgical recording procedures they have inherent limita-

tions which many expect can be overcome with invasive approaches such as **ECoG** (described in Sect. 39.6) and

by implanting electrodes to record the electrical activity of single neurons extracellularly (single unit recordings). Here we focus on some recent studies aimed at testing this scale for use in sensorimotor-related BCIs.

Extracellular recording has many advantageous, including high signal amplitude (up to  $500\text{ }\mu\text{V}$ ), low susceptibility to external noise and artefact (eye movements, cardiac activity, muscle activity) leading to high signal-to-noise ratio, high spatial resolution ( $50\text{ }\mu\text{m}^2$ ), high temporal resolution ( $\approx 1\text{ ms}$ ), and high spectral content (up to  $2\text{ kHz}$ ) due to the close vicinity to the electric source. As a consequence, there is a high correlation between the neural signals recorded and the generated/imagined hand movements, resulting in a short learning duration when employed in a motor BCI system. The disadvantages of the invasive recording technique include a complex and expensive medical procedure, susceptibility to infections (possibly leading to meningitis, epilepsy), pain, prolonged hospitalization, direct damage to the neural tissue (e.g., a flat  $15\text{ }\mu\text{m} \times 60\text{ }\mu\text{m}$  electrode penetrating  $2\text{ mm}$  deep hits, on average, 5 neurons and 40 000 synapses), indirect damage to the neural tissue (small blood vessels are hit by the electrode causing ischemia for distant neurons and synapses and the evolution of an inflammatory response), and evolvement of a scarred tissue which electrically isolates the electrodes from the surroundings and render the system non-responsive after being implanted for extended durations. Furthermore, the electrode material itself, however biocompatible, sooner or later causes an inflammatory reaction and the evolvement of scarred tissue.

Theoretically, however, extracellular recordings offer more accurate information that may enable us to devise realistic BCI systems that allow for additional degrees of freedom and natural control of prosthetic devices, such as a hand and arm prostheses. To this end, substantial efforts have been put into devising novel biocompatible electrodes (e.g., platinum, iridium oxide, carbonic polymers) that will delay immune system stimulation, devising multi-functional micro-electrodes that allow for recording/stimulating while injecting anti-inflammatory agents to suppress inflammatory response, devising hybrid microelectrodes that allow for the inclusion of pre-amplifier and multiplexer on the electrode chip to allow wireless transmission of the data, thus avoiding the necessity for a scalp drill hole used for taking out the flat cable carrying the neural data, which is prone to causing infections.

Extracellular recording, being the most invasive recording technique (compared to non-invasive EEG and MEG recording and partially invasive ECoG recording) allows recording both the high-frequency content neural *output* activity, i. e., spikes, and the low frequency content neural *input* activity, denoted as local field potential (LFP), which is the voltage caused by electrical current flowing from all nearby dendritic synaptic activity across the resistance of the local extracellular space. In the following section, the neural coding schemes, in general, and the cortical correlates of kinematic and dynamic motion attributes, in specific, will be presented along with their suggested use for current and future BCI systems.

### 39.8.1 Neural Coding Schemes

A sequence, or *train*, of spikes may contain information based on different coding schemes. In motor neurons, for example, the strength at which an innervated muscle is flexed depends solely on the *firing rate*, the average number of spikes per unit time (a *rate code*). At the other end, a complex *temporal code* is based on the precise timing of single spikes. They may be locked to an external stimulus such as in the auditory system or be generated intrinsically by the neural circuitry. Whether neurons use rate coding or temporal coding is a topic of intense debate within the neuroscience community, even though there is no clear definition of what these terms mean. Neural schemes include rate coding, spike count rate, time-dependent firing rate, temporal coding, and population coding.

#### Rate coding

*Rate coding* is a traditional coding scheme, assuming that most, if not all, information about the stimulus is contained in the firing rate of the neuron. The concept of firing rates has been successfully applied during the last 80 years. It dates back to the pioneering work of Adrian and Zotterman who showed that the firing rate of stretch receptor neurons in the muscles is related to the force applied to the muscle [39.60]. In the following decades, measurement of firing rates became a standard tool for describing the properties of all types of sensory or cortical neurons, partly due to the relative ease of measuring rates experimentally.

Because the sequence of action potentials generated by a given stimulus varies from trial to trial, neuronal responses are typically treated statistically or probabilistically. They may be characterized by firing rates, rather than as specific spike sequences. In most

sensory systems, the firing rate increases, generally non-linearly, with increasing stimulus intensity. Any information possibly encoded in the temporal structure of the spike train is ignored. Consequently, rate coding is inefficient but highly robust with respect to the inter-spike interval (**ISI**) noise. During recent years, more and more experimental evidences have suggested that a straightforward firing rate concept based on temporal averaging may be too simplistic to describe brain activity [39.61]. In rate coding, learning is based on activity-dependent synaptic weight modifications.

### Spike-count rate

*Spike-count rate* also referred to as temporal average, is obtained by counting the number of spikes that appear during a trial and dividing by the duration of the trial. The length  $T$  of the time window is set by the experimenter and depends on the type of neuron recorded from and the stimulus. In practice, to obtain sensible averages, several spikes should occur within the time window. Typical values are  $T = 100$  ms or  $T = 500$  ms, but the duration may also be longer or shorter.

The spike-count rate can be determined from a single trial, but at the expense of losing all temporal resolution about variations in neural response during the course of the trial. Temporal averaging can work well in cases where the stimulus is constant or slowly varying and does not require a fast reaction of the organism – and this is the situation usually encountered in experimental protocols. Real-world input, however, is hardly stationary, but often changing on a fast time scale. For example, even when viewing a static image, humans perform saccades, rapid changes of the direction of gaze. The image projected onto the retinal photoreceptors changes, therefore, every few hundred milliseconds. Despite its shortcomings, the concept of a spike-count rate code is widely used not only in experiments, but also in models of neural networks. It has led to the idea that a neuron transforms information about a single input variable (the stimulus strength) into a single continuous output variable (the firing rate).

### Time-dependent firing rate

*Time-dependent firing rate* is defined as the average number of spikes (averaged over trials) appearing during a short interval between times  $t$  and  $t + \Delta t$ , divided by the duration of the interval. It works for stationary as well as for time-dependent stimuli. To experimentally measure the time-dependent firing rate, the experimenter records from a neuron while stimulating with some input sequence. The same stimulation sequence is

repeated several times and the neuronal response is reported in a peri-stimulus-time histogram (**PSTH**). The time  $t$  is measured with respect to the start of the stimulation sequence. The  $\Delta t$  must be large enough (typically in the range of 1 or a few milliseconds) so there is a sufficient number of spikes within the interval to obtain a reliable estimate of the average. The number of occurrences of spikes  $n_K(t; t + \Delta t)$  summed over all repetitions of the experiment divided by the number  $K$  of repetitions is a measure of the typical activity of the neuron between time  $t$  and  $t + \Delta t$ . A further division by the interval length  $\Delta t$  yields the time-dependent firing rate  $r(t)$  of the neuron, which is equivalent to the spike density of **PSTH**.

For sufficiently small  $\Delta t$ ,  $r(t)\Delta t$  is the average number of spikes occurring between times  $t$  and  $t + \Delta t$  over multiple trials. If  $\Delta t$  is small, there will never be more than one spike within the interval between  $t$  and  $t + \Delta t$  on any given trial. This means that  $r(t)\Delta t$  is also the fraction of trials on which a spike occurred between those times. Equivalently,  $r(t)\Delta t$  is the probability that a spike occurs during this time interval. As an experimental procedure, the time-dependent firing rate measure is a useful method to evaluate neuronal activity, in particular in the case of time-dependent stimuli. The obvious problem with this approach is that it cannot be the coding scheme used by neurons in the brain. Neurons cannot wait for the stimuli to repeatedly present in exactly the same manner as observed before generating the response. Nevertheless, the experimental time-dependent firing rate measure makes sense, if there are large populations of independent neurons that receive the same stimulus. Instead of recording from a population of  $N$  neurons in a single run, it is experimentally easier to record from a single neuron and average over  $N$  repeated runs. Thus, the time-dependent firing rate coding relies on the implicit assumption that there are always populations of neurons.

### Temporal coding

When precise spike timing or high-frequency firing-rate fluctuations are found to carry information, the neural code is often identified as a temporal code. A number of studies have found that the temporal resolution of the neural code is on a millisecond time scale, indicating that precise spike timing is a significant element in neural coding [39.62]. Temporal codes employ those features of the spiking activity that cannot be described by the firing rate. For example, the time to first spike after the stimulus onset, characteristics based on the second and higher statistical moments of the **ISI** probability dis-

tribution, spike randomness, or precisely timed groups of spikes (temporal patterns) are candidates for temporal codes. As there is no absolute time reference in the nervous system, the information is carried either in terms of the relative timing of spikes in a population of neurons or with respect to an ongoing brain oscillation.

The temporal structure of a spike train or firing rate evoked by a stimulus is determined both by the dynamics of the stimulus and by the nature of the neural encoding process. Stimuli that change rapidly tend to generate precisely timed spikes and rapidly changing firing rates no matter what neural coding strategy is being used. Temporal coding refers to temporal precision in the response that does not arise solely from the dynamics of the stimulus, but that nevertheless relates to properties of the stimulus. The interplay between stimulus and encoding dynamics makes the identification of a temporal code difficult. The issue of temporal coding is distinct and independent from the issue of independent-spike coding. If each spike is independent of all the other spikes in the train, the temporal character of the neural code is determined by the behavior of the time-dependent firing rate  $r(t)$ . If  $r(t)$  varies slowly with time, the code is typically called a rate code, and if it varies rapidly, the code is called temporal.

### Population coding

*Population coding* is a method to represent stimuli by using the joint activities of a number of neurons. In population coding, each neuron has a distribution of responses over some set of inputs, and the responses of many neurons may be combined to determine some value about the inputs.

Currently, **BCI** and **BMI** (brain machine interface) systems rely mostly on population coding. The description of one of the most famous population codes – the motor population vector along with its use in current and future **BCI** and **BMI** systems is presented in Sect. 39.8.2.

### 39.8.2 Single Unit Activity Correlates of Hand Motion Attributes

In 1982, *Georgopoulos et al.* [39.63] found that the activity of single cells in the motor cortex of monkeys, who were making arm movements in eight directions (at  $45^\circ$  intervals) in a two-dimensional apparatus, varied in an orderly fashion with the direction of the movement. Discharge was most intense with movements in a preferred direction and was reduced gradually when movements were made in directions farther and farther

away from the preferred movement. This resulted in a bell-shaped directional tuning curve. These relations were observed for cell discharge during the reaction time, the movement time, and the period that preceded the earliest changes in the electromyographic activity (approximately 80 ms before movement onset) (electromyography (**EMG**) is a technique for evaluating and recording the electrical activity produced by skeletal muscles). In about 75% of the 241 directionally tuned cells, the frequency of discharge  $D$  was a sinusoidal function of the direction of movement  $\theta$

$$D = b_0 + b_1 \sin \Theta + b_2 \cos \Theta , \quad (39.3)$$

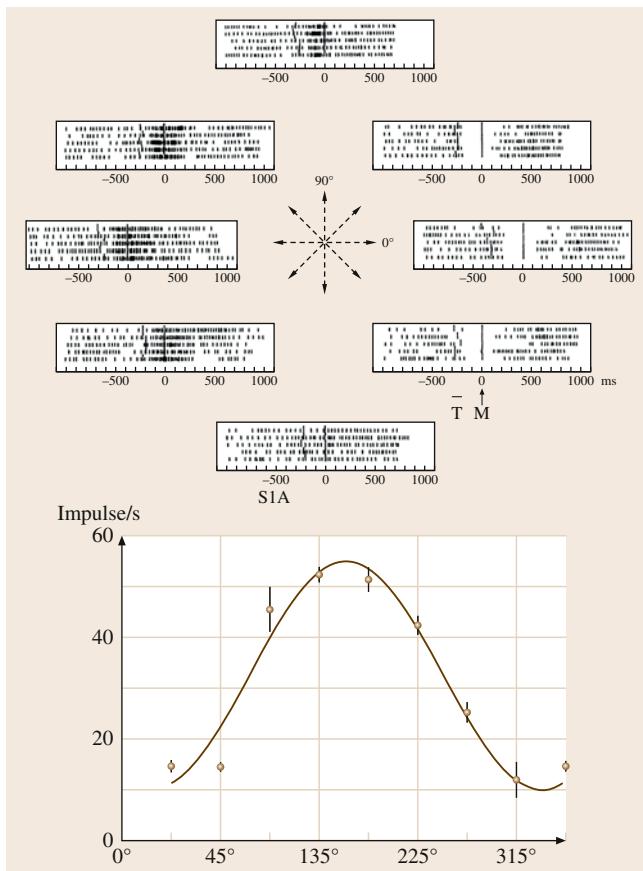

or, in terms of the preferred direction  $\Theta_0$

$$D = b_0 + c_1 \cos(\Theta - \Theta_0) , \quad (39.4)$$

where  $b_0$ ,  $b_1$ ,  $b_2$ , and  $c_1$  are regression coefficients. Preferred directions differed for different cells so that the tuning curves partially overlapped. The orderly variation of cell discharge with the direction of movement and the fact that cells related to only one of the eight directions of movement tested were rarely observed, indicated that movements in a particular direction are not subserved by motor cortical cells uniquely related to that movement. It was suggested, instead, that a movement trajectory in a desired direction might be generated by the cooperation of cells with overlapping tuning curves. The orderly variation in the frequency of discharge of a motor cortical cell with the direction of movement is shown in Fig. 39.8.

Later on, *Amirikian et al.* systematically examined the variation in the shape of the directional tuning profiles among a population of cells recorded from the arm area of the motor cortex of monkeys using movements in 20 directions, every  $18^\circ$  [39.64]. This allowed the investigation of tuning functions with extra parameters to capture additional features of the tuning curve (i.e., tuning breadth, symmetry, and modality) and determine an *optimal* tuning function. It was concluded that motor cortical cells are more sharply tuned than previously thought.

*Paninski et al.* [39.65] using a pursuit-tracking task (**PTT**) in which a monkey had to continuously track a randomly moving visual stimulus (thus providing a broad sample of velocity and position space) with invasive recordings from the **M1** region showed that there is heterogeneity of position and velocity coding in that region, with markedly different temporal dynamics for each – velocity-tuned neurons were approximately sinusoidally tuned for direction, with linear speed scaling; other cells showed sinusoidal tuning for position,

**Fig. 39.8** Orderly variation in the frequency of discharge of a motor cortical cell with the direction of movement. *Upper half:* rasters are oriented to the movement onset M and show impulse activity during five repetitions of movements made in each of the eight directions indicated by the *center diagram*. Notice the orderly variation in cell's activity during the RT (reaction time), MOT (movement time) and TET (total experiment time; TET = RT + MOT). *Lower half:* directional tuning curve of the same cell. The discharge frequency is for TET. The data points are mean  $\pm$  SEM. The regression equation for the fitted sinusoidal curve is  $D = 32.37 + 7.281 \sin \Theta - 21.343 \cos \Theta$ , where  $D$  is the frequency of discharge and  $\Theta$  is the direction of movement, or, equivalently,  $D = 32.37 + 22.5 \cos(\Theta - \Theta_0)$ , where  $\Theta_0$  is the preferred direction ( $\Theta_0 = 161^\circ$ ) (after [39.63], courtesy of A.P. Georgopoulos)

with linear scaling by distance. Velocity encoding led behavior by about 100 ms for most cells, whereas position tuning was more broadly distributed, with leads and lags suggestive of both feed-forward and feedback coding. Linear regression methods confirmed that random, **2-D** hand trajectories can be reconstructed from the firing of small ensembles of randomly selected neurons (3–19 cells) within the **M1** arm area. These findings demonstrate that **M1** carries information about evolving hand trajectory during visually guided pursuit tracking, including information about arm position both during and after its specification.

*Georgopoulos et al.* formulated a population vector hypothesis to explain how populations of motor cortex neurons encode movement direction [39.66]. In the population vector model, individual neurons *vote* for their preferred directions using their firing rate. The final vote is calculated by vectorial summation of individual preferred directions weighted by neuronal rates. This model proved to be successful in description of

motor-cortex encoding of **2-D** and **3-D** reach directions, and was also capable of predicting new effects, e.g., accurately describing mental rotations made by the monkeys that were trained to translate locations of visual stimuli into spatially shifted locations of reach targets [39.67, 68].

The population vector study actually divided the field of motor physiologists between *Evarts' upper motor neuron* group, which followed the hypothesis that motor cortex neurons contributed to control of single muscles [39.69] and the Georgopoulos group studying the representation of movement directions in the cortex. From the theoretical point of view, population coding is one of a few mathematically well-formulated problems in neuroscience. It grasps the essential features of neural coding and, yet, is simple enough for theoretic analysis. Experimental studies have revealed that this coding paradigm is widely used in the sensor and motor areas of the brain. For example, in the visual area medial temporal (**MT**) neurons are tuned to the movement

direction. In response to an object moving in a particular direction, many neurons in **MT** fire, with a noise-corrupted and bell-shaped activity pattern across the population. The moving direction of the object is retrieved from the population activity, to be immune from the fluctuation existing in a single neuron's signal.

Population coding has a number of advantages, including reduction of uncertainty due to neuronal variability and the ability to represent a number of different stimulus attributes simultaneously. Population coding is also much faster than rate coding and can reflect changes in the stimulus conditions nearly instantaneously. Individual neurons in such a population typically have different but overlapping selectivities, so that many neurons, but not necessarily all, respond to a given stimulus. The Georgopoulos vector coding is an example of simple averaging. A more sophisticated mathematical technique for performing such a reconstruction is the method of maximum likelihood based on a multi-variate distribution of the neuronal responses. These models can assume independence, second-order correlations [39.70], or even more detailed dependencies such as higher-order maximum entropy models [39.71].

The finding that arm movement is well represented in populations of neurons recorded from the motor cortex has resulted in a rapid advancement in extracellular recording-based **BCI** in non-human primates and in a limited number of human studies. Several groups have been able to capture complex brain motor cortex signals by recording from neural ensembles (groups of neurons) and using these to control external devices. First, cortical activity patterns have been used in **BCIs** to show how cursors on computer displays can be moved in two and three-dimensional space. It was later realized that the ability to move a cursor can be useful in its own right and that this technology could be applied to restore arm and hand function for amputees and the physically impaired.

Miguel Nicolelis has been a prominent proponent of using multiple electrodes spread over a greater area of the brain to obtain neuronal signals to drive a **BCI**. Such neural ensembles are said to reduce the variability in output produced by single electrodes, which could make it difficult to operate a **BCI**. After conducting initial studies in rats during the 1990s, *Nicolelis et al.* succeeded in building a **BCI** that reproduced owl monkey movements while the monkey operated a joystick or reached for food [39.72]. The **BCI** operated in real time and could also control a separate robot remotely over internet protocol. However, the monkeys could not

see the arm moving and did not receive any feedback, a so-called open-loop **BCI**.

Other laboratories which have developed **BCIs** and algorithms that decode neuron signals include those run by John Donoghue, Andrew Schwartz, and Richard Andersen. These researchers have been able to produce working **BCIs**, even using recorded signals from far fewer neurons than Nicolelis used (15–30 neurons versus 50–200 neurons). *Donoghue et al.* reported training rhesus monkeys to use a **BCI** to track visual targets on a computer screen (closed-loop **BCI**) with or without the assistance of a joystick [39.73].

Later experiments by Nicolelis using rhesus monkeys succeeded in closing the feedback loop and reproduced monkey reaching and grasping movements in a robot arm. With their deeply cleft and furrowed brains, rhesus monkeys are considered to be better models for human neurophysiology than owl monkeys. The monkeys were trained to reach and grasp objects on a computer screen by manipulating a joystick, while corresponding movements by a robot arm were hidden [39.74, 75]. The monkeys were later shown the robot directly and learned to control it by viewing its movements. The **BCI** used velocity predictions to control reaching movements and simultaneously predicted hand gripping force.

The use of cortical signals to control a multi-jointed prosthetic device for direct real-time interaction with the physical environment (*embodiment*) was first demonstrated by *Schwartz et al.* [39.76]. *Schwartz et al.* implanted 96 intracortical microelectrodes in the proximal arm region of the primary motor cortex of monkeys (*Macaca mulatta*) and used their motor cortical activity to control a mechanized arm replica and control a gripper on the end of the arm. The monkey could feed itself pieces of fruit and marshmallows using a robotic arm controlled by the animal's own brain signals. Owing to the physical interaction between the monkey, the robotic arm, and the objects in the workspace, this new task presented a higher level of difficulty than previous virtual (cursor control) experiments.

In 2012 *Schwartz et al.* [39.68] showed that a 52-year-old individual with tetraplegia who was implanted with two 96-channel intracortical microelectrodes in the motor cortex could rapidly achieve neurological control of an anthropomorphic prosthetic limb with seven degrees of freedom (three-dimensional translation, three-dimensional orientation, one-dimensional grasping). The participant was able to move the prosthetic limb freely in the three-dimensional workspace on the second day of training. After 13 weeks, robust seven-

dimensional movements were performed routinely. The participant was also able to use the prosthetic limb to do skillful and coordinated reach and grasp movements that resulted in clinically significant gains in tests of upper limb function. No adverse events were reported.

In addition to predicting kinematic and kinetic parameters of limb movements, BCIs that predict electromyographic or electrical activity of the muscles of primates are being developed [39.77]. Such BCIs may be used to restore mobility in paralyzed limbs by electrically stimulating muscles. Miguel Nicolelis and colleagues demonstrated that the activity of large neural ensembles can predict arm position. This work made possible the creation of BCIs that read arm movement intentions and translate them into movements of artificial actuators. Carmena et al. [39.74] programmed the neural coding in a BCI that allowed a monkey to control reaching and grasping movements by a robotic arm. Lebedev et al. [39.75] argued that brain networks reorganize to create a new representation of the robotic appendage in addition to the representation of the animal's own limbs.

The biggest impediment to BCI technology at present is the lack of a sensor modality that provides safe, accurate, and robust access to brain signals. It is conceivable or even likely, however, that such a sensor will be developed within the next 20 years. The use of such a sensor should greatly expand the range of communication functions that can be provided using a BCI.

To conclude, this demonstration of multi-degree-of-freedom embodied prosthetic control paves the way towards the development of dexterous prosthetic devices that could ultimately achieve arm and hand function at a near-natural level.

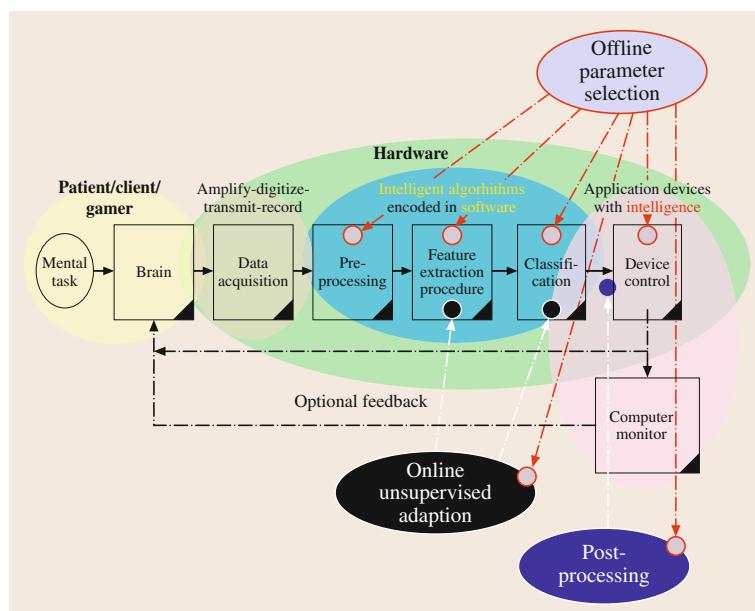

### 39.8.3 Local Field Potential Correlates of Hand Motion Attributes

Local field potentials can be recorded with extracellular recordings, and a number of studies have shown their application; however, as ECoG and EEG (covered in Sects. 39.5 and 39.6) are indirect measures of LFPs we do not cover LFPs here again for brevity.

## 39.9 Translating Brainwaves into Control Signals – BCIs

Heretofore the chapter has focused on the characteristics of the neural correlates of motor control and how these might be deployed in SMR-based EEG, ECoG,

and MEG BCI designs, providing evidence of activations at various scales of the brain and a brief outline of individual methodologies for attaining this evidence.

**Fig. 39.9** Illustration of the various components of a BCI involving a closed-loop learning system as well as offline and online parameter optimization and system adaptation

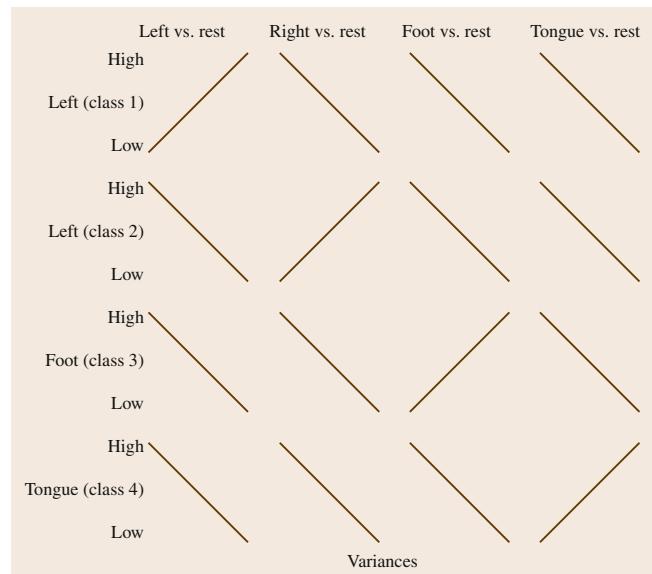

Brain-computer interfaces, however, require a number of stages of signal processing and components to be effective and robust. Figure 39.9 shows common components of a complete BCI system. Although not all components shown are deployed together in every system there is increasing evidence that combining the best approaches deployed for each component and process in a multi-stage framework as well as ensemble methods or multi-classifier approaches can lead to significant performance gains when discriminating sensorimotor rhythms and translating brain oscillations into stable and accurate control signals. Performance here can be considered from various perspectives, including system accuracy in producing the correct response, the speed at which a response is detected (or the number of correct detections possible in a given period), the adaptability to each individual and the inherent non-stationary dynamics of the mutual interaction between the brain and the translating algorithm, the length of training required to reach an acceptable performance, the number of sensors required to derive a useful control signal, and the amount of engagement needed by the participant, to name but a few. The following sections highlight some of the methods which have been tried and tested in sensorimotor rhythm BCIs; however the coverage is by no means exhaustive. Also, the main emphasis is on EEG-based BCI designs as EEG-based BCI has been the driving force behind much of the novel signal processing research conducted in the field over the last 20 years, with some of the more invasive approaches considered less usable in the short term, high risk for experimentation and deployment in humans, with less funding to develop invasive strategies and less data availability.

EEG being the least informative, spectrally and spatially, about the underlying brain processes and subject to deterioration and spatial diffusion by the physical properties of the cerebrospinal fluid, skull, and skin, as well as the ominous susceptibility to contamination from other sources such as muscle and eye movements, poses the most challenges for engineers, mathematicians, and computer scientists. Researchers in these, among many other disciplines, are eager to solve a problem which has dogged the field for long namely, creating an EEG-based BCI which is accurate and robust across time for individual subjects and can be deployed across multiple subjects easily to offer a communication channel which matches or surpasses, at least, other basic, tried and tested computer peripheral input devices and/or basic assistive communication technologies. Signal processing, as shown in Fig. 39.10,

is only one piece of the puzzle with a range of other components being equally as important, including electrode technologies and hardware being critical to data quality, usability, and acceptability of the system. Additionally, the technologies and devices under the control of the BCI are another aspect, which is not dealt with here but is a topic which requires investigation to determine how applications can be adapted to cope with the, as yet, inevitable inconsistencies in the communication and control signals derived from the BCI. Here our intention is not to deal with these elements of brain computer interface but only to provide the reader with an indicative overview of key signal processing and discrimination topics under consideration in the area, perhaps not topics that have received the attention deserved, but show promise. Interested readers are referred to [39.78–87] for comprehensive surveys of BCI-control strategies and signal-processing strategies.

### 39.9.1 Pre-Processing and Feature Extraction/Selection

Oscillatory and rhythmic activity in various frequency bands are a predominant feature in sensorimotor rhythm-based BCIs, as outlined in Sect. 39.7.1. Whilst amplitude of power in subject-specific sub-bands has proven to be a reliable feature to enable discrimination of the lateralized brain activity associated with

**Fig. 39.10** Hypothetical relative variance levels of the CSP transformed surrogate data

gross arm movement imagination from **EEG**, there is a general consensus that there is a necessity to extract much more information about spatial and temporal relationships by correlating the synchronicity, amplitude, phase, and coherence of oscillatory activity across distributed brain regions. To that end, spectral filtering is often accompanied with spatial pattern estimation techniques, channel selection techniques, along with other preprocessing techniques to detect signal sources and for noise removal. These include principle component analysis (**PCA**) and independent component analysis (**ICA**), among others, whilst the most commonly used is the common spatial patterns (**CSP**) approach [39.88–91].

Many of these methods involve linear transformations where a set of possibly correlated observations are transformed into a set of uncorrelated variables and can be used for feature dimensionality reduction, artifact removal, channel selection, and dimensionality reduction. **CSP** is by far the most commonly deployed of all these filters in sensorimotor rhythm-based **BCIs**.

**CSP** maximizes the ratio of class-conditional variances of **EEG** sources [39.88, 89]. To utilize **CSP**,  $\Sigma_1$  and  $\Sigma_2$  are the pooled estimates of the covariance matrices for two classes, as follows

$$\sum_c = \frac{1}{I_c} \sum_{i=1}^{I_c} X_i X_i^t \quad c \in \{1, 2\}, \quad (39.5)$$

where  $I_c$  is the number of trials for class  $c$  and  $X_i$  is the  $M \times N$  matrices containing the  $i$ -th windowed segment of trial  $i$ ;  $N$  is the window length and  $M$  is the number of **EEG** channels. The two covariance matrices,  $\Sigma_1$  and  $\Sigma_2$ , are simultaneously diagonalized such that the eigenvalues sum to 1. This is achieved by calculating the generalized eigenvectors  $W$

$$\sum_1 W = \left( \sum_1 + \sum_2 \right) WD, \quad (39.6)$$

where the diagonal matrix  $D$  contains the eigenvalue of  $\Sigma_1$  and the column vectors of  $W$  are the filters for the **CSP** projections. With this projection matrix the decomposition mapping of the windowed trials  $X$  is given as

$$E = WX. \quad (39.7)$$

To generalize **CSP** to three or more classes (the multi-class paradigm), spatial filters can be produced for each class vs. the remaining classes (one vs. rest approach). If  $q$  is the number of filters used then there

are  $q \times C$  surrogate channels from which to extract features. To illustrate how **CSP** enhances separability among four classes the hypothetical relative variance level of the data in each of the four classes are shown in Fig. 39.10.

**CSP** has been modified and improved substantially using numerous techniques and deployed and tested in **BCIs** [39.88–92]. **CSP** is commonly applied with spectral filters. One of the more successful approaches to spectral filtering combined with **CSP** is the filter bank **CSP** approach [39.93, 94]. Another promising technique for the analysis of multi-modal, multi-channel, multi-tasks, multi-subject, and multi-dimensional data is multi-way (array) tensor factorization/decomposition [39.95]. The technique has been shown to have the ability to discriminate between different conditions, such as right hand motor imagery, left hand motor imagery, or both hands motor imagery, based on the spatiotemporal features of the different **EEG** tensor factorization components observed.

Due to the short sequences of events during motor control it is likely that assessment of activity at a fine granularity such as the optimal embedding parameters for prediction as well as the predictability of **EEG** over short and long time spans and across channels will also provide clues about the temporal sequences of motor planning and activations and the motion primitives involved in different hand movement trajectories. Work has shown that subject, channel, and class-specific optimal time embedding parameter selection using partial mutual information improves the performance of a predictive framework for **EEG** classification in **SMR**-based **BCIs** [39.92, 96–102]. Many other time series modeling, embedding, and prediction through traditional and computational intelligence techniques such as fuzzy and recurrent neural networks (**FNN** and **RNN**) have been promoted for **EEG** preprocessing and feature extraction to maximize signal separability [39.19, 66–69, 103].

The above preprocessing or filtering frameworks have been used extensively, yet rarely independently, but in conjunction with a stream of other signal processing methodologies to extract reliable information from neural data. It is well known that the amplitude and the phase of neural oscillations are spatially and temporally modulated during sensorimotor processing (see Sects. 39.6 and 39.7 for further details). Spectral information and band power extraction have been commonly used as features ([39.82, 83] for reviews); however, phase and cross frequency coupling less so, even though a number of non-invasive and intracortical

studies have emphasized the importance of phase information [39.33, 35, 104, 105]. Furthermore, amplitude-phase cross-frequency coupling has been suggested to play an important role in neural coding [39.106]. While neural representations of movement kinematics and movement imagination by amplitude information in sensorimotor cortex have been extensively reported using different oscillatory signals (**LFP**, **ECOG**, **MEG**, **EEG**) [39.33, 35, 39, 107–111] and used extensively in non-invasive motor imagery-based **BCI** designs phase information has not been given as much attention as possibly deserved [39.35]. As reported in [39.35] there have been some recent developments describing synchronized activity between **M1** and hand speed [39.81, 82], corticomuscular coupling [39.112], and the **LFP** beta oscillations phase locked to target cue onset in an instructed-delay reaching task [39.113], in addition to the studies covered in Sects. 39.6 and 39.7, among others. The role of phase coding in the sensorimotor cortex should be further explored to fully exploit the complementary information encoded by amplitude and phase [39.35].

Parameter optimization can be made more proficient through global searches of the parameter space using evolutionary computation-based approaches such as particle swarm optimization (**PSO**) and genetic algorithms (**GAs**). The importance of features can be assessed and ranked for different tasks using various feature selection techniques using information theoretic approaches such as partial mutual information-based (**PMI**) input variable selection [39.98, 114]. Parameter optimization and feature selection approaches such as these enable coverage of a large parameter space when additional features are identified to enhance performance. Heuristic-based approaches can be used to determine the relative increase in classification associated with each variable along with other more advanced methods for feature selection such as Fisher's criterion and partial mutual information to estimate the level of redundancy among features. Verifying the feature landscape using global heuristic searches is important initially and automated intelligent approaches enable efficient and automated system optimization during application at a later time and easy application to a large sample of participant data, i.e., removing the necessity to conduct global parameter searches.

### 39.9.2 Classification

Various classifier techniques can be applied to the sampled data to determine classification/prediction perfor-

mance, including standard linear methods such as linear discriminant analysis (**LDA**), support vector machines (**SVM**), and probabilistic-based approaches [39.115], as well as non-linear approaches such as backpropagation neural networks (**NN**) and self-organizing fuzzy neural networks (**SOFNN**) [39.116]. Other adaptive methods and approaches to classifier combination have been investigated [39.87, 88, 117, 118] along with Type-2 fuzzy logic approaches to deal with uncertainty [39.119, 120]. Recent evidence has shown that probabilistic classifier vector machines (**PCVM**) have significant potential to outperform other tried and tested classifiers [39.121, 122]. These are just a few of the available approaches (see [39.82] for a more detailed review). Here we focus on one of the latest trends in **BCI** translation algorithms, i.e., automated adaptation to non-stationary changes in the **EEG** dynamics over time.

### 39.9.3 Unsupervised Adaptation in Sensorimotor Rhythms **BCIs**

**EEG** signals deployed in **BCI** are inherently non-stationary resulting in substantial change over time, both within a single session and between sessions, resulting in significant challenges in maintaining **BCI** system robustness. There are various sources of non-stationarities: short-term changes related to modification to the strategy that users apply to motor imagery to enhance performance, drifts in attention, attention to different stimuli or processing other thoughts or stimuli/feedback, slow cortical potential drifts and less specific long-term changes related to fatigue, small day to day differences in the placement of electrodes, among others. However, one which is considered a potential source of change over time is user adaption through motor learning to improve **BCI** performance over time, sometimes referred to as the effects of feedback training [39.123, 124] and sensorimotor learning.

The effects of feedback on the user's ability to produce consistent **EEG**, as he/she begins to become more confident and learns to develop more specific communication and control signals, can have a negative effect on the **BCI**'s feature extraction procedure and classifier. During sensorimotor learning the temporal and spatial activity of the brain continually adapts and the features which were initially suited to maximizing the discrimination accuracy may not remain stable as time evolves, thus degradation in communication occurs. For this reason, the **BCI** must have the ability to adapt and interact with the adaptations that the brain makes in response to the feedback. According to Wol-

paw et al. [39.125] the **BCI** operation depends on the interaction of two adaptive controllers, the user's brain, which produces the signals measured by the **BCI**, and the **BCI** itself, which translates these signals into specific commands [39.125].

With feedback, even though classification accuracy is expected to improve with an increasing number of experiments, the performance has been shown to decrease with time if the classifier is not updated [39.43]. This has been referred to as the *man-machine learning dilemma (MMLD)*, meaning that the two systems involved (man and machine) are strongly interdependent, but cannot be controlled or adapted in parallel [39.43]. The experiments shown in many studies show that feedback results in changing **EEG** patterns, and thus adaptation of the pattern recognition methods is required. It is, therefore, paramount to adapt a **BCI** periodically or continuously if possible. Autonomous adaptive system design is required but a challenge. The recognition and productive engagement of adaptation will be important for successful **BCI** operation. According to Wolpaw et al. [39.125] there are three levels of adaptation which are not always accounted for but have great importance for future adoption of **BCI** systems:

1. When a new user first accesses the **BCI**, the algorithm adapts to the user's signal features.
  - No two people are the same physiologically or psychologically, therefore brain topography differs among individuals, and the electrophysiological signals that are produced from different individuals are unique to each individual, even though they may be measured from the same location on the scalp whilst performing the same mental tasks at the same time. For each new user the **BCI** has to adapt specifically to the characteristics of each particular person's **EEG**. This adaptation may be to find subject-specific frequency bands which contain frequency components that enable maximal discrimination accuracy between two mental tasks or train a static classifier on a set of extracted features.
2. The second level of adaptation requires that the **BCI** system components be periodically adjusted or adapted online to reduce the impact of spontaneous variations in the **EEG**.
  - Any **BCI** system which only possesses the first level of adaptation will continue to be effective only if the user's performance is very stable. Most electrophysiological signals display short and long-term variations due to the complexity

of the physiological functioning of the underlying processes in the brain, among other sources of change as outlined above. The **BCI** system should have the ability to accommodate these variations by adapting to the signal feature values which maximally express the user's intended communication.

3. The third level of adaptation accommodates and engages the adaptive capacities of the brain.

- The **BCI** depends on the interaction of two adaptive controllers, the **BCI** and the user's brain [39.125]:

*When an electrophysiological signal feature that is normally merely a reflection of brain function becomes the end product of that function, that is, when it becomes an output that carries the user intent to the outside world, it engages the adaptive capacities of the brain.*

This means that, as the user develops the skill of controlling their **EEG**, the brain has learned a new function and, hopefully, the brain's newly learned function will modify the **EEG** so as to improve **BCI** operation. The third level of adaptation should accommodate and encourage the user to develop and maintain the highest possible level of correlation between the intended communication and the extracted signal features that the **BCI** employs to decipher the intended communication. Due to the nature of this adaptation (the continuous interaction between the user and the **BCI**) it can only be assessed online and its design is among the most difficult problems confronting **BCI** research.

McFarland et al. [39.126] further categorize adaptation into system adaptation, user adaptation, and system and user co-adaption, asking the question: is it necessary to continuously adapt the parameters of the **BCI** translation algorithm? Their findings show that for sensorimotor rhythms **BCI** it is, whereas perhaps it is not for other stimulus-based **BCIs**.

A review of adaptation methods is included by Hasan [39.127] focusing on questions: what, how, and when to adapt and how to evaluate adaptation success. A range of studies has been aimed at addressing the adaption requirements [39.123, 124, 128–137]. Krusienski et al. [39.35] define the various types of possible adaptation as follows:

- *Covariate shift adaptation/minimization:* Covariate shift refers to when the distribution of the training

features and test features follow different distributions, while the conditional distribution of the output values (of the classifier) and the features is unchanged [39.138]. The shift in feature distribution from session to session can be significant and can result in substantive biasing effects. Without some form of adaption to the features and/or classifier, the classifier trained on a past session would perform poorly in a more recent session. Satti et al. [39.139] proposed a method for covariate shift minimization (**CSM**), where features can be adapted so that the feature distribution is always consistent with the distribution of the features that were used to train the classifier in the first session. This can be achieved in an unsupervised manner by estimating the shift in distribution using a least squares fitting polynomial for each feature and removing the shift by adding the common mean of the training feature distribution so that the feature space distribution remains constant over time as described in [39.139]. Mohammadi et al. [39.140] applied **CSM** in self-paced **BCI** updated features to account for short terms (within trial) drifts in signal dynamics. In [39.138] an importance-weighted cross-validation for accommodating covariate shift under a number of assumptions is described but is not adaptively updated online in an unsupervised manner whereas other offline approaches have been investigated to enable feature extraction methods to accommodate non-stationarity and covariate shifts [39.90, 91].

- **Feature adaptation/regression:** Involves adapting the parameters of the feature extraction methods to account for subject learning, e.g., modifying the subject-specific frequency bands can be easily achieved in a supervised manner but this is not necessarily easily achieved online, unsupervised. An approach to adaptively weight features based on mu and beta rhythm amplitudes and their interactions using regression [39.4] resulted in significant performance improvements and may be adapted for unsupervised feature adaptation.

Covariate shift adaptation/minimization can be considered an *anti-biasing* method because it prevents the classifier biasing, whereas *feature adaptation/regression* is likely to result in the need to adapt the classifier to suit the new feature distributions. Both methods help to improve the performance over time, but it is uncertain if feature adaption followed by *covariate shift minimization* (to shift features towards earlier distribution) would limit the need for

classifier adaptation and/or provide stable performance or negate the benefits of feature regressions. An interesting discussion on the interplay between feature regression and adapting bias and gain terms in the classifier is presented in [39.4].

- **Classifier adaptation:** Unsupervised classifier adaptation has received more attention than feature adaptation with a number of methods having been proposed [39.124, 128]. Classifier adaptation is required when significant learning (or relearning)-induced plasticity in the brain significantly alters the brain dynamics, resulting in a shift in feature distribution, as well as significant changes in the conditional distribution between features and classifier output as opposed to cases where only covariate shift has occurred. In such cases, classifier adaptation can neither be referred to as anti-biasing or de-biasing.
- **Post-processing adaptation:** De-biasing the classifier output, in its simplest form, can be performed in an unsupervised manner by removing the mean calculated from a window of recent classifier outputs from the instantaneous value of the classifier [39.141], also referred to as normalization in [39.142], where the data from recent trials are used to predict the mean and standard deviation of the next trial and the data of the next trial is then normalized by these estimates to produce a control signal which is assumed to be stationary. De-biasing is suitable when covariate shift has not been accounted for and can improve the online feedback response but may only provide a slight performance improvement.
- **EEG data space adaptation (EEG-DSA):** acts on the raw data space and is a new approach to linearly transform the **EEG** data from the target space (evaluation/testing session), such that the distribution difference to the source space (training session) is minimized [39.143]. The Kullback–Leibler (**KL**) divergence criterion is the main method deployed in this approach and it can be applied in a supervised or unsupervised manner either periodically or continuously. Other adaptations (feature space or classifier) can be applied in tandem but accurate minimization of feature space adaptation should negate the need for further anti-biasing and or de-biasing adaptations.

Classifier adaptation (anti-biasing) negates the need for post processing (de-biasing) if the classifier is updated continuously, which is a challenging task to

undertake in an unsupervised manner (with no class labels) and may result in maladaptation, whereas debiasing can be conducted easily, unsupervised, regardless of the classifier used. Because post-processing-based de-biasing only results in removal of bias (shifts it to mean zero) in the feedback signal and not necessarily a change in the dynamics of the feedback signal, feature adaptation or classifier adaptation is necessary during subject learning and adaptation as the conditional distribution between features and classifier output evolves as outlined above.

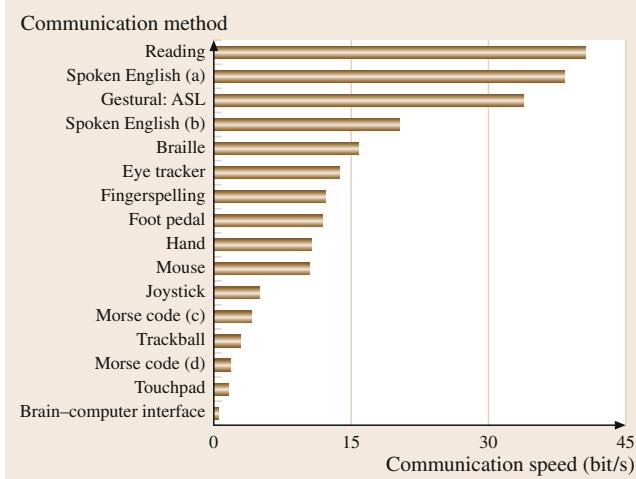

All of the above methods are heavily dependent upon the context in which the **BCI** is used. For example, for a **BCI** applied in alternative communication the objective is to maximize the probability of interpreting the user's intent correctly; therefore the adaptation is performed with that objective, whereas, if the **BCI** is aimed at inducing neuroplastic changes in specific cortical areas, e.g., a **BCI** which is aimed at supporting stroke survivors perform motor imagery as means of enhancing the speed or level of rehabilitation post stroke, the objective is to not only provide accurate feedback but to encourage the user to activate regions of cortex which do not necessarily provide optimal control signals [39.35]. The latter may require electrode/channel adaptation strategies but not necessarily in a fast online unsupervised manner. Abrupt changes

to classifier performance may also lead to negative learning where the user cannot cope with the rate at which the feedback dynamics change, in such cases consistent feedback, even though less accurate, may be appropriate. As outlined in [39.126], there is still debate around whether mutual adaptation of a system and user is a necessary feature of successful **BCI** operation or if fast adaptation of parameters during training is not necessary. A recent study in animal models suggests that there is no negative correlation between decoding performance and the time between model generation and model testing, which suggests that the neural representations that encode kinematic parameters of reaching movements are stable across the months of study [39.147, 148], which further suggests little adaptation is needed for **ECoG** decoding in animal models, but this may not necessarily translate to humans and non-invasive **BCIs** involving motor imagery. Much more research on the issue of what type of adaption methods to apply and at what rate adaptation is necessary. Another important factor is to consider a person's level of ability to control a **BCI** and those persons close to chance levels may actually benefit from an incorrect belief on their performance level [39.149]. This would imply adapting the classifier output based on knowledge of the targets in a supervised manner, such that the user thinks they are performing better – a method which may help in the initial training phases to improve **BCI** performance [39.149]. Most of the techniques outlined above have been tested offline and, therefore, there is need to assess how the techniques improve performance as the user and **BCI** are mutually adapted. Table 39.1 provides a summary of the categories of adaptation and their interrelationships and requirements.

### 39.9.4 BCI Outlook

Translating brain signals into control signals is a complex task. The communication bandwidth given by **BCI** is still lagging behind most other communication methods rates between humans and the external world where the maximum **BCI** communication rate is  $\approx 0.41$  bit/s ( $\approx 25$  bit/min) [39.144] (see Fig. 39.11 for an illustration that nicely illustrates the gap in communication bandwidth between **BCI** and other communication methods, as well as the relatively low communication bandwidth across all human–human and human–computer interaction methods).

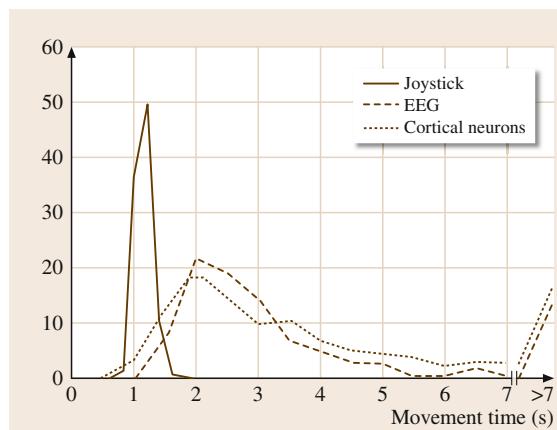

Nevertheless with the many developments and studies highlighted throughout this chapter (a selected few

**Fig. 39.11** Comparison of communication rates between humans and the external world: (a) speech received auditorily; (b) speech received visually using lip reading and supplemented by cues; (c) Morse code received auditorily; (d) Morse code received through vibrotactile stimulation (figure adapted from [39.144] with permission and other sources [39.145, 146])

**Table 39.1** BCI components that can be adapted and the way in which they can be adapted. Interrelationship between components, i. e., indicating when one is adapted which other component or stages of the signal processing pipeline it might be necessary to adapt (whether a calibration session is needed for offline setup or there is certain number of trials needed before adaption begins is not specified in the criteria but is another consideration)

| Adaptation type              | Anti-biasing | De-biasing | Subject relearning | Feature updates | Classifier adaptation | Online | Supervised | Unsupervised | Performance improvement likely |
|------------------------------|--------------|------------|--------------------|-----------------|-----------------------|--------|------------|--------------|--------------------------------|
| Channel adaptation           |              |            | Y                  | Y               | Y                     |        | Y          |              | Y                              |
| Data space adaptation        | Y            |            |                    |                 |                       | Y      |            | Y            | Y                              |
| Feature regression           | Y            |            | Y                  | Y               | Y                     | Y      |            | Y            | Y                              |
| Covariate shift minimization | Y            |            |                    | Y               |                       | Y      |            | Y            | Y                              |
| Covariate shift adaptation   |              |            | Y                  |                 | Y                     |        | Y          |              | Y                              |
| Classifier adaptation        | Y            |            | Y                  |                 | Y                     |        | Y          | Y            | Y                              |
| Gain/bias                    |              | Y          |                    |                 |                       |        |            | Y            | Slight                         |

**Fig. 39.12** Distributions of target-acquisition times (i. e., time from target appearance to target hit) on a 2-D center-out cursor-movement task for joystick control, EEG-based BCI control, and cortical neuron-based BCI control. The EEG-based and neuron-based BCIs perform similarly and both are slower and much less consistent than the joystick. For both BCIs in a substantial number of trials, the target is not reached even in the 7 s allowed. Such inconsistent performance is typical of movement control by present-day BCIs, regardless of what brain signals they use. (Joystick data and neuron-based BCI data from Hochberg et al. [39.150]; EEG-based BCI data from Wolpaw and McFarland [39.57]; figure after [39.58], courtesy of McFarland et al.)

among many) there has been progress, yet there is still debate around whether invasive recordings are more appropriate for BCI, with findings showing that performance to date is not necessarily better or communications faster with invasive or extracellular recordings compared to EEG (see Fig. 39.12 for an illustration [39.58]). As shown, performance is far less consistent than a joystick for 2-D center-out tasks using both methods, however the performance is remarkably similar even though the extracellular recordings are high resolution and EEG is low resolution. Training rates/durations with invasive BCI are probably less onerous on the BCI user compared to EEG-based approaches, which often require longer durations, however only a select few are willing to undergo surgery for BCI implants due to the high risk associated with the surgery required, at least with the currently available technology. This is likely to change in the future and information transfer between humans and machines is likely to increase to overcome the communication bottleneck human–human and human–computer interaction by directly interfacing brain and machine [39.144]. There is one limitation that dogs many movement or motor-related BCI studies and that is that in a large part control relies only a signal from single cortical area [39.58]. Exploiting multiple cortical areas may offer much more and this may be achieved more easily and successfully by exploiting information acquired at different scales using both invasive and non-invasive technologies (many of the studies reported in this chap-

ter have shown advantages that are unique at the various scales of recording). Carmena [39.151] recommends that non-invasive BCIs should not be pitted against invasive ones as both have pros and cons and have gone beyond pitching resolution as an argument to use one type or the other. In the future, BCI systems may very well become a hybrid of different kinds of neural signals, be able to benefit from local, high-resolution information (for generating motor commands) and more global information (arousal, level of attention, and other cognitive states) [39.151].

In summary, BCI technology is developing through a better understanding of the motor system and sensorimotor control, better recording technologies, better signal processing, more extensive trials with users, long-term studies, more multi-disciplinary interactions, among many other reasons. According to report conducted by Berger et al. [39.152] the magnitude of BCI research throughout the world will grow substantially, if not dramatically, in future years with multiple driving forces:

- Continued advances in underlying science and technology
- Increasing demand for solutions to repair the nervous system
- Increase in the aging population worldwide; a need for solutions to age-related, neurodegenerative disorders, and for *assistive BCI* technologies
- Commercial demand for non-medical BCIs.

BCI has the potential to meet many of these challenges in healthcare and is already growing in popularity for non-medical applications. BCI is considered by many as a revolutionary technology.

An analysis of the history of technology shows that technological change is exponential, and accord-

ing to the law of accelerating returns as the technology performance increases, more and more users groups begin to adopt the technology and prices begin to fall [39.153]. In terms of BCI there has been significant progress over recent years, and these trends are being observed with increasing technology diffusion [39.144]. In terms of research there has been an exponential growth in the number of peer reviewed publications since 2000 [39.84].

Many studies over the past two decades have demonstrated that non-muscular communication, based on brain-computer interfaces (BCIs), is possible and, despite the nascent nature of BCIs there is already a range of products, including alternative communication and control for the disabled stroke rehabilitation, electrophysiologically interactive computer systems, neurofeedback therapy, and BCI-controlled robotics/wheelchairs. A range of case studies have also shown that head trauma victims diagnosed as being in a persistent vegetative state (PVS) or a minimally conscious state and patients suffering *locked-in syndrome* as a result of motor neuron disease or brainstem stroke can specifically benefit from current BCI systems, although, as BCIs improve and surpass existing assistive technologies, they will be beneficial to those with less severe disabilities. In addition, the possibility of enriching computer game play through BCI also has immense potential, and computer games as well as other forms of interactive multi-media are currently an engaging interface techniques for therapeutic neurofeedback and improving BCI performance and training paradigms. Brain-computer games interaction provides motivation and challenge during training, which is used as a stepping stone towards applications that offer enablement and assistance. Based on these projections and the ever-increasing knowledge of the brain the future looks bright for BCIs.

## 39.10 Conclusion

The scientific approaches described throughout this chapter often overlook the underpinning processes and rely on correlations between a minimal number of factors only. As a result, current sensorimotor rhythms BCIs are of limited functionality and allow basic motor functions (a two degrees-of-freedom (DOF) limited control of a wheelchair/mouse cursor/robotic arm) and limited communication abilities (word dictation). It is assumed that BCI systems could greatly benefit

from the inclusion of multi-modal data and multi-dimensional signal processing techniques, which would allow the introduction of additional data sources and data from multiple brain scales, and enable detection of more subtle features embedded in the signal. Furthermore, using knowledge about sensorimotor control will be critical in understanding and developing successful learning and control models for robotic devices and BCI, fully closing the sensorimotor learning loop

to enable finer manipulation abilities using BCIs and for retraining or enabling better relearning of motor actions after cortical damage. As demonstrated throughout the chapter, many remarkable studies have been conducted with truly inspirational engineering and scientific methodologies resulting in many very useful and interesting findings.

There are many potential advantages of understanding motor circuitry, not to mention the many clinical and quality of life benefits that a greater understanding of the motor systems may provide. Such knowledge may offer better insights into treating motor pathologies that occur as a result of injury or diseases such as spinal cord injury, stroke, Parkinson's disease, Guillain Barre syndrome, motor diseases, and Alzheimer's disease, to mention just a few. Understanding sensorimotor systems can provide significant gains in developing more intelligent systems that can provide multiple benefits for humanity in general. However, there are still lacunae in our biological account of how the motor system works.

Animals have superb innate abilities to choose and execute simple and extended courses of action and the ability to adapt their actions to a changing environment. We are still a long way from understanding how that is achieved and are exploiting this to tackle the issues outlined above comprehensively. There are number of key questions that need to be addressed [39.154]:

- What are the roles of the cortex, the basal ganglia, and the cerebellum – the three major neural control structures involved in movement planning and generation?
- How do these structures in the brain interact to deliver seamless adaptive control?
- How do we specify how hierarchical control structures can be learned?
- What is the relationship between reflexes, habits, and goal-directed actions?
- Is there anything to be gained for robotic control by thinking about how interactions are organized in sensorimotor regions?
- Is it essential to replicate this lateralized structure in sensorimotor areas to produce better motor control in an artificial cognitive system?
- How can we create more accurate models of how the motor cortex works? Can such models be implemented to provide human-like motor control in an artificial system?
- How can we decode motor activity to undertake tasks that require accurate and robust three dimensional control under multiple different scenarios?

*Wolpert et al.* [39.16] elaborate on some of these questions, in particular, one which has not been addressed in this chapter, namely modeling sensorimotor systems. Although substantial progress has been made in computational sensorimotor control, the field has been less successful in linking computational models to neurobiological models of control. Sensorimotor control has traditionally been considered from a control theory perspective, without relation to neurobiology [39.155]. Although neglected in this chapter, computational motor cortical circuit modeling will be a critical aspect of research into understanding sensorimotor control and learning, and is likely to fill parts of the lacunae in our understanding that are not accessible with current imaging, electrophysiology, and experimental methodology. Likewise, understanding the computations undertaken in many of sensorimotor areas will depend heavily on computational modeling. *Doya* [39.156] suggested the classical notion that the cerebellum and the basal ganglia are dedicated solely to motor control. This is now under dispute given increasing evidence of their involvement in non-motor functions. However, there is enough anatomical, physiological and theoretical evidence to support the hypotheses that the cerebellum is a specialized organism that may support supervised learning, the basal ganglia may perform reinforcement learning role, and the cerebral cortex may perform unsupervised learning. Alternative theories that enable us to comprehend the way the cortex, cerebellum, and the basal ganglia participate in motor, sensory or cognitive tasks are required [39.156].

Additionally, as has been illustrated throughout this work, investigating brain oscillations is key to understanding brain coordination. Understanding the coordination of multiple parts of an extremely complex system such as the brain is a significant challenge. Models of cortical coordination dynamics can show how brain areas may cooperate (integration) and at the same time retain their functional specificity (segregation). Such models can exhibit properties that the brain is known to exhibit, including self-organization, multi-functionality, meta-stability, and switching. Cortical coordination can be assessed by investigating the collective phase relationships among brain oscillations and rhythms in neurophysiological data. Imaging and electrophysiology can be used to tackle the challenge of understanding how different brain areas interact and cooperate.

Ultimately better knowledge of the motor system through neuroengineering sensorimotor–computer in-

terfaces may lead to better methods of understanding brain dysfunction and pathology, better brain–computer interfaces, biological plausible neural circuit models, and inevitably more intelligent systems and machines that can perceive, reason, and act autonomously. It is too early to know the overarching control mech-

anisms and exact neural processes involved in the motor system but through the many innovations of scientists around the world, as highlighted in this chapter, pieces of the puzzle are being understood and slowly assembled to reach this target and go beyond it.

# 40. Evolving Connectionist Systems: From Neuro-Fuzzy-, to Spiking- and Neuro-Genetic

Nikola Kasabov

This chapter follows the development of a class of neural networks (**NN**) called evolving connectionist systems (**ECOS**). The term *evolving* is used here in its meaning of *unfolding, developing, changing, revealing* (according to the Oxford dictionary) rather than *evolutionary*. The latter represents processes related to populations and generations of them. An **ECOS** is a neural network-based model that evolves its structure and functionality through incremental, adaptive learning and self-organization during its *lifetime*. In principle, it could be a simple **NN** or a *hybrid* connectionist system. The latter is a system based on neural networks that also integrate other computational principles, such as linguistically meaningful explanation features of fuzzy rules, optimization techniques for structure and parameter optimization, quantum-inspired methods, and gene regulatory networks. The chapter includes definitions and examples of **ECOS** such as: evolving neuro-fuzzy and hybrid systems; evolving spiking neural networks, neurogenetic systems, quantum-inspired systems, which are all discussed from the point of view of the structural and functional development of a connectionist-based model and the knowledge that it represents. Applications for knowledge engineering across domain areas, such as in bioinformatics, brain study, and intelligent machines are presented.

## 40.1 Principles of Evolving Connectionist Systems (ECOS)

Everything in Nature evolves, develops, unfolds, reveals, and changes in time. The brain is probably the ultimate evolving system, which develops during a lifetime, based on genetic information (Nature) and learning from the environment (nurture). Inspired by information principles of the developing brain, **ECOS** are adaptive, incremental learning and knowledge representation systems that evolve their structure and func-

tionality from incoming data through interaction with the environment, where in the core of a system is a connectionist architecture that consists of neurons (information processing units) and connections between them [40.1]. An **ECOS** is a system based on neural networks and the use of also other techniques of computational intelligence (**CI**), which operates continuously in time and adapts its structure and functionality through

continuous interaction with the environment and with other systems. The adaptation is defined through:

1. A set of evolving rules.
2. A set of parameters (*genes*) that are subject to change during the system operation.
3. An incoming continuous flow of information, possibly with unknown distribution.
4. Goal (rationale) criteria (also subject to modification) that are applied to optimize the performance of the system over time.

**ECOS** learning algorithms are inspired by brain-like information processing principles, e.g.:

1. They evolve in an open space, where the dimensions of the space can change.
2. They learn via incremental learning, possibly in an on-line mode.

3. They learn continuously in a lifelong learning mode.
4. They learn both as individual systems and as an evolutionary population of such systems.
5. They use constructive learning and have evolving structures.
6. They learn and partition the problem space locally, thus allowing for a fast adaptation and tracing the evolving processes over time.
7. They evolve different types of knowledge representation from data, mostly a combination of memory-based and symbolic knowledge.

Many methods, algorithms, and computational intelligence systems have been developed since the conception of **ECOS** and many applications across disciplines. This chapter will review only the fundamental aspects of some of these methods and will highlight some principal applications.

## 40.2 Hybrid Systems and Evolving Neuro-Fuzzy Systems

### 40.2.1 Hybrid Systems

A hybrid computational intelligent system integrates several principles of computational intelligence to enhance different aspects of the performance of the system. Here we will discuss only hybrid connectionist systems that integrate artificial neural networks (**NN**) with other techniques utilizing the adaptive learning features of the **NN**.

Early hybrid connectionist systems combined **NN** with rule-based systems such as production rules [40.3]

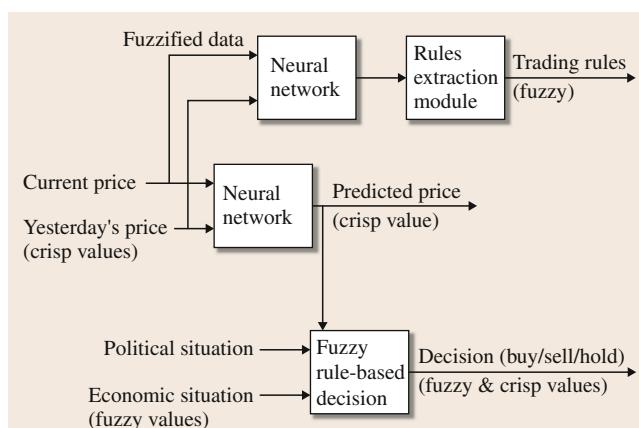

or predicate logic [40.4]. They utilized **NN** modules for a lower level of information processing and rule-based systems for reasoning and explanation at a higher level.

The above principle is applied when fuzzy rules are used for higher-level information processing and for approximate reasoning [40.5–7]. These are expert systems that combine the learning ability of **NN** with the explanation power of linguistically plausible fuzzy rules [40.8–11]. A block diagram of an exemplar system is shown in Fig. 40.1, where at a lower level a neural network (**NN**) module predicts the level of a stock index and at a higher level a fuzzy reasoning module combines the predicted values with some macro-economic variables representing the political and the economic situations using the following types of fuzzy rules [40.2]

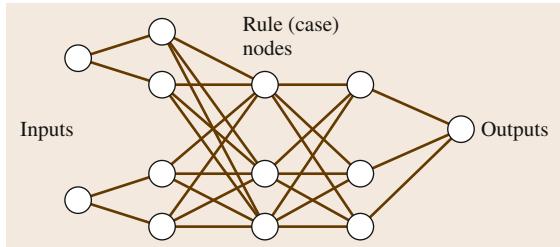

*IF <the predicted by the NN module stock value in the future is high> AND <the economic situation is good> AND <the political situation is stable>*

*THEN <buy stock> .* (40.1)

Along with the integration of **NN** and fuzzy rules for a better decision support, the system from Fig. 40.1 includes an **NN** module for extracting recent rules form data that can be used by experts to analyze the dy-

**Fig. 40.1** A hybrid **NN**-fuzzy rule-based expert system for financial decision support (after [40.2])

**Fig. 40.2** A simple, feedforward EFuNN structure. The rule nodes evolve from data to capture cluster centers in the input space, while the output nodes evolve local models to learn and approximate the data in each of these clusters

namics of the stock and to possibly update the trading fuzzy rules in the fuzzy rule-based module. This NN module uses a fuzzy neural (FNN) network for the rule extraction.

Fuzzy neural networks (FNN) integrate NN and fuzzy rules into a single neuronal model tightly coupling learning and fuzzy reasoning rules into a connectionist structure. One of the first FNN models was initiated by Yamakawa and other Japanese scientists and promoted at a series of IIZUKA conferences in Japan [40.12, 13]. Many models of FNNs were developed based on these principles [40.2, 14, 15].

## 40.2.2 Evolving Neuro-Fuzzy Systems

The evolving neuro-fuzzy systems further extended the principles of hybrid neuro-fuzzy systems and the FNN, where instead of training a fixed connectionist structure,

the structure and its functionality evolve from incoming data, often in an on-line, one-pass learning mode. This is the case with evolving connectionist systems (ECOS) [40.1, 16–19].

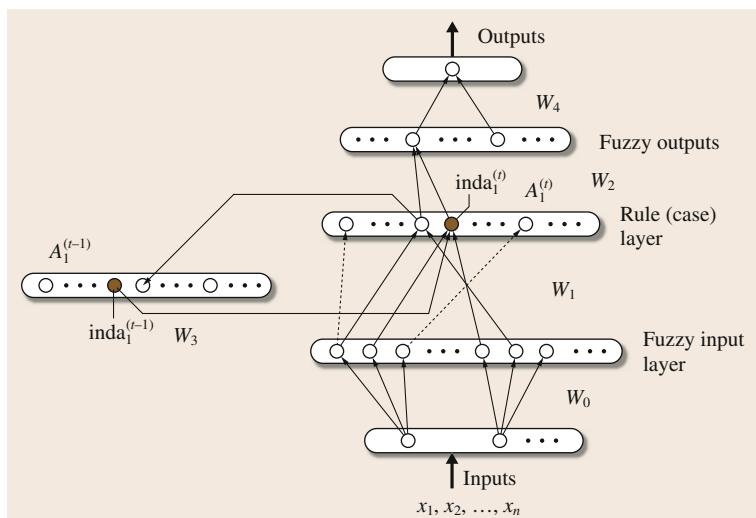

ECOS are modular connectionist-based systems that evolve their structure and functionality in a continuous, self-organized, on-line, adaptive, and interactive way from incoming information [40.17]. They can process both data and knowledge in a supervised and/or unsupervised way. ECOS learn *local models* from data through clustering of the data and associating a local output function for each cluster represented in a connectionist structure. They can learn incrementally single data items or chunks of data and also incrementally change their input features [40.18].

Elements of ECOS have been proposed as part of the early, classical NN models, such as Kohonen's self organising maps (SOM) [40.20], radial basis function (RBF) [40.21], FuzyARTMap [40.22] by Carpenter et al. and Fritzke's growing neural gas [40.23], Platt's resource allocation networks (RAN) [40.24].

Some principles of ECOS are:

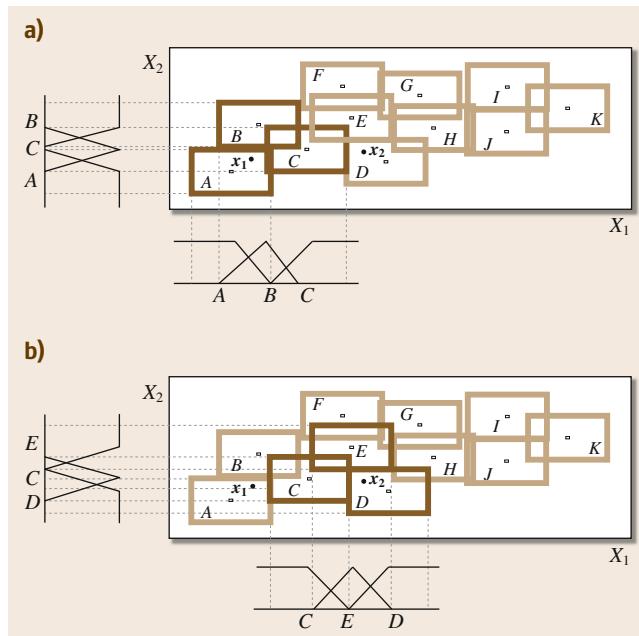

- Neurons are created (evolved) and allocated as centers of (fuzzy) data clusters. Fuzzy clustering, as a means to create local knowledge-based systems, was stimulated by the pioneering work of Bezdek, Yager and Filev [40.27–30].
- Local models are evolved and updated in these clusters.

Here we will briefly illustrate the concepts of ECOS on two implementations: evolving fuzzy neu-

**Fig. 40.3** An EFuNN structure with feedback connections (after [40.16])

tral networks (EFuNN) [40.16] and dynamic neuro-fuzzy inference systems (DENFIS) [40.25]. Examples of EFuNN are shown in Figs. 40.2 and 40.3 and of

**Fig. 40.4a,b** Learning in DENFIS uses the evolving clustering method illustrated on a simple example of 2 inputs and 1 output and 11 data clusters evolved. The recall of the DENFIS for two new input vectors  $x_1$  and  $x_2$  is illustrated with the use of 3 closest clusters to the new input vector (after [40.25]). (a) Fuzzy role group 1 for a DENFIS. (b) Fuzzy role group 2 for a DENFIS

DENFIS in Figs. 40.4 and 40.5. In ECOS, clusters of data are created (evolved) based on similarity between data samples (input vectors) either in the input space (this is the case in some of the ECOS models, e.g., DENFIS), or in both the input and output space (this is the case, e.g., in the EFuNN models). Samples that have a distance to an existing node (cluster center, rule node, neuron) less than a certain threshold are allocated to the same cluster. Samples that do not fit into existing clusters, form (generate, evolve) new clusters. Cluster centers are continuously adjusted according to new data samples, others are created incrementally. ECOS learn from data and automatically create or update a *local* (fuzzy) model/function in each cluster, e.g.,

$$\begin{aligned} & \text{IF } <\text{data is in a (fuzzy) cluster } Ci> \\ & \text{THEN } <\text{the model is } Fi>, \end{aligned} \quad (40.2)$$

where  $Fi$  can be a fuzzy value, a linear or logistic regression function (Fig. 40.5), or an NN model [40.25].

ECOS utilize evolving clustering methods. There is no fixed number of clusters specified a priori, but clusters are created and updated incrementally. Other ECOS that use this principle are: evolving self-organized maps (ESOM) [40.17], evolving classification function [40.18, 26], evolving spiking neural networks (Sect. 40.4).

As an example, the following are the major steps for the training and recall of a DENFIS model:

#### Training:

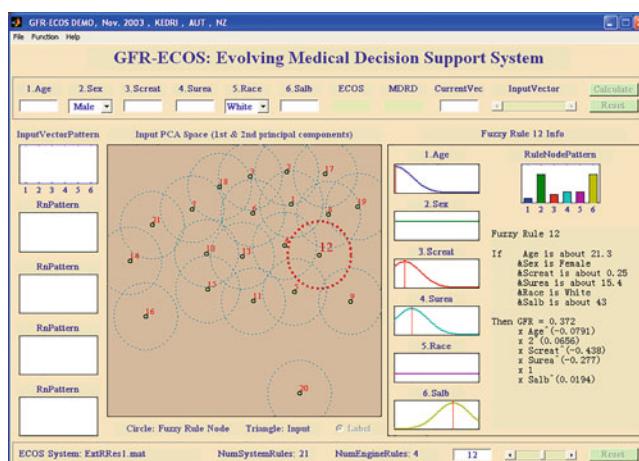

1. Create or update a cluster from incoming data.
2. Create or update a Takagi–Sugeno fuzzy rule for each cluster:  
IF  $x$  is in cluster  $C_j$  THEN  $y_j = f_j(x)$ ,  
where:  $y_i = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_q$ .

The function coefficients are incrementally updated with every new input vector or after a chunk of data. Recall – fuzzy inference for a new input vector:

1. For a new input vector  $x = [x_1, x_2, \dots, x_q]$  DENFIS chooses  $m$  fuzzy rules from the whole fuzzy rule set for forming a current inference system.
2. The inference result is

$$y = \frac{\sum_{i=1,m} [\omega_i f_i(x_1, x_2, \dots, x_q)]}{\sum_{i=1,m} \omega_i}, \quad (40.3)$$

where  $i$  is the index of one of the  $m$  closets to the new input vector  $x$  clusters,  $\omega_i = 1 - d_i$  is the weighted distance between this vector the cluster center,  $f_i(x)$  is the calculated output for  $x$  according to the local model  $f_i$  for cluster  $i$ .

**Fig. 40.5** An example of the DENFIS model (after [40.26]) for medical renal function evaluation

### 40.2.3 From Local to Transductive (Individualized) Learning and Modeling

A special direction of ECOS is transductive reasoning and personalized modeling. Instead of building a set of local models  $f_i$  (e.g., prototypes) to cover the whole problem space and then using these models to classify/predict any new input vector, in transductive modeling for every new input vector  $x$  a new model  $f_x$  is created based on selected nearest neighbor vectors from the available data. Such ECOS models are neuro-fuzzy inference systems (NFI) [40.31] and the transductive weighted neuro-fuzzy inference system (TWNFI) [40.32]. In TWNFI for every new input vector the neighborhood of the closest data vectors is optimized using both the distance between the new vector and the neighboring ones and the weighted importance of the input variables, so that the error of the model is minimized in the neighborhood area [40.33]. TWNFI is a further development of the weighted-weighted nearest neighbor method (WWKNN) proposed in [40.34]. The output for a new input vector is calculated based on the outputs of the  $k$ -nearest neighbors, where the weighting is based on both distance and a priori calculated importance for each variable using a ranking method such as signal-to-noise ratio or the  $t$ -test.

Other ECOS were been developed as improvements of EFuNN, DENFIS, or other early ECOS models by Ozawa et al. and Watts [40.35–37], including ensembles of ECOS [40.38]. A similar approach to ECOS

was used by Angelov in the development of the (ETS) models [40.39].

### 40.2.4 Applications

ECOS have been applied to problems across domain areas. It is demonstrated that local incremental learning or transductive learning are superior when compared to global learning models and when compared in terms of accuracy and new knowledge obtained. A review of ECOS applications can be found in [40.26]. The applications include:

- Medical decision support systems (Fig. 40.5)
- Bioinformatics, e.g., [40.40]
- Neuroinformatics and brain study, e.g., [40.41]
- Evolvable robots, e.g., [40.42]
- Financial and economic decision support systems, e.g., [40.43]
- Environmental and ecological modeling, e.g., [40.44]
- Signal processing, speech, image, and multimodal systems, e.g., [40.45]
- Cybersecurity, e.g., [40.46]
- Multiple time series prediction, e.g., [40.47].

While classical ECOS use a simple McCulloch and Pitts model of a neuron and the Hebbian learning rule [40.48], evolving spiking neural network (eSNN) architectures use a spiking neuron model, applying the same or similar ECOS principles.

## 40.3 Evolving Spiking Neural Networks (eSNN)

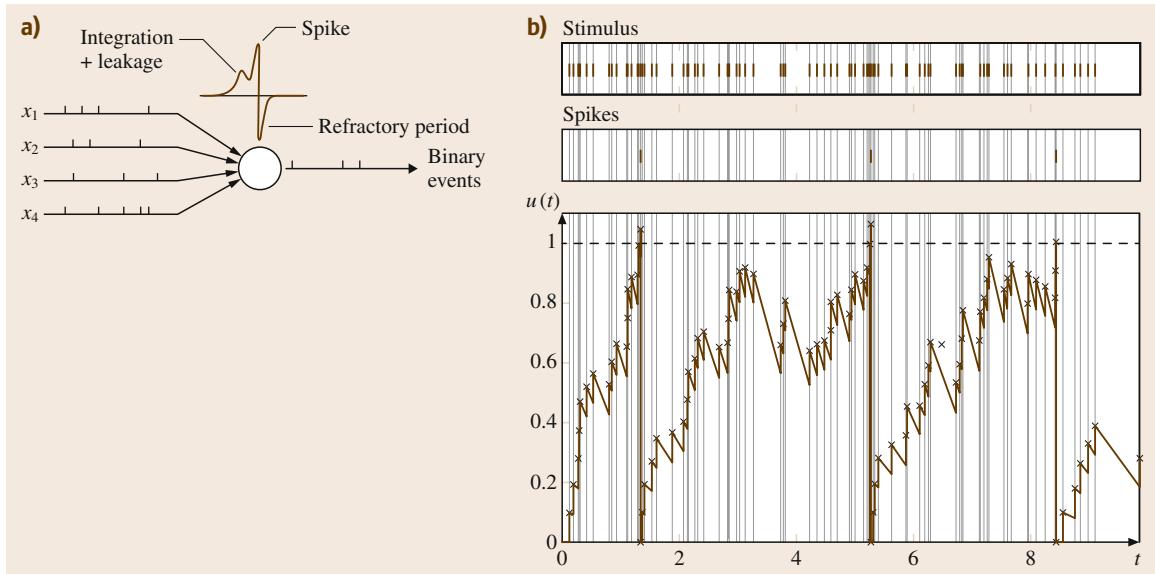

### 40.3.1 Spiking Neuron Models

A single biological neuron and the associated synapses is a complex information processing machine that involves short-term information processing, long-term information storage, and evolutionary information stored as genes in the nucleus of the neuron. A spiking neuron model assumes input information represented as trains of spikes over time. When sufficient input spikes are accumulated in the membrane of the neuron, the neuron's post-synaptic potential exceeds a threshold and the neuron emits a spike at its axon (Fig. 40.6a,b). Some of the-state-of-the-art models of spiking neurons include: early models by Hodgkin and Huxley [40.49], and Hopfield [40.50]; and more recent models by Maass, Gerstner, Kistler, Izhikevich, Thorpe and van Rullen [40.51–54]. Such models are spike response models (SRMs),

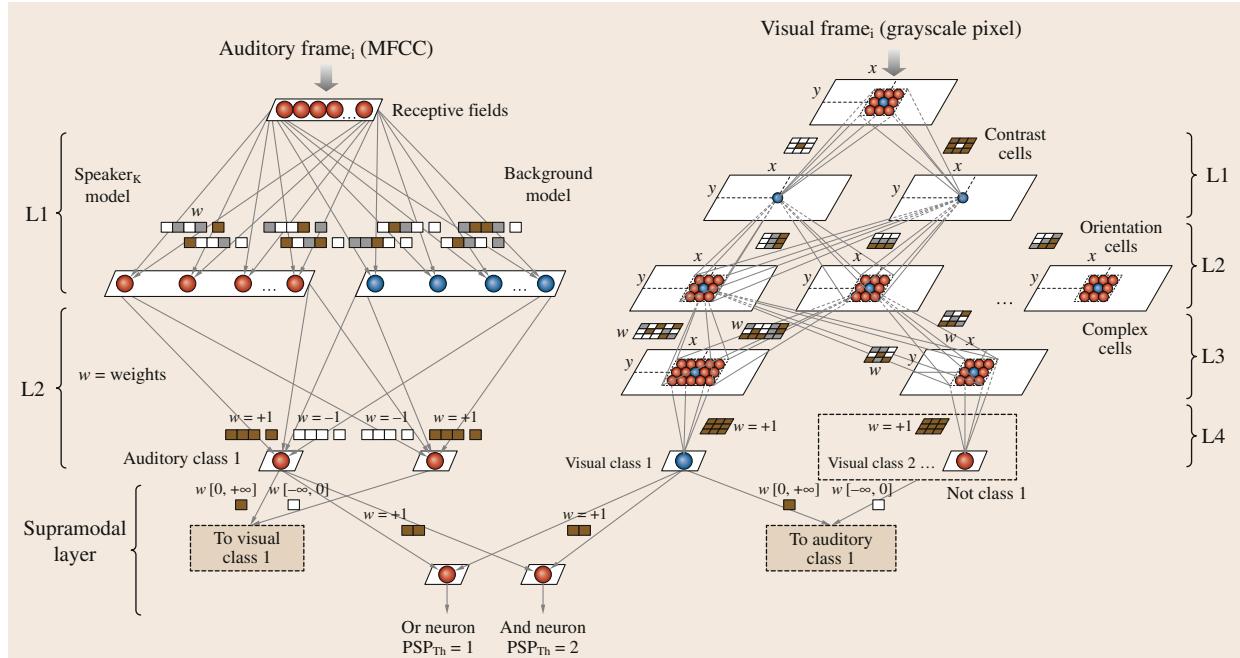

the leaky integrate-and-fire model (LIFM) (Fig. 40.6), Izhikevich models, adaptive LIFM, and probabilistic IFM [40.55].

### 40.3.2 Evolving Spiking Neural Networks (eSNN)

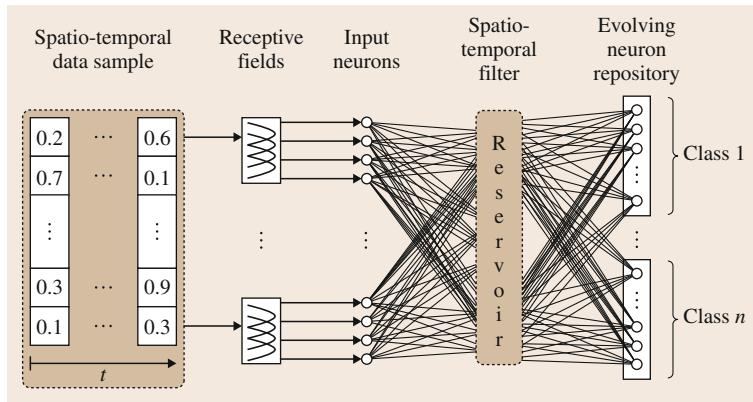

Based on the ECOS principles, an evolving spiking neural network architecture (eSNN) was proposed in [40.26], which was initially designed as a visual pattern recognition system. The first eSNNs were based on Thorpe's neural model [40.54], in which the importance of early spikes (after the onset of a certain stimulus) is boosted, called rank-order coding and learning. Synaptic plasticity is employed by a fast supervised one-pass learning algorithm. An exemplar eSNN for multimodal auditory-visual information processing on

**Fig. 40.6** (a) LIFM of a spiking neuron. (b) The LIFM increases its membrane potential  $u(t)$  with every incoming spike at time  $t$  until the potential reaches a threshold, after which the neuron emits an output spike and its potential is reset to an initial value

**Fig. 40.7** An exemplar eSNN for multimodal auditory-visual information processing in the case study problem of speaker authentication (after [40.56])

**Fig. 40.8** A reservoir-based eSNN for spatio-temporal pattern classification (after [40.55])

the case study problem of speaker authentication is shown in Fig. 40.7.

Different eSNN models use different architectures. Figure 40.8 shows a reservoir-based eSNN for spatio-temporal pattern recognition where the reservoir [40.57] uses the spike-time-dependent plasticity (STDP) learning rule [40.58], and the output classifier that classifies spatio-temporal activities of the reservoir uses rank-order learning rule [40.54].

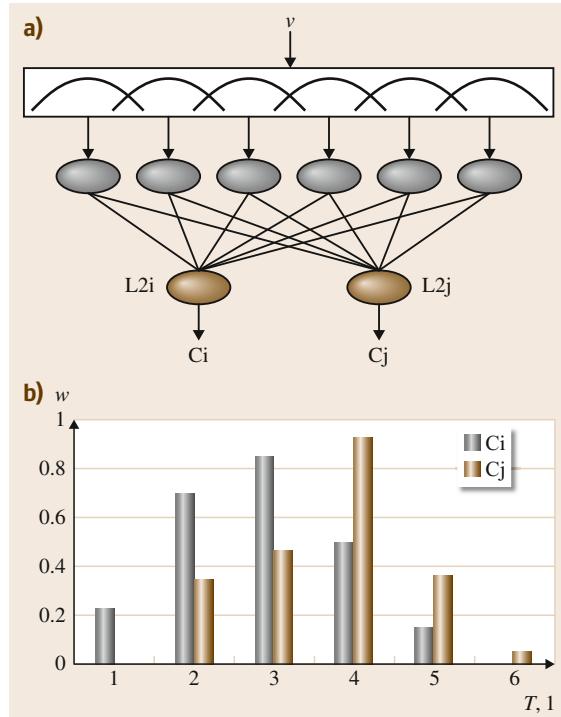

### 40.3.3 Extracting Fuzzy Rules from eSNN

Extracting fuzzy rules from an eSNN would make eSNN not only efficient learning models, but also knowledge-based models. A method was proposed in [40.59] and illustrated in Fig. 40.9a,b. Based on the connection weights  $w$  between the receptive field layer L1 and the class output neuron layer L2 fuzzy rules are extracted.

### 40.3.4 eSNN Applications

Different eSNN models and systems have been developed for different applications, such as:

- eSNN for spatio- and spectro-temporal pattern recognition – <http://ncs.ethz.ch/projects/evospike>
- Dynamic eSNN (deSNN) for moving object recognition – [40.60]
- Spike pattern association neuron(SPAN) for generation of precise time spike sequences as a response to recognized input spiking patterns – [40.61]
- Environmental and ecological modeling – [40.44]
- EEG data modeling – [40.62]
- Neuromorphic SNN hardware – [40.63, 64]
- Neurogenetic models (Sect. 40.4).

**Fig. 40.9 (a)** A simple structure of an eSNN for 2-class classification based on one input variable using six receptive fields to convert the input values into spike trains.  
**(b)** The connection weights of the connections to class  $C_i$  and  $C_j$  output neurons, respectively, are interpreted as fuzzy rules: IF(input variable  $v$  is SMALL) THEN class  $C_i$ ; IF( $v$  is LARGE)THEN class  $C_j$

A review of eSNN methods, systems and their applications can be found in [40.65].

## 40.4 Computational Neuro-Genetic Modeling (CNGM)

### 40.4.1 Principles

A neuro-genetic model of a neuron was proposed in [40.41, 66]. It utilizes information about how some proteins and genes affect the spiking activities of a neuron such as *fast excitation, fast inhibition, slow excitation, and slow inhibition*. An important part of the model is a dynamic gene/protein regulatory network (GRN) model of the dynamic interactions between genes/proteins over time that affect the spiking activity of the neuron – Fig. 40.10.

A CNGM is a dynamical model that has two dynamical sub-models:

- GRN, which models dynamical interaction between genes/proteins over time scale T1
- eSNN, which models dynamical interaction between spiking neurons at a time scale T2.

The two sub-models interact over time.

### 40.4.2 The NeuroCube Framework

A further development of the eSNN and the CNGM was achieved with the introduction of the NeuroCube framework [40.67]. The main idea is to support the creation of multi-modular integrated systems, where different modules, consisting of different neuronal types and genetic parameters *correspond* in a way to different parts of the brain and different functions (e.g., vision, sensory information processing, sound recognition, motor-control) and the whole system works in an integrated mode for brain signal pattern recognition. A concrete model built with the use of the NeuroCube would have a specific structure and a set of algorithms depending on the problem and the application conditions, e.g., classification of EEG, recognition of func-

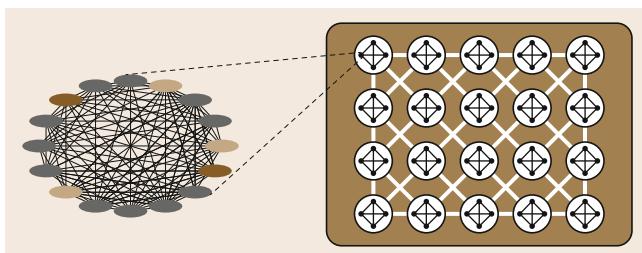

tional magneto-resonance imaging (fMRI) data, brain computer interfaces, emotional cognitive robotics, and modeling Alzheimer's disease.

A block diagram of the NeuroCube framework is shown in Fig. 40.11. It consists of the following modules:

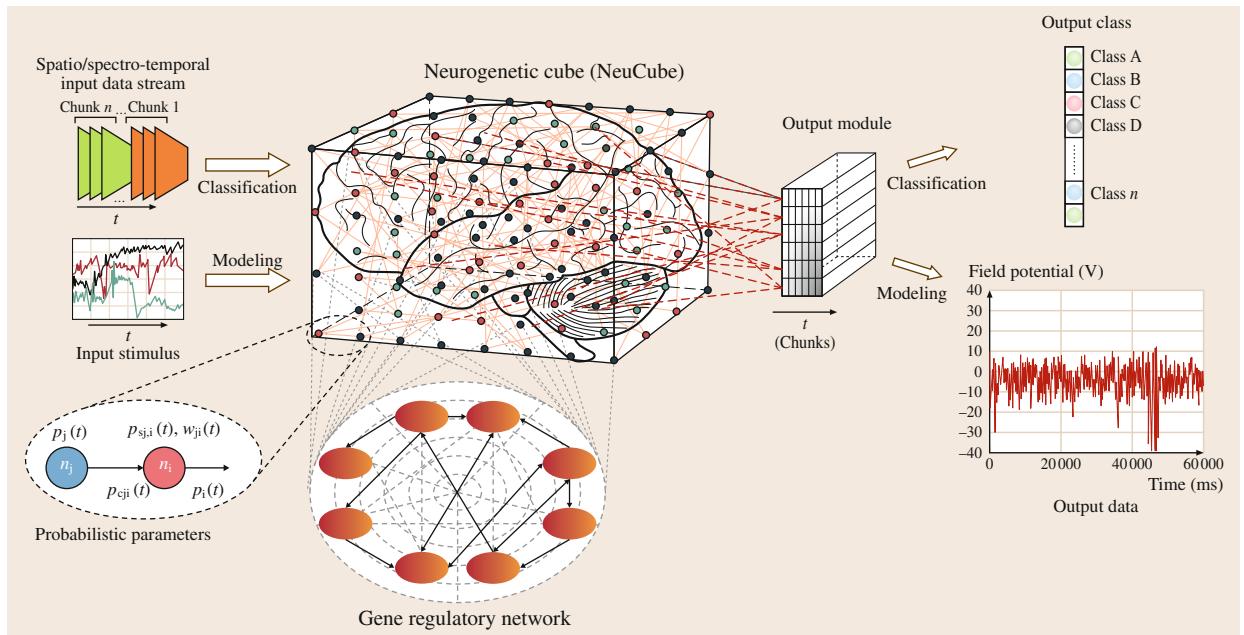

- An input information encoding module
- A NeuroCube module
- An output module
- A gene regulatory network (GRN) module.

The main principles of the NeuroCube framework are:

1. NeuroCube is a framework to model brain data (and not a brain model or a brain map).
2. NeuroCube is a selective, approximate map of relevant to the brain data brain regions, along with relevant genetic information, into a 3-D spiking neuronal structure.
3. An initial NeuroCube structure can include known connections between different areas of the brain.
4. There are two types of data used for both training a particular NeuroCube and to recall it on new data: (a) data, measuring the activity of the brain when certain stimuli are presented, e.g., (EEG, fMRI); (b) direct stimuli data, e.g., sound, spoken language, video data, tactile data, odor data, etc.
5. A NeuroCube architecture, consisting of a NeuroCube module, (GRN)s at the lowest level, and a higher-level evaluation (classification) module.
6. Different types of neurons and learning rules can be used in different areas of the architecture.
7. Memory of the system is represented as a combination of: (a) short-term memory, represented as changes of the neuronal membranes and temporary changes of synaptic efficacy; (b) long-term memory, represented as a stable establishment of synaptic efficacy; (c) genetic memory, represented as a change in the genetic code and the gene/protein expression level as a result of the above short-term and long-term memory changes and evolutionary processes.
8. Parameters in the NeuroCube are defined by genes/proteins that form dynamic GRN models.
9. NeuroCube can potentially capture in its internal representation both spatial and temporal characteristics from multimodal brain data.
10. The structure and the functionality of a NeuroCube architecture evolve in time from incoming data.

**Fig. 40.10** A schematic diagram of a computational neuro-genetic modeling (CNGM) framework consisting of a gene/protein regulatory network (GRN) as part of an eSNN (after [40.41])

**Fig. 40.11** The NeuroCube framework (after [40.67])

#### 40.4.3 Quantum-Inspired Optimization of eSNN and CNGM

A **CNGM** has a large number of parameters that need to be optimized for an efficient performance. Quantum-inspired optimization methods are suitable for this purpose as they can deal with a large number of variables and will converge in much faster time than any other optimization algorithms [40.68]. Quantum-inspired eSNN (QeSNN) use the principle of superposition of states to represent and optimize features (input variables) and parameters of the eSNN including genes in a GRN [40.44]. They are optimized through a quantum-inspired genetic algorithm [40.44]

or a quantum-inspired particle swarm optimization algorithm [40.69]. Features are represented as *qubits* in a superposition of 1 (selected), with a probability  $\alpha$ , and 0 (not selected) with a probability  $\beta$ . When the model has to be calculated, the quantum bits *collapse* in 1 or 0.

#### 40.4.4 Applications of CNGM

Various applications of **CNGM** have been developed such as:

- Modeling brain diseases [40.41, 70]
- **EEG** and **fMRI** spatio-temporal pattern recognition [40.67].

## 40.5 Conclusions and Further Directions

This chapter presented a brief overview of the main principles of a class of neural networks called evolving connectionist systems (**ECOS**) along with their applications for computational intelligence. **ECOS** facilitate fast and accurate learning from data and new knowledge discovery across application areas. They

integrate principles from neural networks, fuzzy systems, evolutionary computation, and quantum computing. The future directions and applications of **ECOS** are foreseen as a further integration of principles from information science-, bio-informatics, and neuro-informatics [40.71].

# Machine Learning Applications

Piero P. Bonissone

We describe the process of building computational intelligence (**CI**) models for machine learning (**ML**) applications. We use offline metaheuristics to design the models' run-time architectures and online metaheuristics to control/aggregate the object-level models (base models) in these architectures. **CI** techniques complement more traditional statistical techniques, which are the core of **ML** for unsupervised and supervised learning. We analyze **CI/ML** industrial applications in the area of prognostics and health management (**PHM**) for industrial assets, and describe two **PHM** case studies. In the first case, we address anomaly detection for aircraft engines; in the second one, we rank locomotives in a fleet according to their expected remaining useful life. Then, we illustrate similar **CI**-enabled capabilities as they are applied to risk management for commercial and financial assets. In this context, we describe three case studies in insurance underwriting, mortgage collateral valuation, and portfolio optimization. We explain the current trend favoring the use of model ensemble and fusion over individual models, and emphasize the need for injecting diversity during the model generation phase. We present a model-agnostic fusion mechanism, which can be used with commoditized models obtained from crowdsourcing, cloud-based evolution, and other sources. Finally, we explore research trends, and future challenges/opportunities for **ML** techniques in the emerging context of big data and cloud computing.

## 41.1 Motivation

Based on the definition provided by the IEEE Computational Intelligence Society, computational intelligence (**CI**) covers *biologically and linguistically motivated computational paradigms*. Its scope broadly overlaps with that of soft computing (**SC**), a similar concept also conceived in the 1990s. The original definition of soft computing was [41.1]:

*An association of computing methodologies that includes as its principal members fuzzy logic (**FL**), neuro-computing (**NC**), evolutionary computing (**EC**) and probabilistic computing (**PC**).*

Thus, in its original scope, **CI** excluded probabilistic reasoning systems, while including other nature-inspired methodologies, such as swarm computing, ant colony optimization, etc. More recently, however, **CI** has extended its scope to include statistically inspired machine-learning techniques. Throughout this review, we will adopt this less restrictive definition of **CI** techniques, increasing its overlapping with **SC** even more [41.2, 3]. Readers interested in the historical origins of the **CI** concept should consult [41.4–6].

In addressing real-world problems, we usually deal with physical systems that are difficult to model and possess large solution spaces. In these situations, we leverage two types of resources: domain knowledge of the process or product and field data that characterize the system's behavior. The relevant engineering knowledge tends to be a combination of first principles and empirical knowledge. Usually, it is captured in physics-based models, which tend to be more precise than data-driven models, but more difficult to construct and maintain. The available data are typically a collection of input–output measurements, representing instances of the system's behavior. Usually, data tend to be incomplete and noisy. Therefore, we often augment knowledge-driven models by integrating them with approximate solutions derived from **CI** methodologies, which are robust to this type of imperfect data. **CI** is a flexible framework that offers a broad spectrum of design choices to perform such integration.

Domain knowledge can be integrated within **CI** models in a variety of ways. Arguably, the simplest integration is the use of physics-based models (derived from domain knowledge) to predict expected values of variables of interest. By contrasting the expected values with the actual measured values, we compute the residuals for the same variables and use **CI** based mod-

els to explain the differences. Domain knowledge can also be used to design **CI**-based models: it can influence the selection of the features (functions of raw data) that are the inputs to the **CI** models; it can suggest certain topologies for graphical models (e.g., **NN** architectures) to approximate known functional dependences; it can be represented by linguistics fuzzy terms and relationships to provide coarse approximations; it can be used to define data structures of individuals in the population of an evolutionary algorithm (**EA**); it can be used explicitly in metaheuristics (**MH**'s) that leverage such knowledge to focus its search in a more efficient way. For a more detailed discussion of the use of domain knowledge in **EAs**, see [41.7].

Computational intelligence started in the 1990s with three pillars: *Neural networks* (**NNs**), to create functional approximations from input–outputs training sets; *fuzzy systems*, to represent imprecise knowledge and perform approximate deductions with it; and *Evolutionary systems*, to create efficient global search methods based on optimization through adaptation. Over the last decade, the individual developments of these pillars have become intertwined, leading to successful hybridizations.

### 41.1.1 Building Computational Intelligence Object- and Meta-Models

Recently, as described in [41.21], this hybridization has been structured as a three-layer approach, in which each layer has a specific purpose:

- Layer 1: *Offline MHs*. They are used in batch mode, during the model creation phase, to design, tune, and optimize run-time model architectures for deployment. Then they are used to adapt them and maintain them over time. Examples of offline **MHs** are global search methods, such as **EAs**, scatter search, tabu search, swarm optimization, etc.
- Layer 2: *Online MHs*. They are part of the run-time model architecture, and they are designed by offline **MHs**. The *online MHs* are used to integrate/interpolate among multiple (local) object-models, manage their complexity, and improve their overall performance. Examples of online **MHs** are fuzzy supervisory systems, fusion modules, etc.
- Layer 3: *Object-level Models*. They are also part of the run-time architecture, and they are designed by offline **MHs** to solve object-level prob-

lems. For simpler cases, we use *single object-level models* that provide an individual **SC** functionality (functional approximation, optimization, or reasoning with imperfect data). For complex cases, we use *multiple object-level models* in parallel configuration (ensemble) or sequential configuration (cascade, loop), to integrate functional approximation with optimization and reasoning with imperfect data (imprecise and uncertain).

The underlying idea is to reduce or eliminate manual intervention in any of these layers, while leveraging **CI** capabilities at every level. We can manage complexity by finding the best model architecture to support problem decomposition, create high-performance local models with limited competence regions, allow for smooth interpolations among them, and promote robustness to imperfect data by aggregating diverse

models. Let us examine some case studies that further illustrate this concept.

### Examples of Offline MH, Online MH, and Object Models

In Table 41.1, we observe a variety of **CI** applications in which we followed the separation between object- and meta-level described earlier. In most of these applications, the object-level models were based on different technologies such as machine learning (support vector machines, random forest), statistics (multivariate adaptive regression splines, **MARS**), Hotelling's  $T^2$ , neural networks (feedforward, self-organizing maps), fuzzy systems, **EAs**, Case based. The online metaheuristics were mostly based on fuzzy aggregation (interpolation) of complementary local models or fusion of competing models. The offline **MHs** were mostly implemented by evolutionary search in the model design space. Descriptions of these applications can be found in the

**Table 41.1** Examples of **CI** applications at meta-level and object-level

| Case study | Problem instance                        | Problem type                  | Model design (offline MHs)                          | Model controller (online MHs) | Object-level models                                                                                   | References  |

### 41.1.2 Model Lifecycle

In real-world applications, before using a model in a production environment we must address the model's complete life cycle, from its design and implementation to its validation, tuning, production testing, use, monitoring, and maintenance. By maintenance, we refer to all the steps required to keep the model vital (e.g., nonobsolete) and to adapt it to changes in the environment in which it is deployed. Many reasons justify

this focus on model maintenance. Over the model's life cycle, maintenance costs are the by far most expensive ones (as software maintenance costs are the most expensive ones in the life of a software system). Furthermore, when dealing with mission-critical software we need to guarantee continuous operation or at least fast recovery from system failures or model obsolescence to avoid lost revenues and other business costs.

The use of **MHs** in the design stage allows us to create a process for automating the model building phase and subsequent model updates. This is a critical step to quickly deploy and maintain **CI** models in the field, and it will be further described in the case studies. Additional information on this topic can be found in [41.22].

## 41.2 Machine Learning (ML) Functions

Machine learning techniques can be roughly subdivided into *supervised*, *semisupervised reinforcement*, and *unsupervised learning*. The distinction among these categories depends on the complete, partial, or lack of available ground truth (i.e., correct outputs for each input vector) during the training phase.

*Unsupervised learning* techniques are used when no ground truth is available. Their goal is to identify structures in the input space that could be used to decompose the problem and facilitate local model building. Typical examples of unsupervised learning are cluster analysis, self-organizing maps (**SOMs**) [41.23], and dimension reduction techniques, such as principal components analysis (**PCA**), independent components analysis (**ICA**), multidimensional scaling (**MDS**), etc.

*Reinforcement learning* (**RL**) does not rely on ground truth. It assumes that an agent operates in an environment and after performing one or more actions it receives a reward that is a consequence of its actions, rather than an explicit expression of ground truth. *Sutton and Barto* [41.24] were among the first proponents of this technique, which is quite promising to model adversarial situations, but it has not generated many industrial or commercial applications. A succinct description of **RL** can be found in [41.25].

*Semisupervised* and *supervised learning* techniques are used when partial or complete ground truth is available, such as labels for *classification* problems and real-values for *regression* problems. There are many traditional linear models for classification and regression. For instance, we have linear discriminant analysis (**LDA**) and logistic regression (**LR**) for classification,

and least-squares techniques – combined with feature subset selection or shrinkage methods (e.g., Ridge, least absolute shrinkage and selection operator (**LASSO**)) – for regressions. **CI** techniques usually generate nonlinear solutions to these problems. We can group the most of the commonly used nonlinear techniques, as

- *Directed graphical-based models*, such as neural networks, neural fuzzy systems, Bayesian belief networks, Bayesian neural networks, etc.
- *Tree based*: Classification analysis and regression trees (**CARTs**) [41.26], ID3/C4.5 [41.27], etc.
- *Grammar based*: Genetic programming, evolutionary programming, etc.
- *Similarity and metric learning*: Lazy learning (or instance-based learning) [41.28, 29], case-based reasoning, (fuzzy)  $k$ -means, etc.
- *Undirected graphical models*: Markov graphs, restricted Boltzmann machines [41.30], etc.

The reader can find a comprehensive treatment of these techniques in [41.31]. Some of these models are used as part of on ensemble, rather than individually. Such is the case of random forest [41.32], which is based on a collection of **CART** trees [41.26]. Similarly, a fuzzy extension of random forest using fuzzy decision trees [41.33] can be found in [41.34]. This trend toward the use of ensembles is covered in Sect. 41.5. We will now focus on a subset of the **CI/ML** applications. Specifically, we will analyze two case studies in industrial applications (Sect. 41.3) and three in financial applications (Sect. 41.4).

## 41.3 CI/ML Applications in Industrial Domains: Prognostics and Health Management (PHM)

To provide a coherent theme for the **ML** industrial application, we will focus on prognostics and health management (**PHM**). The main goal of **PHM** for assets such as locomotives, medical scanners, and aircraft engines is to maintain these assets' operational performance over time, improving their utilization while minimizing their maintenance cost. This tradeoff is critical for the proper execution of contractual service agreements (**CSAs**) offered by original equipment manufacturer's (**OEM**) to their valued customers.

**PHM** is a multidiscipline field, as it includes aspects of electrical engineering (reliability, design, service), computer and decision sciences (artificial intelligence, **CI**, **MI**, statistics, operations research (**OR**)), mechanical engineering (geometric models for fault propagation), material sciences, etc. Within this paper, we will focus on the role that **CI** plays in **PHM** functionalities.

**PHM** can be divided into two main components:

- **Health assessment:** the evaluation and interpretation of the asset's current and future health state.
- **Health management:** the control, operation, and logistic plans to be implemented in response to such assessment.

**PHM** functional architecture is illustrated in Fig. 41.1, adapted from [41.35].

The first two tasks:

- (1) Remote monitoring, and
- (2) Input data preprocessing, are platform dependent, as they need domain knowledge to identify and

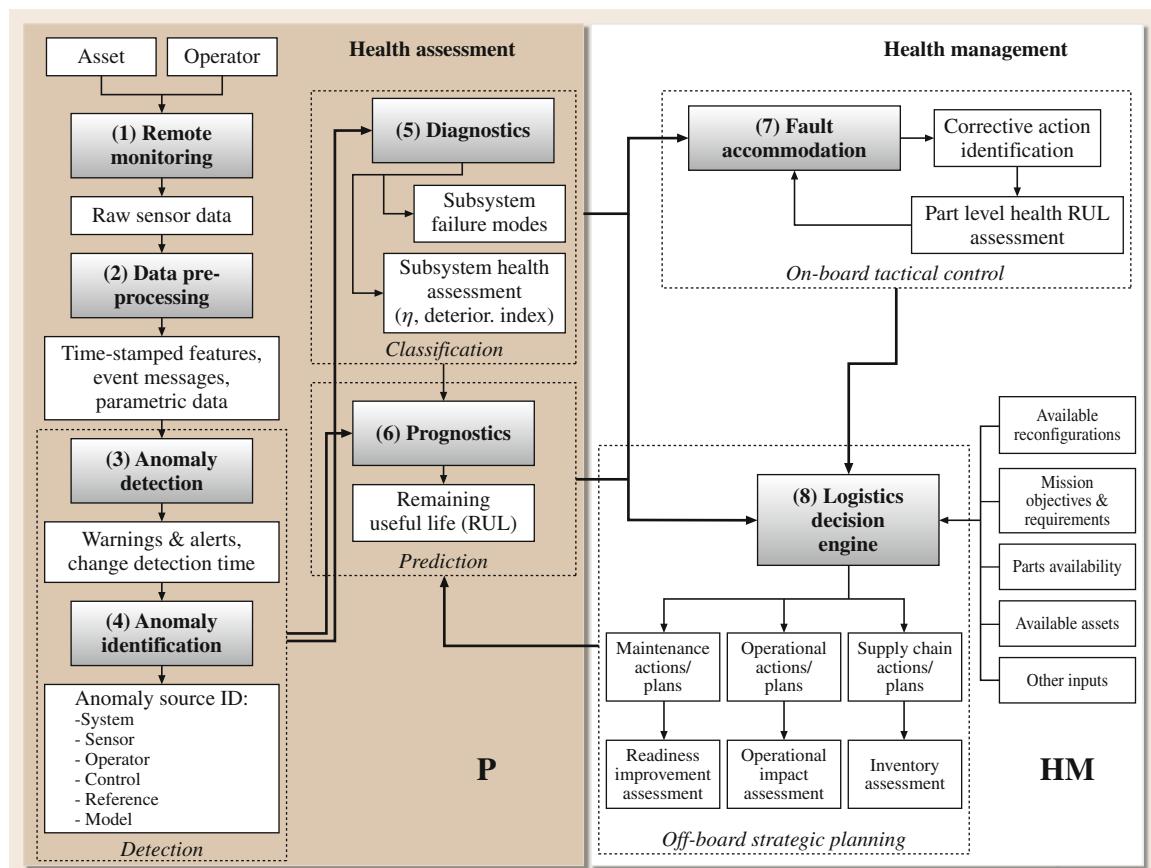

Fig. 41.1 PHM functional architecture

select the most informative inputs, perform data curation (de-noising, imputation, and normalization), aggregate them, and prepare them to be suitable inputs for the models.

The remaining decisional tasks could be considered platform independent (to the extent that their functions could be accomplished by data-driven models alone.) These tasks are:

- (3) Anomaly detection and identification
- (4) Anomaly resolution
- (5) Diagnostics
- (6) Prognostics
- (7) Fault accommodation
- (8) Logistics decisions.

Health assessment, which is based on *descriptive* and *predictive* analytics, is contained in the left block of Fig. 41.1 (annotated with P). Health management (**HM**), which is based on *prescriptive* analytics, is contained in the right block of Fig. 41.1 (annotated with **HM**). In the remaining of this section, we will cover two case studies related to anomaly identification and prognostics.

### 41.3.1 Health Assessment and Anomaly Detection: An Unsupervised Learning Problem

#### Anomaly Detection (AD)

Using platform-deployed sensors, we collect data remotely. We preprocess it, via segmentation, filtering, imputation, validation, and we summarize it by extracting feature subsets that provide a more succinct, robust representation of its information content. These features, which could contain a combination of categorical and numerical values, are analyzed by an anomaly detection model to assess the degree of abnormal behavior of each asset in the fleet. If the degree of abnormality exceeds a given threshold, the model will identify the asset, determine the time when the anomaly was first noticed and suggest possible causes of the anomaly (usually a coarse identification at the systems/subsystem level). Anomaly detection usually leverages unsupervised learning techniques, such as clustering. Its goal is to extract the underlying structural information from the data, define normal structures and regions, and identify departures from such regions.

#### Anomaly Identification (AI)

After detecting an abnormal change, e.g., a departure from a normal region of the state space, we need to

identify its cause. There are many factors that could cause such change:

- (a) A *system fault*, which could eventually lead to a failure.
- (b) A *sensor fault*, which is creating incorrect measurements.
- (c) An *inadequate anomaly detection model*, which is falsely reporting anomalies due to poor design, inadequate model update, execution outside its region of competence, etc.
- (d) A sudden, unexpected *operational transient*, which is stressing the system by creating an abrupt load change. This transient could be originated by an operator error, who is requesting such sudden change; by an incorrect reference vector (in case of operation automation), which is also requesting such abrupt change; or by a poorly designed controller, which is either over- or under-compensating for a perceived state change.

The first factor (system fault) represents a correct anomaly classification and should trigger the rest of the workflow (diagnostics, prognostics, fault accommodation, and maintenance optimization), while the other three factors generate false alarms (false positives.) In the next case study, we will focus on how to improve the accuracy of an anomaly detection model, (third factor in the list) and decrease the probability of causing false positives. This increase in model fidelity will also create a sharper distinction between system faults and sensor faults (first and second factors in the list).

#### Anomaly Detection for Aircraft Engines

**Problem Definition.** As noted in Sect. 41.1, one of the best way to leverage domain knowledge is to create expected values using highly tuned physics based simulators, compare them with actual values and analyze the differences (residuals) using data-driven models.

**Physics-Based Simulator.** In this case study, we focused on the detection of anomalies in a simulated aircraft engine. A component level model (**CLM**), a thermodynamic model that has been widely used to simulate the performance of an aircraft engine, provided the physics-based model. Flight conditions, such as *altitude*, *Mach number*, *ambient temperature*, and *engine fan speed*, and a large variety of model parameters, such as module efficiency and flow capacity are inputs

to the **CLM**. The outputs of the **CLM** are the values for pressures, core speed and temperatures at various locations of engine, which simulate sensor measurements. Realistic values of sensor noise can be added after the **CLM** calculation. In this study, we used a steady state **CLM** model for a commercial, high-bypass, twin spool, turbofan engine.

**Actual Values.** We used engine data collected under cruise conditions to monitor engine health changes.

**Data-Driven Model.** We realized that a single, global model – regardless of the technology used to implement it – would be inadequate for large operating spaces of the simulated engine. Global models are designed to achieve a compromise among completeness (for coverage), high fidelity (for accuracy), and transparency (for maintainability). As a result, we usually end up with models that in order to maintain small biases exhibit large variability. This variability might be too large to distinguish between model error and anomalous system behavior and can be a significant factor in the generation of false alarms.

**CI-Based Approach.** To solve the model fidelity problem, we decomposed the engine's operating space into several, partially overlapping regions and developed a set of local models, trained on each region. This schema required a supervisory model (or meta model) to determine the competence region of each local model and select the appropriate one. In control problems, this supervisory module typically selects one controller (out of a collection of low-level controllers) to close the loop with the dynamic system. In many fuzzy controllers application [41.36, 37], a fuzzy supervisory module determines the applicability degree of the low-level controller and interpolates their outputs. Usually, this is done with a weighted, convex sum of the controllers' outputs. The weights used in the convex sum are the applicability degrees of the low-level controllers in the part of the state space that contains the input. The transition from *mode selection* to *mode melting* [41.38] generates a smoother response surface by avoiding discontinuities.

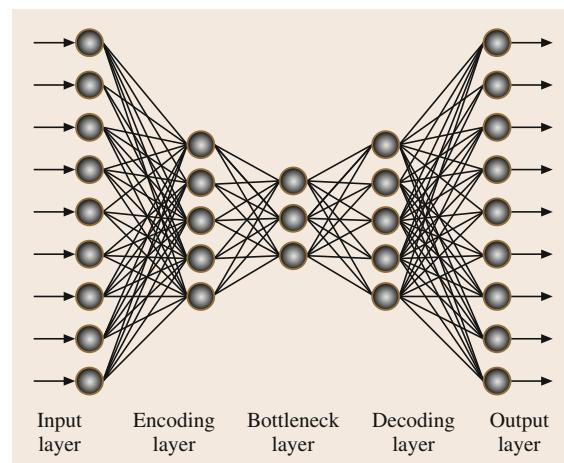

We applied the same concept to the problem of improving the fidelity of data-driven models for anomaly detection. First, we decided to use auto-associative NNs (**AANN**) to implement the local models. Then, we developed a fuzzy supervisory controller, defining the applicability of each **AANN** as a fuzzy region in the engine's three-dimensional operating space, defined by

*altitude, Mach number, and Ambient temperature.* Finally, we used and evolutionary algorithm to tune the term set of the fuzzy supervisory and find the best fuzzy boundaries to interpolate between **AANNs** with overlapping applicability.

**Local Models.** Auto-Associative Neural Networks (**AANN**'s) are feedforward neural networks with structure satisfying requirements for performing restricted auto-association. The inputs to the **AANN** go through a dimensionality reduction, as their information is combined and compressed in intermediate layers. For example, in Fig. 41.2 the nine nodes in the input layer are reduced to five and then three, in the second layer (encoding) and third layer (bottleneck), respectively. Then, the nodes in the 3rd layer are used to recreate the original inputs, by going through a dimensionality expansion (fourth layer, decoding) and fifth layer, outputs). In the ideal case, the **AANN** outputs should be identical to the inputs. Their difference (residuals) and their gradient information are used to train the **AANN** to minimize such difference.

This network computes the largest nonlinear principal components (**NLPCA**'s) – the nodes in the intermediate layer – to identify and remove correlations among variables. Besides the generation of residuals this type of network can also be used in dimensionality reduction, visualization, and exploratory data analysis. As noted in [41.39]:

*While (principal component analysis) **PCA** identifies only linear correlations between variables,*

**Fig. 41.2** Architecture of a 9-5-3-5-9 auto associative neural network

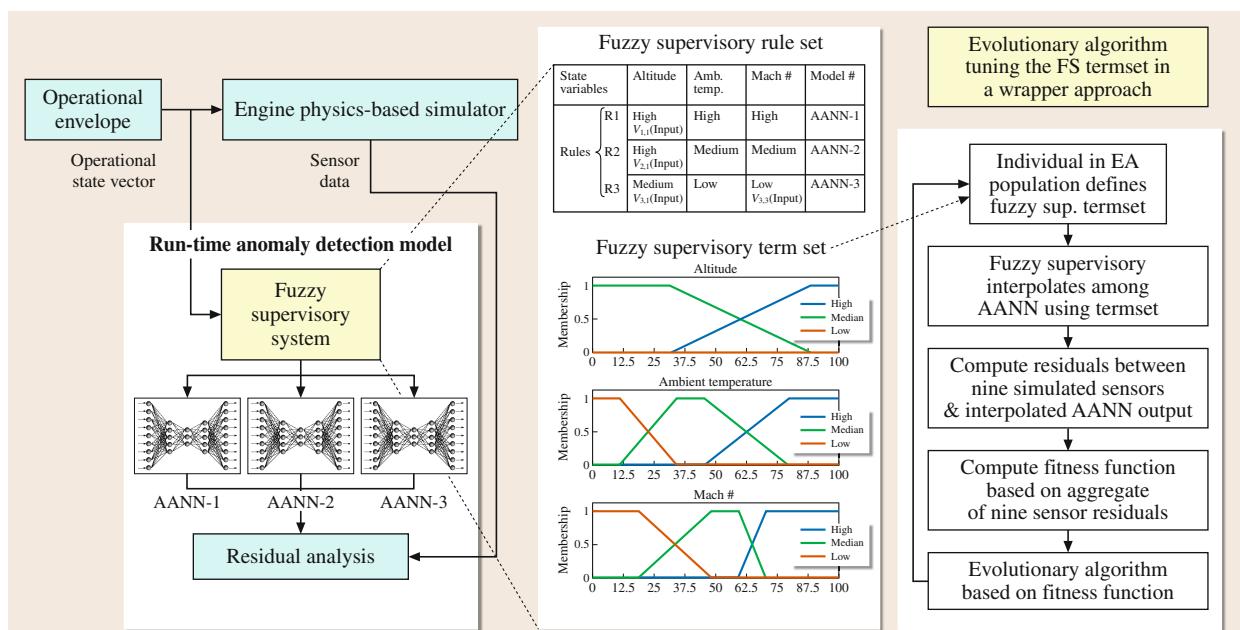

**NLPCA** uncover both linear and nonlinear correlations, without restriction on the character of the nonlinearities present in the data.

**NLPCA** operates by training a feedforward neural network to perform the identity mapping, where the network inputs are reproduced at the output layer. The network contains an internal *bottleneck* layer (containing fewer nodes than input or output layers), which forces the network to develop a compact representation of the input data, and two additional hidden layers. Additional information about **AANNs** can be found in [41.39–41].

The complete **CI** approach is illustrated in Fig. 41.3, adapted from [41.10]. The left part of the figure shows the run-time anomaly detection (**AD**) model. The center part of Fig. 41.3 shows an instance of the term set used by the fuzzy supervisory system (the scale of the operational state variables was normalized as a percentage of the range of values to preserve proprietary information). In the right part of Fig. 41.3, we can see the evolutionary algorithm (**EA**) in a wrapper configuration, used to tune the membership functions (term sets). Each individual in the **EA** population is a set of parameters that represents an implementable term set configuration. For *Altitude*, we varied two pa-

rameters. For each of *ambient temperature* and *Mach number*, we varied four parameters, with a total of ten search parameters. Each individual was a set of ten parameters that created a corresponding set of membership functions that controlled residuals behavior of the fuzzy supervisory model. The fitness of each individual was computed based on the aggregate of the nine sensor residuals, with a goal toward maximizing fitness or minimizing overall residuals. The **EA** used was based on the genetic algorithm optimization toolbox (**GATOT**) toolkit. The population size was set at 500, and the generation count was set at 1000. The **EA** execution was very efficient taking only about 2 h of execution time on a standard desktop machine.

**Results.** As a result of this experiment, we were able to drastically reduce the residuals generated under steady state, no-fault assumption, and we improved the fidelity of the local model ensemble by more than a factor of four with respect to a reference global data-driven model. This fidelity allowed us to create a sharper baseline used to identify true engine anomalies, distinguishing them from sensor anomalies. For a more detailed description of these results see [41.10].

**Fig. 41.3** Evolutionary algorithms tune the term sets of the fuzzy supervisory system to interpolate the outputs of an ensemble of local auto associative NNs

### 41.3.2 Health Assessment – Diagnostics: A Semisupervised and Supervised Learning Problem

The information generated by the anomaly identification model allows a diagnostic module to focus on a given unit's subsystem, analyzing key variables associated with the subsystem, and trying to match their patterns with a library of signatures associated with faults or incipient failure modes. The result is a ranked list of possible faults. Therefore diagnostics is a classification problem, mapping a feature space into a labeled fault space.

Usually, data-driven diagnostics leverages supervised learning techniques to extract potential signatures from the historical data and use them to recognize different failure modes automatically. A large variety of statistical and AI-based techniques can be used for automatic fault diagnostics, including neural networks, decision tree, random forest, Bayesian belief network, case-based reasoning, hidden Markov model, support vector machine, fuzzy logic etc. Those data-driven diagnostics methods are able to learn the faulty signatures or patterns from the training data and associate them with different failure modes when new data arrives.

Data-driven approaches have many benefits. First, they can be designed to be independent of domain knowledge related to a particular system. We could use this approach with data recorded for almost any component/system, as long as the recorded data is relevant to the health condition of the interested component. This reduces the effort involved with eliciting and incorporating domain specific knowledge. A second benefit is the use of fusion techniques to take advantage of diverse information from multiple data sources/models to boost diagnostics performance. The third benefit is the robustness to noise exhibited by most of data-driven methods, such as fuzzy logic and neural networks. However, all data-driven techniques require the availability of labeled historical data so these data collection step must precede the application of these methods.

Domain knowledge, when available, can still be leveraged to initialize the structures of the data-driven models (feature selection, network topology, etc.) and provide better initial conditions for optimization and tuning techniques applied to the data-driven diagnostics models.

Supervised learning is a very mature topic in ML. As a result, there are many diagnostics applications of CI techniques to medical [41.42–45] industrial [41.46, 47] automotive [41.48], and other domains. Given its

widespread use, we will not provide additional case studies for diagnostics.

### 41.3.3 Health Assessment – Prognostics: A Regression Problem

Prognostics is the prediction of *remaining useful life* (RUL), when the anomaly detection and diagnostics modules can identify and isolate an incipient failure through its preceding faults. This incipient failure changes the graph of RUL versus time from a linear, normal-wear trajectory to an exponentially decaying one. The fault time and incipient failure mode determine the inflection point in such curve and the deterioration steepness, respectively. These estimates are usually in units of time or utilization cycles, and have an associated uncertainty, e.g., a probability density curve around the actual estimate. Typically, this uncertainty (e.g., RUL confidence interval) increases as the prediction horizon is extended. Operators can choose a confidence level that allows them to incorporate a risk level into their decision making. They can change operational characteristics, such as load, which may prolong the life of components at risk. They can also account for upcoming maintenance and set in motion a logistics process to support a smooth transition from faulted equipment to fully functioning.

Predicting RUL is not trivial, because RUL depends on current deterioration state and future usage, such as unit load and speed, among others. Prognostics is closely linked with diagnostics. In the absence of any evidence of damage or faulted condition, prognostics reverts to statistical estimation of fleet-wide life. It is common to employ prognostics in the presence of an indication of abnormal wear, faults, or other abnormal situation. Therefore, it is critical to provide accurate and quick diagnostics to allow prognostics to operate. At the heart of prognostics is the ability to properly model the accumulation and propagation of damage. A common approach to prognostics is to employ a model of damage propagation contingent on future use. Such models are often times based on detailed materials knowledge and makes use of finite element modeling. This requires an in depth understanding of the local conditions the particular component is exposed to.

For example, for spall propagation in bearings, we need to know the local load, speed, and temperature conditions at the site of the damage, e.g., at the outer race (or ball or cage). In addition, we need to know the geometry and local material properties at the suspected damage site. This information is used to derive

the stresses that components are expected to experience, typically using a finite element approach. The potential benefit of this process is the promise of accurate prediction of when the bearing will fail. For a different fault mode, the process needs to be repeated. Because of the cost and effort involved, this method is reserved for a set of components that, if left undetected and without remaining life information, might experience catastrophic failure that transcends the entire system and causes system failure. However, there is a large set of components that will not benefit from this approach, either because a physics-based damage model is not achievable or is too costly to develop. Therefore, it is desirable to increase coverage of prognostics for a range of fault modes. To this end, the techniques would ideally utilize existing models and sensor data.

**ML** provides us with an alternative approach, which is based on analyzing time series data where the equipment behavior has been monitored via sensor measurements during the normal operation until equipment failure. When a reasonable set of these observations exists, **ML** algorithms can be employed to recognize these trends and predict remaining life (albeit, often times under the assumption of near-constant future load conditions.) Usually, specific faults have preferred directions in the health related feature space. By extrapolating the propagation in this parameter space and by mapping the extrapolation into the time domain, we can derive **RUL** information.

A prerequisite to leverage **RUL** estimation is to have a narrow confidence interval, so that this information is *actionable* and can be used in the asset health management part of **PHM** as a time horizon to optimize the logistics/maintenance scheduling plan. In most cases, however, we do not have run-to-failure data in the time series. Usually, when a failure is identified it is corrected promptly, causing the time series to be statistically censored on the right. The lack of run-to-failure data further compounds the technical difficulty of predicting **RUL** with a small variance.

We consider two options to address this problem. The first option is to use of an ensemble of *diverse* predictive models (Sect. 41.5.3 for a definition of diversity) such that the fusion of the ensemble will reduce the variance and make the output more actionable – Sect. 41.5 is devoted to this topic. The second option is to relax the problem formulation, by increasing the granularity of the models output. This granularity is determined by the actions that we will perform with such information. For example, we could formulate prognostics as:

- (1) A *partial ordering* over **RUL**. This formulation could be used to estimate the risk of claims in term life policies. Insurance underwriters estimate the applicants' expected mortality at a coarse level by classifying each applicant into a given rate-class from a set of sorted classes that define decreasing **RUL**. Applicants inside each class are indistinguishable in terms of risk and are charged the same premium (gender and age being equal). This will be further described in the case study of Sect. 41.4.1. In a **PHM** context, this formulation could be used to price the contractual service agreement renewals for different units within a fleet, in a fashion similar to the risk-based pricing of insurance underwriting.
- (2) An *ordinal ordering* over **RUL** (ranking). This formulation could be used to select the most reliable units of a fleet for mission-critical assignments. This will be further described in the case study of Sect. 41.3.3, where we illustrate how a train dispatcher could select the best locomotives to create a *hot train*, e.g., a freight train with a guaranteed arrival time.
- (3) A *cardinal ordering* over **RUL** (rating). This formulation could be used to understand the relative level of readiness of units in a fleet, to prioritize the need for instruments calibration, power management assessment/verification, etc.
- (4) A *binary classification* of whether a given event (causing the end of **RUL**) will happen within a given time window. This formulation could be used to generate a time-dependent risk assessment to optimize fleet scheduling and unit allocation.
- (5) A *regression* on **RUL**, including the confidence interval of the prediction. This formulation provides the finest granularity. If we were able to reduce the confidence intervals of these predictions, we could refine and optimize the condition-based maintenance of the assets in the fleet.

The following case study will illustrate the second problem reformulation (ranking). In this case, genetic algorithms are used to evolve fuzzy instance-based models that will generate a ranking of the most reliable locomotives within a fleet.

### Case Study 2: **RUL**-Driven Ranking of Locomotives in a Fleet

**Problem Definition.** The problem of selecting the best units from a fleet of equipment occurs in many military and commercial applications. Given a specific mission profile, a commander may have to decide which

five armored vehicles to deploy in order to minimize the chance of a breakdown. In the commercial world, rail operators need to make decisions on which locomotives to use in a train traveling from coast to coast with time sensitive shipments.

The behavior of these complex electromechanical assets varies considerably across different phases of their life cycle. Assets that are identical at the time of manufacture will evolve into somewhat individual systems with unique characteristics based on their usage and maintenance history. Utilizing these assets efficiently requires a) being able to create a model characterizing their expected performance, and b) keeping this model updated as the behavior of the underlying asset changes.

In this problem formulation, **RUL** prediction for each individual unit is computed by aggregating its own track record with that of a number of *peer* units – units with similarities along three key dimensions: *system design, patterns of utilization, and maintenance history*. The notion of a *peer* is close to that of a neighbor in **CBR**, except the states of the peers are constantly changing. Odometer-type variables like mileage and age increase, and discrete events like major maintenance or upgrades occur. Thus, it is reasonable to assume that after every significant mission, the peers of a target unit may change based upon changes in both the unit itself, and the fleet at large. Our results suggest that estimating unit performance from peers is a practical, robust, and promising approach. We conducted two experiments – one for *retrospective* estimation and one for *prospective* estimation. In the first experiment, we explored how well the median **RUL** of any unit could be estimated from the medians of its peers. In the second experiment, for a given instant in time, we predicted the time to the next failure for each unit using the history of the peers. In these experiments, the retrospective (or prospective) **RUL** estimates were used to induce a ranking over the units. The selection of the best  $N$  units was based on this ranking. The precision of the selection was the percentage of the correctly selected units among the  $N$  units (based on ground truth).

**CI-Based Approach.** Our approach was based on fuzzy instance-based model (**FIM**), which can be found in [41.11]. We addressed the definition of similarity among peers by evolving the design of a similarity function in conjunction with the design of the attribute space in which the similarity was evaluated. Specifically, we used the following four steps:

- (1) *Retrieval* of similar instances from the database (**DB**).
- (2) *Evaluation of similarity measures* between the probe and the retrieved instances.
- (3) *Creation of local models* based on the most similar instances.
- (4) *Aggregation of local models outputs* (weighted by their similarity measures).

**(1) Retrieval.** We looked for all units in the fleet **DB** whose behavior was similar to the probe. These instances are the potential peers of the probe. The peers and probe can be seen as points in an  $n$ -dimensional feature space. For instance, let us assume that a probe  $Q$  is characterized by an  $n$ -dimensional vector of feature  $\bar{X}_Q$ , and  $O(Q) = [D_{1,Q}, D_{2,Q}, \dots, D_{k(Q),Q}]$  the history of its operational availability durations

$$\begin{aligned} Q &= [\bar{X}_Q; O(Q)] \\ &= [x_{1,Q}, \dots, x_{n,Q}; D_{1,Q}, \dots, D_{k(Q),Q}] . \end{aligned} \quad (41.1)$$

Any other unit  $u_i$  in the fleet has a similar characterization

$$\begin{aligned} u_i &= [\bar{X}_j; O(u_j)] \\ &= [x_{1,j}, x_{2,j}, \dots, x_{n,j}; D_{1,j}, D_{2,j}, \dots, D_{k(j),j}] . \end{aligned} \quad (41.2)$$

For each dimension  $i$  we defined a *truncated generalized Bell function*,  $TGBF_i(x_i; a_i, b_i, c_i)$ , centered at the value of the probe  $c_i$ , which represents the degree of similarity along that dimension. Specifically

$$TGBF_i(x_i; a_i, b_i, c_i) = \begin{cases} \left[ 1 + \left| \frac{x_i - c_i}{a_i} \right|^{2b_i} \right]^{-1} & \text{if } \left[ 1 + \left| \frac{x_i - c_i}{a_i} \right|^{2b_i} \right]^{-1} > \varepsilon \\ 0 & \text{otherwise} \end{cases} , \quad (41.3)$$

where  $\varepsilon$  is the truncation parameter, e.g.,  $\varepsilon = 10^{-5}$ .

Since the parameters  $c_i$  in each  $TGBF_i$  are determined by the values of the probe, each  $TGBF_i$  has only two free parameters  $a_i$  and  $b_i$  to control its spread and curvature. In a coarse retrieval step, we extracted an instance in the **DB** if all of its features are

within the *support* of the TGBF's. Then we formalized the retrieval step,  $P(Q)$ , the set of potential peers of  $Q$ , is composed of all units within a range from the value of  $Q : P(Q) = \{u_j, j = 1, \dots, m \mid u_j \in N(\bar{X}_Q)\}$  where  $N(\bar{X}_Q)$  is the neighborhood of  $Q$  in the state space  $\bar{X}$ , defined by the constraint  $\|x_{i,Q} - x_{i,j}\| < R_i$  for all potential attributes  $i$  for which the corresponding weight is nonzero.  $R_i$  is half of the support of the TGBF $_i$ , centered on the probe's coordinate  $x_{i,Q}$ .

**(2) Similarity Evaluation.** Each TGBF $_i$  is a membership function representing the partial degree of satisfaction of constraint  $A_i(x_i)$ . Thus, it represents the *closeness* of the instance around the probe value for that particular attribute. For a given peer  $P_j$ , we evaluated the function  $S_{i,j} = \text{TGBF}_i(x_{i,j}; a_i, b_i, x_{i,Q})$  along each potential attribute  $i$ . The values  $(a_i, b_i)$  are design choices manually initialized, and later refined by the **EAs**. Since we wanted the most similar instances to be the closest to the probe along *all n* attributes, we used a similarity measure defined as the intersection of the constraint-satisfaction values. Furthermore, to represent the different relevance that each criterion should have in the evaluation of similarity, we attached a weight  $w_i$  to each attribute  $A_i$ . Therefore, we extended the notion of a similarity measure between  $P_j$  and the probe  $Q$  as a weighted minimum operator

$$\begin{aligned} S_j &= \min_{i=1}^n \{\max[(1-w_i), S_{i,j}]\} \\ &= \min_{i=1}^n \{\max[(1-w_i), \text{TGBF}_i(x_{i,j}; a_i, b_i, x_{i,Q})]\}, \end{aligned} \quad (41.4)$$

where  $w_i \in [0, 1]$ . The set of values for the weights  $\{w_i\}$  and parameters  $\{(a_i, b_i)\}$  are critical design choices that impact the proper selection of peers.

**(3) Local Models.** The idea of creating a local model on demand can be traced back to memory-based approaches [41.28, 29] and lazy learning [41.49]. Within this case study, we focused on the creation of local predictive models used to forecast each unit's remaining life. First, we used each local model to generate an estimated value of the predicted variable. Then, we used an aggregation mechanism based on the similarities of the peers to determine the final output.

The generation of local models can vary in complexity, depending on the task difficulty. In the first experiment, we used the *Median* operator as the local model, hence we did not need to define any parameter

$$y_j = \text{Median}[D_{1,j}, D_{2,j}, \dots, D_{k(j),j}]. \quad (41.5)$$

In the second experiment we used an exponential average, requiring the definition of a forgetting factor  $\alpha$

$$\begin{aligned} y_j &= D_{k(j)+1,j} = \bar{D}_{k(j),j} = \alpha \times D_{k(j),j} \\ &\quad + (1-\alpha) \times \bar{D}_{k(j)-1,j} \quad [\text{where } \bar{D}_{i,j} = D_{1,j}]. \end{aligned} \quad (41.6)$$

**(4) Aggregation.** We needed to combine the individual outputs  $y_j$  of the peers  $P_i(Q)$  to generate the estimated output  $y_Q$  for the probe  $Q$ . median (for experiment I) or the prediction of the *next* availability duration,  $D_{\text{Next}, Q}$  (for experiment II) for the probe  $Q$ . To this end, we computed the weighted average of the peers' individual outputs using their normalized similarity to the probe as a weight, namely

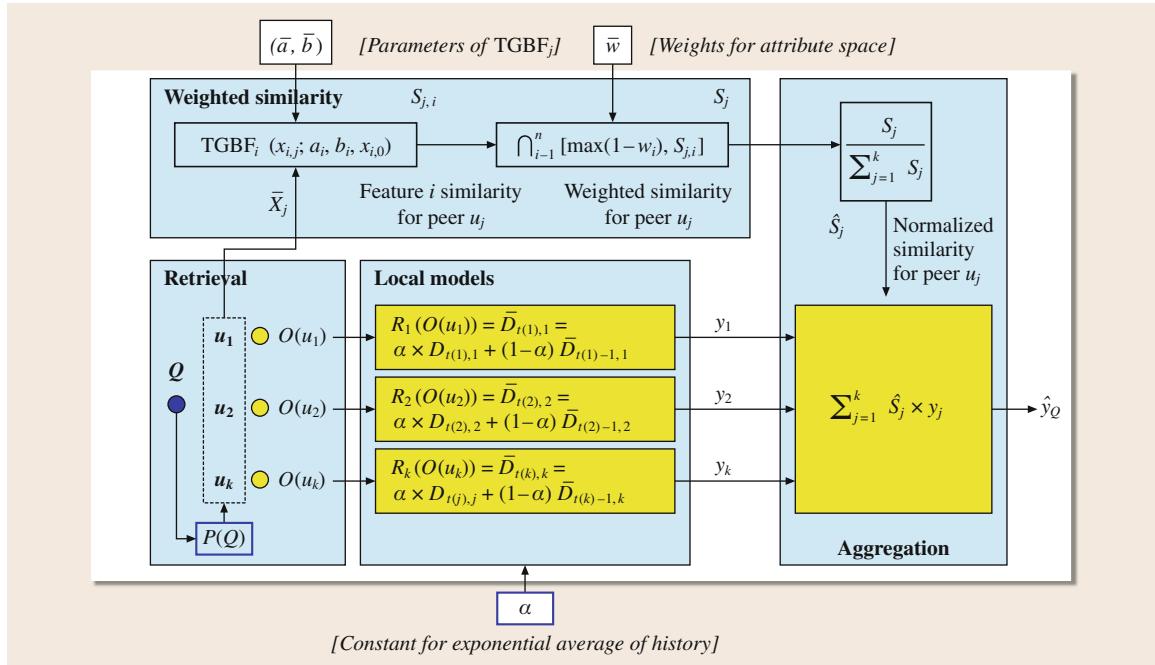

$$\begin{aligned} y_Q &= \text{Median}_Q = \frac{\sum_{j=1}^m S_j \times y_j}{\sum_{j=1}^m S_j} \\ &\quad \text{where } y_j = \text{Median}[D_{1,j}, D_{2,j}, \dots, D_{k(j),j}] \\ &\quad \text{for Exp. I} \\ y_Q &= D_{\text{Next}, Q} = \frac{\sum_{j=1}^m S_j \times y_j}{\sum_{j=1}^m S_j} \\ &\quad \text{where } y_j = D_{k(j)+1,j} \quad \text{for Exp. II}. \end{aligned} \quad (41.7)$$

The entire process is summarized in Fig. 41.4, adapted from [41.11].

### Structural and Parametric Tuning

Given the critical design roles of the weights  $\{w_i\}$ , the parameters  $\{(a_i, b_i)\}$ , and the forgetting factor  $\alpha$ , it was necessary to create a methodology to generate their best values according to our metric, i. e., classification precision. After testing several manually created peer-based models, we decided to use evolutionary search to develop and maintain the fuzzy instance-based classifier, following a wrapper methodology detailed in [41.13]. In this application, however, we extended evolutionary to include structural search, via attribute selection and weighting [41.50], besides the parametric tuning.

The **EAs** were composed of a population of individuals, each of which containing a vector of elements that represented distinct tunable parameters within the **FIM** configuration. Examples of tunable parameters included the range of each parameter used to retrieve neighbor instances and the relative parameter weights used for similarity calculation. The **EAs** used two types of mutation operators (Gaussian and uniform), and no crossover. Its population (with 100 individuals) was evolved over 200 generations.

**Fig. 41.4** Description of Fuzzy instance-based models (FIM) aggregated by convex sum

Each chromosome defined an instance of the attribute space used by the associated classifier by specifying a vector of weights  $[w_1, w_2, \dots, w_n]$ . If  $w_i \in \{0, 1\}$ , we perform *attribute selection*, i.e., we select a crisp subset from the universe of potential attributes. If  $w_i \in [0, 1]$ , we perform *attribute weighting*, i.e., we define a fuzzy subset from the universe of potential attributes

$$[w_1, w_2, \dots, w_n][(a_1, b_1), (a_2, b_2), \dots, (a_n, b_n)][\alpha], \quad (41.8)$$

where

- $w_i \in [0, 1]$  for attribute weighting and
- $w_i \in \{0, 1\}$  for attribute selection
- $n = \text{Cardinality of universe of } U, |U| = n$
- $d = \sum_i^n w_i$  (fuzzy) cardinality of selected features
- $(a_i, b_i) = \text{Parameters for GBF}_i$
- $\alpha = \text{Parameter for exponential average}$ .

The first part of the chromosome, containing the weights vector  $[w_1, w_2, \dots, w_n]$ , defines the attribute space (the FIM structure) and the relevance of each attribute in evaluating similarity. The second part of the chromosome, containing the vector of pairs  $[(a_1, b_1), \dots, (a_i, b_i), \dots, (a_n, b_n)]$  defines the parameter

for retrieval and similarity evaluation. The last part of the chromosome, containing the parameter  $\alpha$ , defines the forgetting factor for the local models. The fitness function is computed using a *wrapper* approach [41.50]. For each chromosome, represented by (41.8) we instantiated its corresponding FIM. Following a *leave-one-out* approach, we used FIM to predict the expected life of the probe unit following the four steps described in the previous subsection. We repeated this process for all units in the fleet and ranked them in decreasing order, using their predicted duration  $D_{\text{Next}, Q}$ . We then selected the top 20%. The fitness function of the chromosome was the precision of the classification,  $\text{TP}/(\text{TP} + \text{FP})$ , where TP is the count of *True Positives* and FP is the count of *False Positives*. This is illustrated in Fig. 41.5.

**Results.** We used 18 months worth of data and performed the experiments at three different times, after 6, 12, and 18 months, respectively. We wanted to test the adaptability of the learning techniques to environmental, operational, or maintenance changes. We also wanted to determine if their performance would improve over time with incremental data acquisition. For each start-up time, we used EA to generate an opti-

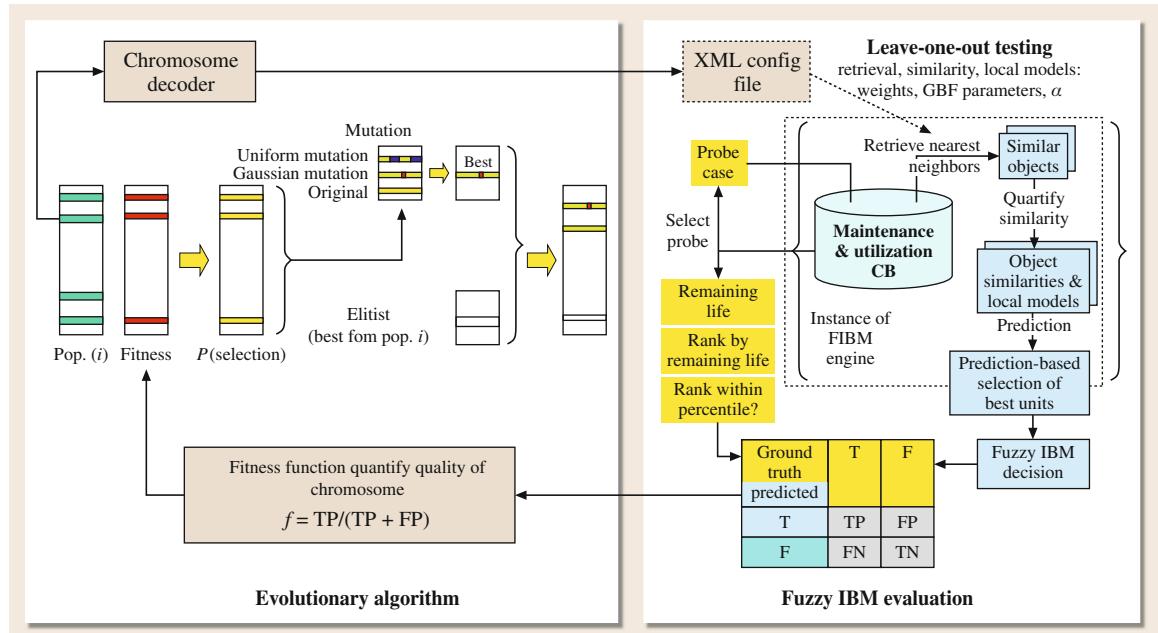

Fig. 41.5 FRC optimization using EA

mized weighted subset of attributes to define the *peers* of each unit.

**Experiment 1: Retrospective Selection.** The goal was to select the current best 20% units of the fleet based on their peers past performance. In this case, a random selection, which could be used as a baseline, would yield 20%. However, the size of the fleet at each start-up time was different, ranging from 262 (after 6 months) to 634 (after 12 months), to 845 (after 18 months.) We decided to keep the number of selected units constant (i.e.,

52 units) over the three start-up times. Thus the baseline random selection for each start-up time was [20%–8%–6%], i.e.,  $52/262 = 20\%$ ;  $52/634 = 8\%$ ;  $52/845 = 6\%$ .

**Experiment 2: Prospective Selection.** We wanted to select the future best 20% units for the next-pulse duration. In this case, a random selection would yield 20%.

The peers designed by the EA provided the best accuracy overall:

- Experiment 1 (*Retrospective selection*): Precision = 63.5%, which was more than 10× better than random selection, and 1.7× better than existing heuristics.
- Experiment 2 (*Prospective selection*): Precision = 55.0%, which was more than 2.5× better than random selection, and 1.5× better than existing heuristics.

Figures 41.6 and 41.7 illustrate the results of these two experiments.

As mentioned in Sect. 41.1.2, successfully deployed intelligent systems must remain valid and accurate over time, while compensating for drifts and accounting for contextual changes that might otherwise render their design stale or obsolete. In this case study, we repeated the last set of experiments using dynamic and static

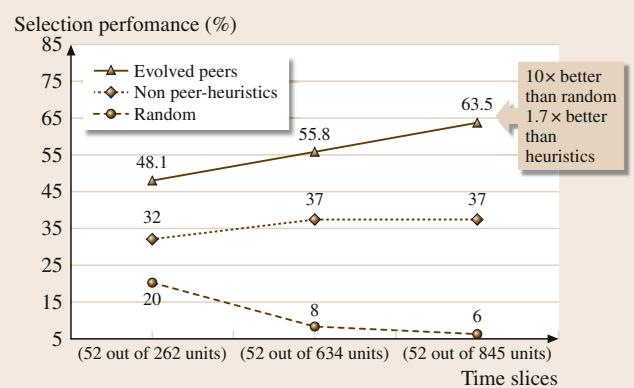

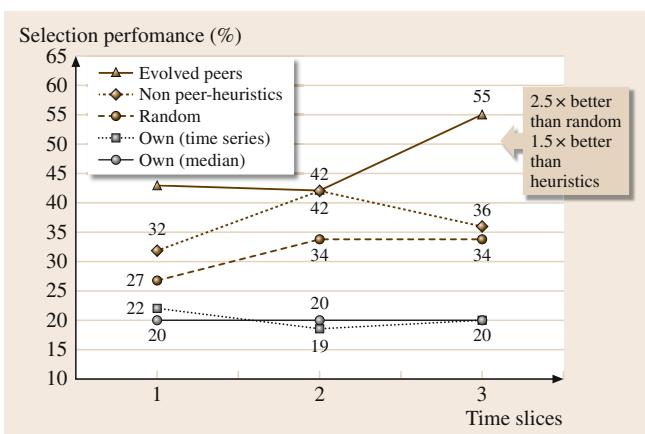

Fig. 41.6 Dynamic models first experiment

models. The dynamic models were *fresh* models, redeveloped at each time slice by using the methodology described. The static models were developed at time slice 1 and applied, unchanged, at time slices 2 and 3. In this experiment, the original models showed significant deterioration over time: 43% → 29% → 25%. In contrast, the dynamic models exhibited robust, improved precision: 43% → 43% → 55%. This is illustrated in Fig. 41.8.

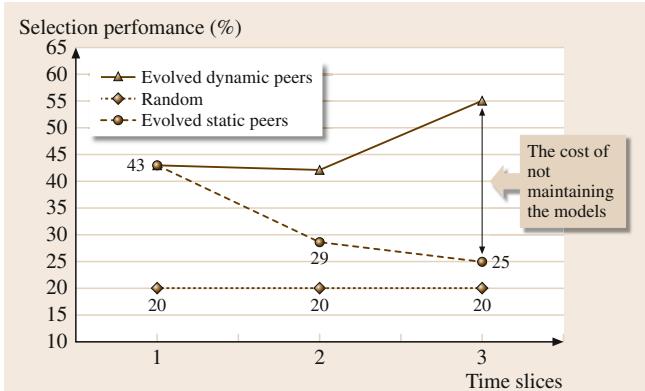

This comparison shows the benefit of automated model updating. By using an offline metaheuristics such as **EAs**, we can automate model development and model re-tuning. This allows us to maintain model performance over time, through frequent updates, and avoid the obsolescence-driven model deterioration, which in this example occurred 1 year after the first deployment. A more detailed description of this case study can be found in [41.11, 12].

#### 41.3.4 Health Management – Fault Accommodation and Optimization

All the functions described in Sects. 41.3.1–41.3.3 could be described as *descriptive* and *predictive* analytics, as they provide assessments and projections of the system's health state. These assessments lead to *prescriptive* analytics, as they determine the on-board control action and an off-board logistics, repair and planning actions. On-board control actions are usually focused on maintaining performance or safety margins, and are performed in real-time. Off-board maintenance/repair actions cover more offline decisions. They require a decision support system (**DSS**) performing multiobjective optimizations, exploring Pareto frontiers of corrective actions, and combining them with preference aggregations to generate the best decision tradeoffs. The underline techniques are intelligent control for fault accommodation [41.18] and multiobjective optimization

**Fig. 41.7** Dynamic models second experiment

**Fig. 41.8** Dynamic models versus static models in second experiment

techniques [41.51–54], aimed at minimizing the impact that maintenance and repairs event could cause to the profitable operation of the assets. For the sake of brevity, we will not provide a case study of optimization in the **PHM** domain, but we will present one in the financial domain (Sect. 41.4.3).

## 41.4 CI/ML Applications in Financial Domains: Risk Management

Prognostics and health management of industrial assets bears a strong analogy with risk management of financial and commercial assets. We have shown how *unsupervised learning* can be used to identify abnormal behaviors, i. e., deviations from normal states/structures. In **PHM**, units in a fleet that stray away from normal performance baselines are usually anomalies lead-

ing to incipient failure modes. In financial domains, nonconforming user behaviors could be precursors to fraudulent transactions and could be identified using similar techniques. Similarly, *supervised learning* could be used to classify the root cause of an anomaly (diagnostics) or to classify the risk class of an applicant for a financial/insurance product (risk classification). Re-

gressions could be used to forecast the remaining useful life of an asset under future load assumptions, or to forecast the residual value of assets after their lease period (or to create an instant valuation for an asset, such as in mortgage collateral valuation). *Multiobjective* optimization techniques could be used to balance production values with life erosion cost (or combustion efficiency with emissions) or to balance an investment portfolio using multiple metrics of returns and risk. We will illustrate this analogy with the following three case studies, in which we will describe the use of **CI** techniques in risk classification for insurance underwriting, residential property valuation, and portfolio rebalancing optimization.

#### 41.4.1 Automation of Insurance Underwriting: A Classification Problem

##### Problem Definition

In many transaction-oriented processes, human decision makers evaluate new applications for a given service (mortgages, loans, credits, insurances, etc.) and assess their associated risk and price. The automation of these business processes is likely to increase throughput and reliability while reducing risk. The success of these ventures depends on the availability of generalized decision-making systems that are not just able to reliably replicate the human decision-making process, but can do so in an explainable, transparent fashion. Insurance underwriting is one such high-volume application domain where intelligent automation can be highly beneficial, and reliability and transparency of decision-making are critical. Traditionally, highly trained individuals perform insurance underwriting. A given insurance application is compared against several standards put forward by the insurance company and classified into one of the risk categories (rate classes) available for the type of insurance requested. The risk categories then affect the premium paid by the applicant – the higher the risk category, the higher the premium. The *accept/reject* decision is also part of this risk classification, since risks above a certain tolerance level set by the company will simply be rejected.

There can be a large amount of variability in the underwriting process when performed by human underwriters. Typically the underwriting standards cannot cover all possible cases, and sometimes they might be ambiguous. The subjective judgment of the underwriter will almost always play a role in the process. Variation

in factors such as underwriter training and experience, and a multitude of other effects can cause different underwriters to issue inconsistent decisions. Sometimes these decisions fall in a *gray area* not explicitly covered by the standards. In these cases, the underwriter uses his/her own experience to determine whether the standards should be adjusted. Different underwriters could apply different assumption regarding the applicability of the adjustments, as they might use stricter or more liberal interpretations of the standards.

##### CI-Based Approach

To address these problems, we developed a system to automate the application placement process for cases of low or medium complexity. For more complex cases, the system provided the underwriter with an *assist* based on partial analysis and conclusions.

We used a fuzzy-rule-based classifier (**FRC**) to capture the underwriting standards derived from the actuarial guidance. Then we tuned the **FRC** with an evolutionarily algorithms to determine the best **FRC** parameters to maximize precision and recall, while minimizing the cost of misclassification. The remaining of this section will summarize this solution.

**Fuzzy Rule-Based Classifier (**FRC**)**. The fuzzy-rule based classifier (**FRC**), which is briefly described in [41.13, 14], uses rule sets to encode underwriting standards. Each rule set represents a set of fuzzy constraints defining the boundaries between rate classes. These constraints were first determined from the underwriting guidelines. They were then refined using knowledge engineering sessions with expert underwriters to identify factors such as blood pressure levels and cholesterol levels, which are critical in defining the applicant's risk and corresponding premium. The goal of the classifier is to assign an applicant to the most competitive rate class, providing that the applicant's vital data meet all of the constraints of that particular rate class to a minimum degree of satisfaction. The constraints for each rate class  $r$  are represented by  $n$  fuzzy sets:  $A_i^r(x_i)$ ,  $i = 1, \dots, n$ . Each constraint  $A_i^r(x_i)$  can be interpreted as the *degree of preference* induced by value  $x_i$  for satisfying constraint  $A_i^r(x_i)$ . After evaluating all constraints, we compute two measures for each rate class  $r$ . The first one is the degree of intersection of all the constraints and measures the *weakest constraint satisfaction*

$$I(r) = \bigcap_{i=1}^n A_i^r(x_i) = \min_{i=1}^r A_i^r(x_i). \quad (41.9)$$

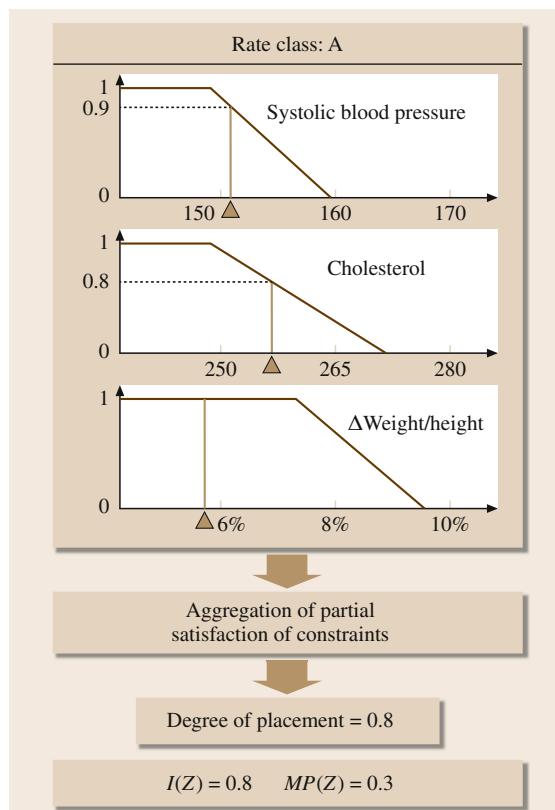

This expression implies that each criterion has equal weight. If we want to attach a weight  $w_i$  to each criterion  $A_i$  we could use the weighted minimum operator:

$$\begin{aligned} I'(r) &= \bigcap_{i=1}^n W_i A_i^r(x_i) \\ &= \min_{i=1}^n (\max((1 - w_i), A_i^r(x_i))), \end{aligned}$$

where  $w_i \in [0, 1]$ . The second one is a cumulative measure of missing points (the complement of the average satisfaction of all constraints), and measures the *overall tolerance* allowed to each applicant, i. e.,

$$\begin{aligned} MP(r) &= \sum_{i=1}^n (1 - A_i^r(x_i)) = n \left( 1 - 1/n \sum_{i=1}^n A_i^r(x_i) \right) \\ &= n(1 - \bar{A}^r). \end{aligned} \quad (41.10)$$

The final classification is obtained by comparing the two measures,  $I(r)$  and  $MP(r)$  against two lower bounds

**Fig. 41.9** Example of three fuzzy constraints for rate class  $Z$

defined by thresholds  $\tau_1$  and  $\tau_2$ . The parametric definition of each fuzzy constraint  $A_i^r(x_i)$  and the values of  $\tau_1$  and  $\tau_2$  are design parameters that were initialized with knowledge engineering sessions.

Figure 41.9 – adapted from [41.13] – illustrates an example of three constraints (trapezoidal membership functions) associated with rate class  $Z$ , the input data corresponding to an application, and the evaluation of the first measure, indicating the weakest degree of satisfaction of all constraints.

**Optimization of Design Parameters of the FRC Classifier.** The **FRC** design parameters were tuned, monitored, and maintained to assure the classifier's optimal performance. To this end, we used **EAs**, composed of a population of *chromosomes*. Each chromosome contained a vector of elements that represent distinct tunable parameters to configure the **FRC** classifier, i. e., the parametric definition of the fuzzy constraints  $A_i^r(x_i)$  and thresholds  $\tau_1$  and  $\tau_2$ .

A chromosome, the genotypic representation of a model, defines the complete parametric configuration of the classifier. Thus, an instance of such classifier can be created for each chromosome, as shown in Fig. 41.10. Each chromosome  $c_i$ , of population  $P(t)$  (left-hand side of Fig. 41.10), goes through a decoding process to allow them to create the classifier on the right. Each classifier is then tested on all the cases in the case base, assigning a rate class to each case. We can determine the quality of the configuration encoded by the chromosome, i. e., the *fitness* of the chromosome, by analyzing the results of the test. Our **EA** uses two types of mutations (uniform and Gaussian) to produce new individuals in the population by randomly varying parameters of a single chromosome. The more fit chromosomes in generation  $t$  will be more likely to be selected for this and pass their genetic material to the next generation  $t + 1$ . Analogously, the less fit solutions will be culled from the population. At the conclusion of the **EAs** execution the *best* chromosome of the *last* generation determines the classifier's configuration. Note the similarity between Figs. 41.10 and 41.5, which underlies the similar role that **EAs** play as the offline **MHs** to design the best fuzzy classifier (in this case study), or the best **FIM** (in the case of the second case study).

**Standard Reference Dataset (SRD).** To test and tune the classifiers, we needed to establish a benchmark. Therefore, we generated a *standard reference dataset* (**SRD**) of approximately 3000 cases taken from a stratified random sample of the historical case population.

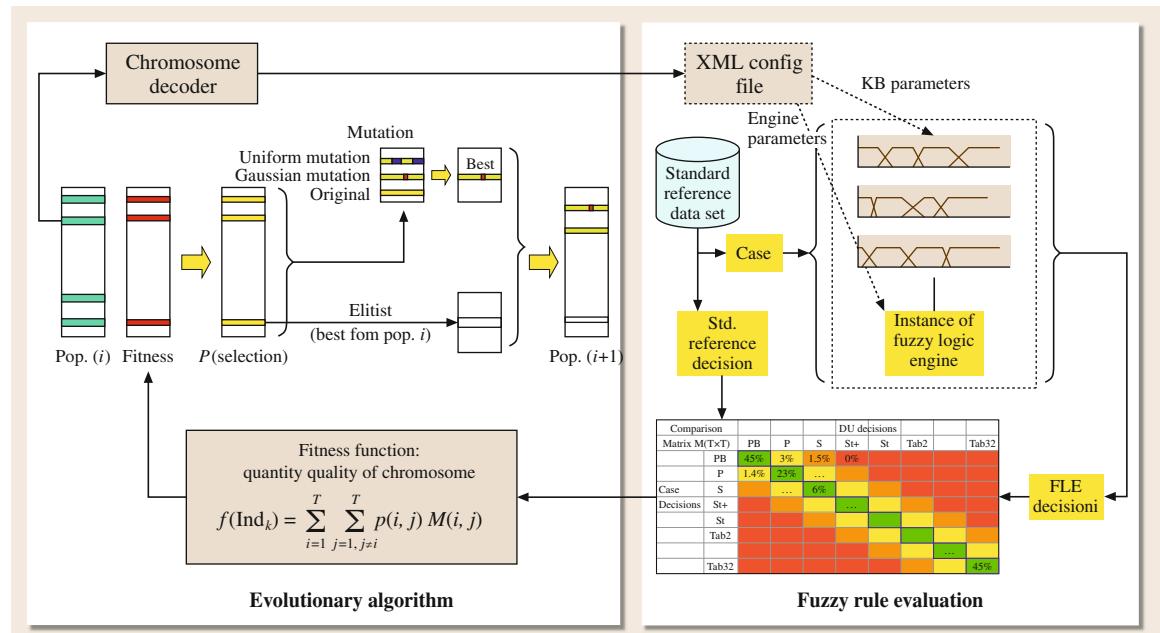

Fig. 41.10 FRC optimization using EA

Each of these cases received a rate class decision when it was originally underwritten. To reduce variability in these decisions, a team of experienced underwriters performed a *blind* review of selected cases to determine the *standard reference* decisions. These cases were then used to create and optimize the **FRC** model.

**Fitness Function.** In classification problems such as this one, we can use two matrices to construct the fitness function that we want to optimize. The first matrix is a  $T \times T$  *confusion matrix*  $M$  that contains frequencies of correct and incorrect classifications for all possible combinations of the standard reference decisions (**SRDs**), which represent ground truth rate class decisions as reached by consensus among senior expert underwriters for a set of insurance applications and classifier decisions. The frequencies of correct classifications can be found on the main diagonal of matrix  $M$ . The first  $(T - 1)$  columns represent the rate classes available to the classifier. Column  $T$  represents the classifier's choice of not assigning any rate class, sending the case to a human underwriter. The same ordering is used to sort the rows for the **SRD**. The second matrix is a  $T \times T$  *penalty matrix*  $P$  that contains the *value loss* due to misclassification. The entries in the *penalty matrix*  $P$  are zero or negative values. They were computed from actuarial data showing the net present value (**NPV**) for

each entry  $(j, k)$ . The penalty value  $P(j, k)$  was the difference between the **NPV** of the entry  $(j, kj)$  and the highest **NPV** – corresponding to the correct entry  $(j, j)$ , located on the main diagonal. The fitness function  $f$  combined the values of  $M$ , resulted from a test run of the classifier configured with chromosome  $c_i$ , with the penalty matrix  $P$  to produce a single value

$$f(c_i) = \sum_{j=1}^T \sum_{k=1}^T M(j, k) * P(j, k). \quad (41.11)$$

Function  $f$  represents the expected value loss for that chromosome computed over the **SRD** and is the fitness function used to drive the evolutionary search.

## Results

**Testing and Validation of FRC.** We defined *Coverage* as the percentage of cases as a fraction of the total number of input cases; *Relative accuracy* as the percentage of correct decisions on those cases that were not referred to the human underwriter; *Global accuracy* as the percentage of correct decisions, including making correct rate class decisions and making a correct decision to refer cases to human underwriters as a fraction of total input cases. Then we performed a comparison against the **SRD**. The results, reported in [41.13], show

**Table 41.2** Typical performance of the un-tuned and tuned rule-based decision system (**FRC**)

| Metrics           | Initial parameters based on written guidelines (%) | Best knowledge engineered parameters | Optimized parameters |
|-------------------|----------------------------------------------------|--------------------------------------|----------------------|
| Coverage          | 94.01                                              | 90.38                                | 91.71                |
| Relative accuracy | 75.92                                              | 92.99                                | 95.52                |
| Global accuracy   | 74.75                                              | 90.07                                | 93.63                |

**Table 41.3** Average **FRC** performance over 5 tuning case sets compared to five disjoint test sets

| Metrics           | Average performance on training sets | Average performance on disjoint test sets |
|-------------------|--------------------------------------|-------------------------------------------|
| Coverage          | 91.81                                | 91.80                                     |
| Relative accuracy | 94.52                                | 93.60                                     |
| Global accuracy   | 92.74                                | 91.60                                     |

a remarkable improvement in all measures. Specifically, we obtained the following results:

Using the initial parameters (first column of Table 41.2) we can observe a large moderate *Coverage* ( $\approx 94\%$ ) associated with a low *relative accuracy* ( $\approx 76\%$ ) and a lower *global accuracy* ( $\approx 75\%$ ). These performance values are the result of applying a strict interpretation of the underwriter (UW) guidelines, without allowing for any tolerance. Had we implemented such crisp rules with a traditional rule-based system, we would have obtained these results. This strictness would prevent the insurer from being price competitive, and would not represent the typical *modus operandi* of human underwriters. However, by allowing each underwriter to use his/her own interpretation of such guidelines, we could introduce large underwriters' variability. One of our main goals was to provide a *uniform* interpretation, while still *allowing for some tolerance*. This goal is addressed in the second column of Table 41.2, which shows the results of performing *knowledge engineering* and encoding the desired tradeoff between risk and price competitiveness as fuzzy constraints with *preference* semantics. This intermediate stage shows a different tradeoff since both *Global* and *relative accuracy* have improved. *Coverage* slightly decreases ( $\approx 90\%$ ) for a considerable gain in *relative accuracy* ( $\approx 93\%$ ). Although we obtained this initial parameter set by interviewing the experts, we had no guarantee that such parameters were optimal. Therefore, we used **EAs** to tune them. We allowed the parameters to move within a predefined range centered on their initial values and, using the **SRD** and the fitness function described above, we obtained an optimized parameter set, whose results are described in the third column of Table 41.2. The results of the optimization show the point corresponding to the final parameter set dominates the second set point (in a Pareto sense), since both *cover-*

*age* and *relative accuracy* were improved. Finally, we can observe that the final metric, *global accuracy* (last row in Table 41.2), improves monotonically as we move from using the strict interpretation of the guidelines ( $\approx 75\%$ ), through the knowledge-engineered parameters ( $\approx 90\%$ ), to the optimized parameters ( $\approx 94\%$ ).

While the reported performance of the optimized parameters, shown in Table 41.2, is typical of the performance achieved through the optimization, a five-fold cross-validation on the optimization was also performed to identify stable parameters in the design space and stable metrics in the performance space. This is shown in Table 41.3.

With this kind of automation, variability of the risk category decision was greatly reduced. This also eliminated a source of risk exposure for the company, allowing it to operate more competitively and profitably. The intelligent automation process, capable of determining its applicability for each new case, increased underwriting capacity by enabling them to handle larger volume of applications. Additional information on this approach can be found in [41.13, 14].

#### 41.4.2 Mortgage Collateral Valuation: A Regression Problem

##### Problem Definition

Residential property valuation is the process of determining a dollar estimate of the property value for given market conditions. Within this case study, we will restrict ourselves to a single-family residence designed or intended for owner occupancy. The value of a property changes with market conditions, so any estimate of its value must be periodically updated to reflect those market changes. Any valuation must also be supported by current evidence of market conditions, e.g., recent real estate transactions.

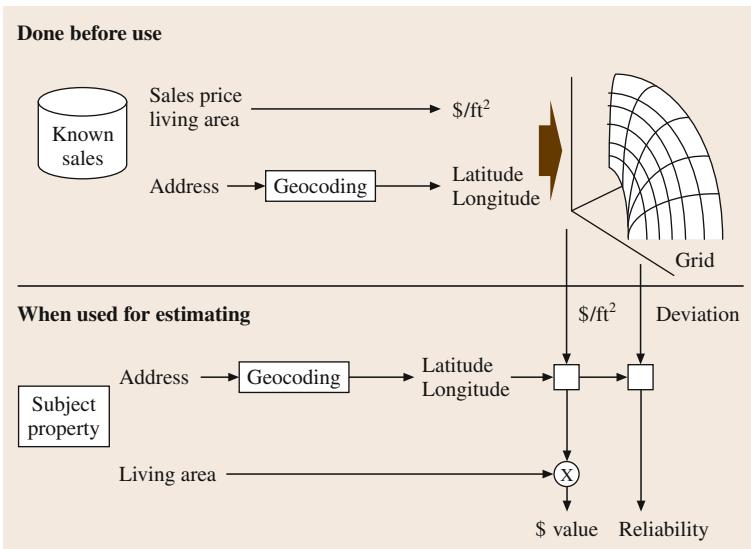

Fig. 41.11 Locational Value method (LOCVAL)

Current manual process for estimating the value of properties usually requires an on-site visit by a human appraiser. This process is slow and expensive for batch applications such as those used by banks for updating their loan and insurance portfolios, verifying risk profiles of servicing rights, or evaluating default risks for securitized packages of mortgages. The appraisal process for these batch applications is currently estimated, to a lesser degree of accuracy, by sampling techniques. Secondary buyers and mortgage insurers may also require verification of property value on individual transactions. Some of the applications also require that the output be qualified by a reliability measure and some justification, so that questionable data and unusual circumstances can be flagged for the human who uses the output of the system. Thus, the automation of residential property was motivated by a broad spectrum of application areas.

The most common and credible method used by appraisers is the *sales comparables* approach. This method consists of finding comparable cases, i.e., recent sales that are comparable to the subject property (using sales records); contrasting the subject property with the comparables; adjusting the comparables' sales price to reflect their differences from the subject property (using heuristics and personal experience); and reconciling the comparables adjusted sales prices to derive an estimate for the subject property (using any reasonable averaging method). This process assumes that the item's market value can be derived by the prices demanded by similar items in the same market.

#### CI-Based Approach: LOCVAL, AIGEN, AICOMP, Fusion

To automate the valuation process, we developed a program that combined the result of three independent estimators. The first one, locational value (LOCVAL), was a coarse estimator based on the locational value of the property. The second one, generative AI model (AIGEN), was a generative estimator based on neuro-fuzzy networks that only used five features from our training set. The third one, comparable based AI model (AICOMP), was a fuzzy case-based reasoned that followed the comparable-based approach of the appraisers. Finally, we fused the output of the estimators into a single estimate and reliability value.

**Locational value model (LOCVAL).** The first model was based solely on two features of the property: its location, expressed by a valid, geocoded address, and its living area, as shown in Fig. 41.11 (adapted from [41.15].)

A dollar per square foot measure was constructed for each point in the county, by suitably averaging the observed, filtered historical market values in the vicinity of that point. This locational value estimator (LOCVAL) produced two output values: *Locational\_Value* (a \$/ft<sup>2</sup> estimate) and *Deviation\_from\_prevailing\_value*. The local averaging was done by an exponentially decreasing radial basis function with a *space constant* of 0.15–0.2 miles. It could be described as the weighted sum of radial basis functions (all of the same width), each situated at the site of a sale within the past 1-year

and having amplitude equal to the sales price. Deviation from prevailing value was the standard deviation for houses within the area covered and was derived using a similar approach. The output of **LOCVAL** was a coarse estimate of the property value, which was used as an input for the generative approach (**AIGEN**).

**AIGEN: Fuzzy-Neural Network.** The generative AI model (**AIGEN**) relied on a fuzzy-neural net that, after a training phase, provided an estimate of the subject's value. The specific model was an extension of ANFIS [41.55], which implemented a fuzzy system as a five-layer neural network so that the structure of the net could be interpreted in terms of high-level rules. The extension developed allowed the output to be linear functions of variables that did not necessarily occur in the input. In this fashion, we achieved more fidelity with the local models (linear functions) without incurring in the computational complexity caused by a large number of inputs. **AIGEN** inputs were five property features (*total\_rooms*, *num\_bedrooms*, *num\_baths*, *living\_area*, and *lot\_size*) and the output of **LOCVAL** (*locational\_value*).

**AICOMP: Fuzzy Case-Based Reasoner (CBR).** **AICOMP** is a fuzzy CBR system that used fuzzy predicates and fuzzy-logic-based similarity measures to estimate the value of residential property. This process consisted of selecting relevant cases (which would be nearby house sales), adapting them, and aggregating those adapted cases into a single estimate of the property value. **AICOMP** followed a process similar to the sales comparison used by certified appraisers to estimate a residential property's value. This approach, which is further described in [41.56], consisted of:

- (1) *Retrieving recent sales from a case base.* Upon entering the subject property attributes, **AICOMP** retrieves potentially similar comparables from the case-base. This initial selection uses six attributes: address, date of sale, living area, lot area, number of bathrooms, and bedrooms.
- (2) *Comparing the subject property with the retrieved cases.* The comparables are rated and ranked on a similarity scale to identify the most similar ones to the subject property. This rating is obtained from a weighted aggregation of the decision maker preferences, expressed as fuzzy membership distributions and relations.
- (3) *Adjusting the sales price of the retrieved cases.* Each property's sales price is adjusted to reflect

their differences from the subject property. These adjustments are performed by a rule set that uses additional property attributes, such as construction quality, conditions, pools, fireplaces, etc.

- (4) *Aggregating the adjusted sales prices of the retrieved cases.* The best four to eight comparables are selected. The adjusted sales price and similarity of the selected properties are combined to produce an estimate of the subject value with an associated reliability value.

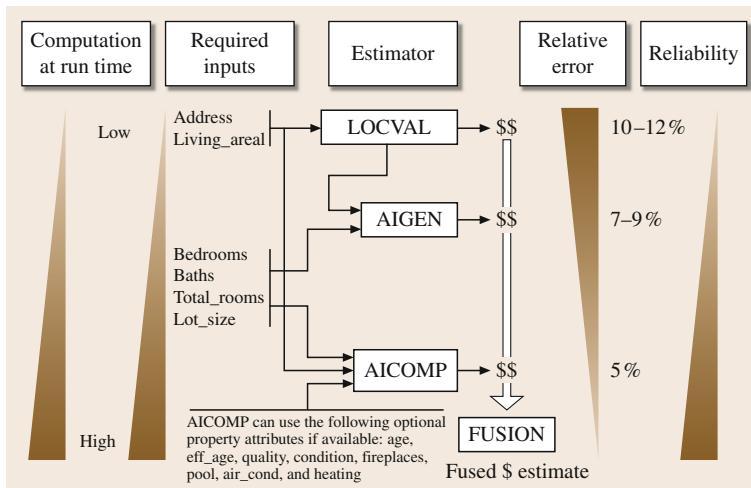

**Fusion.** Each model produced a property value and an associated reliability value. The latter was a function of the *typicality* of the subject property based on its physical characteristics (such as lot size, living area, and total room). These typical values were represented by possibilistic distributions (fuzzy sets). We computed the degree to which each property satisfied each criterion. The overall property value reliability was obtained by considering the conjunction of these constraint satisfactions (i.e., the minimum of the individual reliability values).

The computation times, required inputs, errors, and reliability values for these three methods are shown in Fig. 41.12. The locational value (**LOCVAL**) model took the least time and information, but produced the largest error. The **CBR** approach (**AICOMP**) took the largest time and number of inputs, but produced the lowest error.

The fusion of the three estimators exhibited several advantages:

- The fusion process provided an indication of the reliability in the final estimate:
  - If reliability was high, the fused estimate was more accurate than any of the individual ones
  - If reliability was limited, the system generated an explanation in human terms
- The fused estimates were more robust.

These characteristics allowed the user to determine the suitability of the estimate within the given business application context. Knowledge-based rules were used for constructing this fusion at a supervisory level, and the few parameters were determined manually, by inspection and experimentation. A more detailed description of this process can be found in [41.15]. This case study was the oldest case study to use model ensemble and fusion. However, the use of metaheuristics to guide the design phase at that time was still not well understood as in the more recent case studies.

**Fig. 41.12** Data comparison of multiple approaches

### Results

The reliability values generated by the fusion were divided into three classes, labeled *good*, *fair*, and *poor*. From a test sample of 7293 properties, 63% were classified as *good*, with a median absolute error of 5.4% (an error that was satisfactory for the intended application.) Of the remaining subjects, 24% were classified as *fair*, and 13% as *poor*. The fair set had a medium error of 7.7%, and the poor set had a median error of 11.8%.

The reliability computation and the fusion increased the robustness and usefulness of the system, which achieved good accuracy and was scalable for thousands of automated transactions. This approach made it a transparent, interpretable, fast, and inexpensive choice for bulk estimates of residential property value for a variety of financial applications.

### 41.4.3 Portfolio Rebalancing: An Optimization Problem

#### Problem Definition

The goal of portfolio optimization is to manage risk through diversification and obtain an optimal risk-return tradeoff. In this case study, we address portfolio optimization within the context of an asset-liability management (**ALM**) application. The goal was to find the optimal allocation of available financial resources to a diversified portfolio of 1500+ long and short-term financial assets, in accordance with risk, liability, and regulatory constraints.

To characterize the investor's risk objectives and capture the potential risk-return tradeoffs, we used var-

ious measures to quantify different aspects of portfolio risk. For **ALM** applications, a typical measure of risk is *surplus variance*. We computed portfolio variance using an analytical method based on a multifactor risk framework. In this framework, the value of a security can be characterized as a function of multiple underlying risk factors. The change in the value of a security can be approximated by the changes in the risk factor values and risk sensitivities to these risk factors. The portfolio variance equation can be derived analytically from the underlying value change function.

In **ALM** applications, the portfolios have assets and liabilities that are affected by the changes in common risk factors. Since a majority of the assets are fixed-income securities, the dominant risk factors are *interest rates*. In **ALM** applications, in addition to maximizing return or minimizing risk, portfolio managers are constrained to match the characteristics of asset portfolios with those of the corresponding liabilities to preserve portfolio surplus due to interest rate changes. Therefore, the **ALM** portfolio optimization problem formulation has additional linear constraints that match the asset-liability characteristics when compared with the traditional Markowitz model. We use the following **ALM** portfolio optimization formulation

$$\begin{aligned}
 & \text{Maximize} && \text{Portfolio expected return} \\
 & \text{Minimize} && \text{Surplus variance} \\
 & \text{Minimize} && \text{Portfolio value at risk}
 \end{aligned} \tag{41.12}$$

*Subject to:*

- Duration mismatch  $\leq \text{target}_1$
- Convexity mismatch  $\leq \text{target}_2$ ; and
- Linear portfolio investment constraints.

To measure the three objectives in (41.12), namely portfolio expected return, surplus variance, and portfolio value at risk, we used *book yield*, *portfolio variance*, and *simplified value at risk* (SVaR), respectively. These metrics are defined as follows:

- *Portfolio book yield* represents its accounting yield to maturity and is defined as

$$\text{BookYield}_P = \frac{\sum_i \text{BookValue}_i \times \text{BookYield}}{\sum_i \text{BookValue}_i} \quad (41.13)$$

- *Portfolio variance* is a measure of its variability and is defined as the second moment of its value change  $\Delta V$

$$\sigma^2 = E[(\Delta V)^2] - E[(\Delta V)]^2 \quad (41.14)$$

- *Portfolio simplified value at risk* is a complex measure of the portfolio's catastrophic risk and is described in details in [41.57].

These metrics define the 3D optimization space. Now, let us analyze its constraints. The change in the value  $\Delta V$  of a security can be approximated by a second order Taylor series expansion given by

$$\begin{aligned} \Delta V \approx & \sum_{i=1}^m \left( \frac{\partial V}{\partial F_i} \right) \Delta F_i \\ & + \frac{1}{2} \sum_{i=1}^m \sum_{j=1}^m \left( \frac{\partial^2 V}{\partial F_i \partial F_j} \right) \Delta F_i \Delta F_j. \end{aligned} \quad (41.15)$$

The first- and second-order partial derivatives in (41.15) are the risk sensitivities, i.e., the change in the security value with respect to the change in the risk factors  $F_i$ . These two terms are typically called *delta* and *gamma*, respectively [41.58]. For fixed-income securities, these measures are *duration* and *convexity*. The duration and convexity mismatches, which constrain our optimization space in (41.12), are the absolute

values of the differences between the effective durations and convexities of the assets and liabilities in the portfolio, respectively. Though they are nonlinear (because of the absolute value function), the constraints can easily be made linear by replacing each of them with two new constraints that ensure that the actual value of the mismatch is less than the target mismatch and greater than the negative of the target mismatch, respectively. The other portfolio investment constraints include asset-sourcing constraints that impose a maximum limit on each asset class or security, overall portfolio credit quality, and other linear constraints.

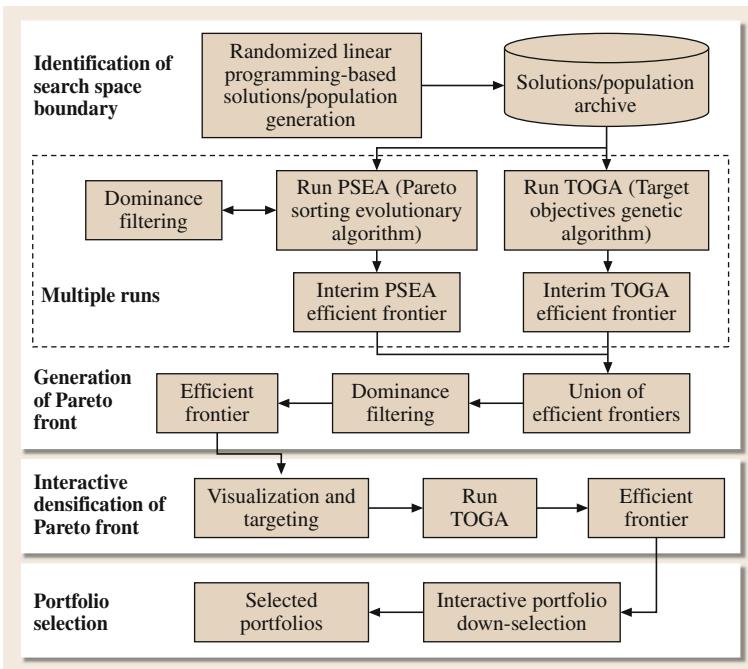

### CI-Based Approach

Given the explicit need for customization and hybridization in methods for portfolio optimization, we could not find an existing multiobjective optimization algorithms could be applied without extensive modifications. Specifically, the requirement to optimize while satisfying a large number of linear constraints excluded the ready application of prior evolutionary multiobjective optimization approaches. This aspect was a principal motivation to develop a novel hybrid techniques.

Figure 41.13 illustrates the process used to drive the search for the efficient frontier. The process consisted of three steps, corresponding to the three boxes in Fig. 41.13. The first step (box 1 in Fig. 41.13) was the *generation of the Pareto front*. It consisted of:

- Initializing the population of candidate portfolios using a randomized linear programming (RLP)
- Generating an interim Pareto front with a Pareto sorting evolutionary algorithm (PSEA)
- Completing gaps in the Pareto front with a target objective genetic algorithm (TOGA) and
- Storing the results in a repository. After many runs, we filtered the repository with an efficient dominance filter and generated the first efficient frontier.

The second step (box 2 in Fig. 41.13) was the *interactive densification of the Pareto front*. This richly sampled Pareto front was analyzed for possible gaps, and augmented with a last run of TOGA, leading to the generation of the second efficient frontier. Each point in this front represented a nondominated solution, i.e., a viable portfolio. The third step (box 3 in Fig. 41.13) was the *portfolio selection*. We needed to incorporate the decision maker's *preferences* in the return-risk tradeoff. Our goal is to reduce the large number of viable so-

**Fig. 41.13** Portfolio optimization process/workflow

solutions into a much smaller subset that could then be further analyzed for a final portfolio selection.

We will briefly describe the major components of this process.

**Randomized Linear Programming (RLP).** The key challenge in solving the portfolio optimization problem was presented by the large number of linear allocation constraints. The feasible space defined by these constraints is a high dimensional real-valued space (1500+ dimensions), and is a highly compact convex polytope, making for an enormously challenging constraint satisfaction problem. We leveraged our knowledge on the geometrical nature of the feasible space by designing a randomized linear programming algorithm that robustly sampled the boundary vertices of the convex feasible space. These extremity samples were seeded in the initial population of the **PSEA** and were exclusively used by the evolutionary multiobjective algorithm to generate interior points (via interpolative convex crossover) that were always geometrically feasible. This was similar in principle to the *preprocess phase*, proposed by Kubalik and Lazansky [41.59].

**Pareto Sorting Evolutionary Algorithm (PSEA).** We developed a Pareto sorting evolutionary algorithm (**PSEA**) that was able to robustly identify the Pareto

front of optimal portfolios defined over a space of returns and risks. The algorithm used a secondary storage and maintains the diversity of the population by using a convex crossover operator, incorporating new random solutions in each generation of the search; and using a noncrowding filter. Given the reliance of the **PSEA** on the continuous identification of nondominated points, we developed a fast dominance filter to implement this function very efficiently.

**Target Objectives Genetic Algorithm (TOGA).** We further enhanced the quality of the Pareto front by using a target objectives genetic algorithm (**TOGA**), a non-Pareto nonaggregating function approach to multiobjective optimization. Unlike the **PSEA**, which was driven by the concept of dominance, the **TOGA** found solutions that were *as close as possible* to a predefined target for one or more criterion [41.60]. We used this to fill potential gaps in the Pareto front.

**Decision Maker Preferences.** We incorporated the decision-maker's *preferences* in the return-risk tradeoff to perform our selection. The goal was to reduce thousands of nondominated solutions into a much smaller subset (of  $\approx 10$  points), which could be further analyzed for a final portfolio selection. After obtaining a 3D Pareto front, we augmented this space with three ad-

ditional metrics, to reflect additional constraints for use in the tradeoff process. This augmented 6D space was used for the down-selection problem. To incorporate progressive ordinal preferences, we used a graphical tool to visualize 2D projections of the Pareto front. After applying a set of constraints to further refine the best region, we used an *ordinal* preference, defined by the order in which we visited and executed *limited, local tradeoffs* in each of the available 2D projections of the Pareto front. In this approach, the decision maker could understand the available space of options and

the costs/benefits of the available tradeoffs. The use of progressive preference elicitation provided a natural mechanism to identify a small number of the good solutions.

**Results.** The optimization process was successfully tested on large portfolios of fixed-income base securities – each portfolio involving over fifteen hundred financial assets, and investment decisions of several billion dollars. For a more complete description of this application refer to [41.16].

## 41.5 Model Ensembles and Fusion

Over the last decade, we have witnessed an emerging trend favoring the use of model ensembles over individual models. The elements of these ensembles are object-level models, the fusion mechanism is an *online MHS*, and their overall design is guided by *offline MHS*, as discussed in Sect. 41.1.

### 41.5.1 Motivations for Model Ensembles

This trend is driven by the improved performance obtained by ensembles. By fusing the outputs of an ensemble of *diverse* predictive models, we boost the overall prediction accuracy while reducing the variance. Fumera and Roli et al. [41.61] confirmed theoretically the claims of Dietterich [41.62]. They proved that averaging of classifiers outputs guarantees a better test set performance than the worst classifier of the ensemble. Moreover, under specific hypotheses, such as linear combiners of individual classifiers with unbiased and uncorrelated errors, the fusion of multiple classifiers can *improve the performance of the best individual classifiers*. Under ideal circumstances (e.g., with an infinite number of classifiers) the fusion can provide the optimal Bayes classifier [41.63]. All this is possible if individual classifiers make *different* errors (diversity), as we will discuss in Sect. 41.5.3.

There is also a computational motivation for using model ensembles. Many learning algorithms are based on local search and suffer from the problem of local minima, which is usually resolved by multiple independent initializations. In other cases, generating the optimal training might be computationally hard even with enough training data. The fusion of multiple classifiers trained from different starting points or training sets can better approximate the

optimal classifier at a fraction of the computational cost.

### 41.5.2 Construction of Model Ensembles

The ensemble construction requires the creation of base models, an ensemble topology, and a fusion mechanism. Let us briefly review these concepts.

**Base Models.** Base models are the elements to be fused – they are the object-level models discussed in Sect. 41.1.1. They need to be *diverse*, e.g., they need to have low error correlations. They could differ in their parameters, and/or in their structure, and/or in the **ML** techniques used to create them. The process for injecting diversity in their design is described in Sect. 41.5.3.

**Topology.** The ensemble can be constructed by following a *parallel* or *serial* topology (or in some cases, a hybrid one). The most common topology is the parallel one, in which multiple models are fed the same inputs and their outputs are merged by the fusion mechanism. In the serial topology, the models are applied sequentially (as in the case when we first use a primary model, and in case of it failing to accept a pattern, a secondary model is used to attempt a classification).

**Fusion Mechanism.** We divide the fusion mechanisms based on two criteria: (a) the type of aggregation that they perform; (b) the dependency on their inputs. The former is concerned with the regions of competence of the base models to be aggregated and divides the fusion mechanisms into: *selection*, *interpolation*, and *integration*. The latter is concerned with the dependency of the meta-model (fusion) on the inputs to the

ensemble and divides the fusion mechanisms into *static* and *dynamic* ones.

Based on the first criterion, we have the following types of fusion mechanisms:

- *Selection* – used to fuse *disjoint, complementary* models. In this case, the base models were trained on disjoint regions of the feature space and, for each pattern, just one model is responsible for the final decision. Selection determines a *binary relevance weight* of each complementary model (where all but one of the weights are zero). This mechanism is typically used in hierarchical control systems, in which a supervisory controller (meta controller) selects the most appropriate low-level controller for any given state. Another example of this mechanism is the use of decision trees [41.26], in which the leaf node reached by the input/state determines the selected model.
- *Interpolation* – used to fuse *overlapping complementary* models. In this case, the base models were trained on different but overlapping regions of the feature space and, for each state, a subset of models is responsible for the final decision. Interpolation determines a *fuzzy relevance weight* of each complementary model (where the weights are in the  $[0, 1]$  interval and they are usually normalized to add up to 1). By interpolating rather than switching between models, we introduce smoothness in the response surface induced by the ensemble. This interpolation mechanism is typical of hierarchical fuzzy systems, usually found in fuzzy control applications [41.36, 55].
- *Integration*, – used to fuse *competitive* models. In this case, all base models were trained on the same feature space and, for each input, all models contribute to the final decision according to their relevance weight. Integration determines the *relevance weight* of each competitive model.

Based on the second criterion (input dependency of the meta model), we have the following fusion mechanisms:

- *Static fusion*. The relevance weights are determined in a *batch mode* by a static fusion meta-model (online MHs). The mechanism is applied uniformly to all inputs. This is the typical case of algebraic expressions used to compute the relevance weights [41.64].

- *Dynamic fusion*. The relevance weights are determined at *run time*, by a dynamic fusion meta-model (online MHs). The weights vary according to the inputs. This is the typical case of dynamic systems used to compute the relevance weights [41.36–38].

As noted by Roli et al. [41.65], the design of a successful fusion system consists of three parts: design of the individual object-level models, selection of a set of diverse models, and design of the fusion mechanism. The operating word is *diverse*, where model diversity is defined by low correlation among the object-level model errors. In other words, these models should be as accurate as possible while avoiding coincident errors. This concept is described by Kuncheva and Whitaker [41.66], where the authors propose four *pairwise* and six *nonpairwise* diversity measures to determine the models difference. A more complete treatment of this topic can be found in [41.67].

### 41.5.3 Creating Diversity in the Model Ensembles

Let us consider a model as a mapping from an  $n$ -dimensional feature space  $\mathbf{F}$  to a  $k$ -dimensional output space  $\mathbf{Y}$ . The model training dataset could be represented as a flat file, in which each row is a point in the cross-product  $\mathbf{F} \times \mathbf{Y}$  and each column represent a coordinate dimension for such points (either in the feature space  $\mathbf{F}$  or in the output space  $\mathbf{Y}$ ).

Among the many approaches for injecting diversity in the creation of an ensemble of models, we find *bagging*, *boosting*, *random subspace*, *randomization*, and *random forest*. Some of these approaches subsample the rows of the training set (points or examples), some other ones subsample the columns (features), and a few do both. Let us review some of these approaches in chronological order.

*Bootstrap* [41.68–70] or *bagging* [41.71] is arguably the oldest techniques for creating an ensemble of models. In this approach, diversity is obtained by building each model with a different set of examples, which are obtained from the original training dataset by *resampling the rows with replacement* (using a uniform probability distribution over the rows). *Bagging* combines the decisions of the classifiers using uniform-weighted voting. For each new training dataset, we must maintain the same number of rows as in the original training dataset, by sampling it that many times. Sampling with replacement leads  $\approx 63.2\%$  unique rows. Sampling with replacement creates a series of inde-

pendent Bernoulli trials, so the number of times a row is sampled from  $k$  trials out of  $N$  rows is  $B(k, 1/N)$ . For large values of  $N$ , the Bernoulli series can be approximated by a Poisson distribution with mean  $(k/N)$ . Therefore, the proportion of rows not sampled will be approximately  $e^{-k/N}$ . In bootstrap, the number of samples is equal to the number of rows, i.e.,  $k = N$ , so the Poisson approximation has a mean 1 and the proportion of sampled data is  $(1 - e^{-k/N}) = (1 - e^{-1}) = 63.2\%$ . As a result, we can achieve the same storage reduction by not duplicating the same rows and instead attach a count at the end of each sampled record to indicate the number of time it was selected. An interesting variation of this concept is the *Bag of Little Bootstraps* (**BLBs**) [41.72], which modifies the bootstrap approach to be usable with much larger data sets (where 63.2% of the original data would still be prohibitively large). Their proposed **BLB** approach performs a more drastic subsampling while maintaining the unbiased estimation and convergence rate of the original bootstrap method.

An alternative to *bagging* is *boosting*, which is rooted in the probably approximately correct (**PAC**) learning model [41.73–75]. Instead of training all classifiers in parallel (as in the case of bagging), we construct the ensemble in a serial fashion, by adding one model at a time. The model added to the ensemble at step  $j$  is trained on a dataset sampled selectively from the original dataset. The sampling distribution starts from a uniform distribution (as in bagging) and progresses toward increasing likelihood of misclassified examples in the new dataset. Thus, the distribution is modified at each step, increasing the likelihood of the examples misclassified by the classifier at step  $(j-1)$  being in the training dataset at step  $j$ . Like *Bagging*, *Boosting* combines the decisions of the classifiers using uniform-weighted voting.

*Adaboost* (or *adapting boosting*) [41.74] extends *boosting* from binary to multiclass classification problems and regression models. It adapts the probability distribution over the rows in the training set to increase the difficulty of the training points by including more instances misclassified or wrongly predicted by previous models. *Adaboost* combines the decisions of the classifiers using a weighted voting. For regressions, it aggregates all the normalized confidences for the output. For multiclass classification it selects the class with the highest votes, calculated from the normalized classification errors of each class.

A different approach to inject diversity is to limit the number of columns (features), rather than the number of rows (points). *Ho's random subspaces* tech-

nique [41.76] selects random subsets of the available features to be used in training the individual classifiers in the ensemble.

*Dietterich* [41.77] introduced an approach called *randomization*. In this approach, at each node of each tree of the ensemble, the 20 best attributes to split the node are determined and one of them is randomly selected for use at that node.

*Breiman* [41.32] presented *random forest* ensembles, where bagging is used in combination with random feature subspace selection. At each node of each tree of the forest, a subset of  $m$  attributes (out of  $n$  available ones) is randomly selected, and the best split available based on the  $m$  attributes is selected for that node. Clearly, if  $m$  were too small, the tree performance would be severely affected, while if  $m$  were too close to the value of  $n$ , each tree performance would be higher, but diversity would suffer. In the case of *random forest*, a tradeoff between individual performance and overall diversity is achieved by using a value of  $m$  around the  $\lfloor \sqrt{n} \rfloor$  for classification problems, and around  $\lfloor n/3 \rfloor$  for regression problems.

Other approaches to increase diversity rely on the use of a high-level model to combine object-level models derived from different machine-learning techniques, e.g., *stacked generalization* [41.78]. Alternatively, we can inject structural diversity in the design of the object models by using different topologies/architectures in graphical models (e.g., neural networks) or different function sets/grammars in genetic programming algorithms to construct models [41.79].

The above approaches allow us to extract different types of information from the data, which should lead to lower error correlations among the models. With these approaches we can generate a space of diverse models, which can then be searched by *offline MHs* to tune and optimize the model ensemble, according to tradeoffs of performance and diversity.

#### 41.5.4 Lazy Meta-Learning: A Model-Agnostic Fusion Mechanism

A second trend in the development of analytics models is the inevitable commoditization of object-level models. Multiple sources for model creation are now available, ranging from Crowdsourcing analytics by competition (e.g., [41.80]) or by collaboration (e.g., [41.81]) to cloud-based model automation tools, such as evolving model populations using genetic programming [41.79]. This situation creates different requirements for the fusion mechanism, which now should be *agnostic* with

respect to the genesis of the object-level models in the ensemble.

We should note that all the previous approaches to fusion described in Sect. 41.5.3 use static fusion mechanisms, as they focus primarily on the creation of diverse base models (or object-level models). If we want to be agnostic with respect to these models, we need to have a *smarter* fusion mechanism, i.e., a meta model that can reason about the performance and applicability of the available object level models.

This issue is partially addressed by *Lazy Meta-Learning*, proposed in [41.82]. In this approach, for each query we instantiate a customized fusion mechanism. Such mechanism is a meta model, i.e., a model that operates on the object-level models whose predictions we want to fuse. Specifically, for a given query we dynamically (i.e., based on the query) create a model ensemble, followed by a customized fusion. The dynamic model ensemble consists of:

- (1) Finding the most relevant object-level models from a DB of models, by matching their meta-information with the query.
- (2) Identifying the relevant models with higher performance.
- (3) Selecting a subset of models with highly uncorrelated errors to create the ensemble.

The customized fusion uses the meta-information of the models in the ensemble for dynamic bias compensation and relevance weighting. The output is a weighted interpolation or extrapolation of the outputs of the model ensemble.

More specifically the *Lazy Meta-Learning* process is divided into three stages:

- *Model creation*, an offline stage in which we create the initial building blocks for the assembly (or we collect them/acquire them from other sources) and we compile their meta-information
- *Dynamic model assembly*, an online stage in which, for a given query we select the best subset of models
- *Dynamic model fusion*, an online stage in which we evaluate the selected models and dynamically fuse them to solve the query.

### Model Creation: The Building Blocks

We assume the availability of an initial training set that samples an underlying mapping from a feature space  $X$  to an output  $y$ . In the case of supervised learning, we also know the ground truth-value  $t$  for each record in

the training set. We create a database **DB** of  $m$  diverse, local or global models developed by any source. If we have control on the model creation, we can increase model diversity by any of the techniques described in Sect. 41.5.3. Every time, we add a model to the **DB**, we need to capture its associated meta-information, i.e., information about the model itself, its training set, and its local/global performance. Such meta-information is used to create indices in the **DB** that will make its search more efficient. For each model  $M_i$ , we use a compiled summary of its performance, represented by a **CART** tree  $T_i$ , of depth  $d_i$ , and trained on the model error vector obtained during the validation of the model. To avoid overfitting, each tree is pruned to allow at least 25 points in each leaf node.

### Dynamic Model Ensemble:

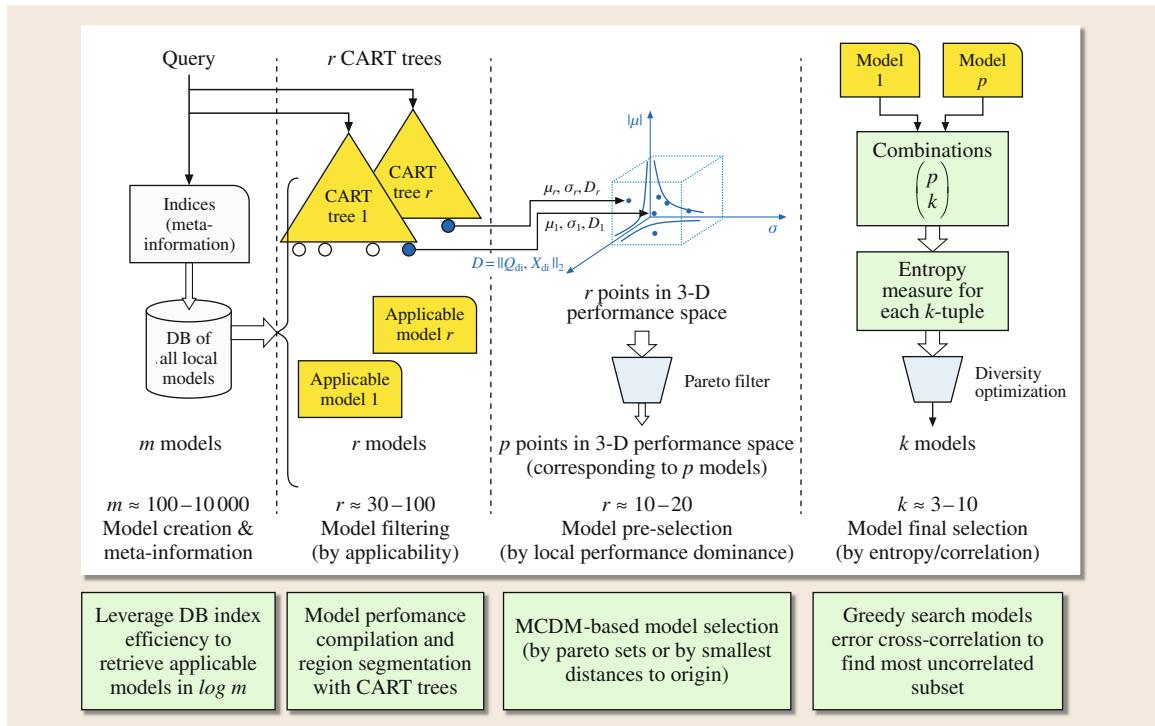

#### Query-Driven Model Selection and Ensemble

This stage is divided into three steps:

- *Model Filtering*, in which we retrieve from the **DB** the applicable models for the given query. For a query  $q$ , the process starts with a set of constraints to define its related feasibility set. In this case the constraints are:
  - (a) Model *soundness* and *competency* in its region of applicability (i.e., there must be sufficient points in the training set to develop a reliable model).
  - (b) Model *vitality* (i.e., the model is up-to-date, not obsolete).
  - (c) Model *applicability* to the query (i.e., the query is in the model's competence region).

The intersection of these constraints satisfaction gives us a set of retrieved models for the query  $q$ . Let us denote the cardinality of this set as  $r$ .

- *Model Preselection*, in which we reduce the number of models, based on their local performance characteristics, such as bias, variability, and distance from the query. For a query  $q$ , having retrieved its feasible  $r$  models from the previous step, we classify the query using the same **CART** tree  $T_i$ , associated to each model, and reach leaf node  $L_i(q)$ . Each leaf node will be defined by its path to the root of the tree and will contain  $d_i$  constraints over (at most)  $d_i$  features. Leaf  $L_i(q)$  provides performance estimates of model  $M_i$  in the region of the query. These estimates are used to retrieve the set of Pareto-best models to be used in the next step. Let us denote the cardinality of this set as  $p$ .

**Fig. 41.14** Dynamic model ensemble on demand (filtering, selection)

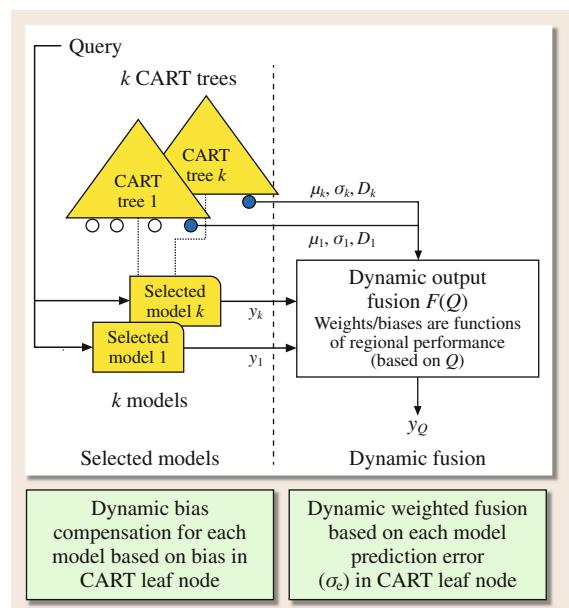

- **Model Final Selection**, in which we define the final model subset. We need to use an ensemble whose elements have the most uncorrelated errors. We use the *Entropy Measure E*, proposed by Kuncheva and Whitaker, as the way to find the  $k$  most diverse models to form the ensemble. To avoid the intrinsic combinatorial complexity, we approximate our search via a greedy algorithm (further described in [41.82]).

The process is described in Fig. 41.14.

**Dynamic Model Fusion: Generating the Answer**  
Finally, we evaluate the selected  $k$  models, compensate for their biases, and aggregate their outputs using a relevance weight that is a function of their proximity to the query to generate the solution to the query. This is illustrated in Fig. 41.15.

This approach was successfully tested against a regression problem for a coal-fired power plant optimization. The optimization problem, described in [41.83], required to adjust 20+ set-point values for the power

plant multivariable controller to match the generated power with the required *Load*, while minimizing emis-

**Fig. 41.15** Dynamic model fusion on demand ►

| Dynamic fusion     | 0.01627 | 0.01651 | 0.01541     | 70.95  | 73.90  | 70.90       | 0.8474 | 0.8243 | 0.8209      |
| Percentage gain    | 28.6%   | 49.5%   | 46.4%       | 22.7%  | 32.3%  | 29.9%       | 20.0%  | 46.0%  | 37.6%       |

sions ( $\text{NO}_x$ ) and *heat rate* (inverse of efficiency). The optimization was predicated on having a reliable fitness function, i. e., a high fidelity mapping between the 20+ input vector and the three outputs (*load*,  $\text{NO}_x$ , *heat rate*).

In [41.82], we focused on generating this mapping via dynamic fusion. We used a data base of approximately 75 models: 30 neural networks (**NNs**) trained using bootstrapping and about 45 symbolic regression (**SR**) models evolved on the MIT Cloud using with the same training set of 5000+ records. We applied the dynamic fusion approach, described in this section, and evaluated it on a disjoint validation set made of 2200+ records. The results of the mean of the absolute error (**MAE**) computed over this validation set are summarized in Table 41.4.

The first conclusion is that dynamic fusion consistently outperformed static fusion, as shown by the

percentage gain (last row in Table 41.4), which was computed as the difference between baseline and dynamic fusion, as a percentage of the baseline. In the cases of  $\text{NO}_x$  and *load*, the baseline (average) for the 45 **SR** models was  $\approx 50\%$  worse than that of the 30 **NNs**. In creating the **SR**, we sacrificed individual performance to boost diversity, as described in Sect. 41.5.3. On the other hand, the **NNs** were trained for performance, while diversity was only partially addressed by bootstrap (but the **NNs** were trained with the same feature set and the same topology). After dynamic fusion the performance of the **SR** was roughly comparable with the **NNs** (within 2.7%), and the overall performance of the combined models was 3–5% better than that of the **NNs** alone. This experiment verified the importance of diversity during model creation. A more complete treatment of *Lazy Meta Learning*, including results of these experiments can be found in [41.82].

## 41.6 Summary and Future Research Challenges

We illustrated the use of **CI** techniques in **ML** applications. We explained how to leverage **CI** to build meta models (for offline design and online control/aggregation) and object-level models (for solving the problem at hand.) We described the most typical **ML** functions: unsupervised learning (clustering), supervised learning (classification and regressions), and optimization. To structure the cases studies described in this review, we presented two similar paradigms: **PHM** for industrial assets, and risk management for financial and commercial assets. We analyzed five case studies to show the use of **CI** models in:

- (1) Unsupervised learning for anomaly detection (based on neural networks, fuzzy systems, and **EAs**).

- (2) Supervised learning (classification) for assessing and pricing risk in insurance products (based on fuzzy systems and **EAs**).
- (3) Supervised learning (regression) for valuating mortgage collaterals (based on radial basis functions, fuzzy systems, neural fuzzy systems, and fusion).
- (4) Supervised learning (regression-induced ranking) for selecting the best units in a fleet (based on fuzzy systems and **EAs**).
- (5) Multiobjective optimization for rebalancing a portfolio of investments (based on multiobjective **EAs**).

In the last section we covered model ensembles and fusion, and emphasize the need for injecting diversity during the model creation stage. We proposed a model–agnostics fusion mechanism that could be used to fuse commoditized models (such as the ones obtained

by crowdsourcing). We will conclude this review with a prospective view of research challenges for **ML**.

### 41.6.1 Future Research Challenges

All applications described in the five case studies were developed before the advent of cloud computing and big data. Since then, we have encountered situations in which we need to analyze very large data sets, enabled by the Internet of things (**IoT**) [41.84], machine-to-machine (**M2M**) connectivity, and social media. In this new environment, we need to scale up the **CI/ML** capabilities and address the underlying *three v's* in big data: *volume*, *velocity*, and *variability*. Large data volumes pose new challenges to data storage, organization, and query; data feed velocity requires novel streaming capabilities; data variability requires the collection and analysis of structured, unstructured, and semistructural (e.g., locational) data and the ability to learn across multiple modalities. The use of cloud computing will also result in the commoditization of analytics. In this context, **ML** applications will also include the delivery of *Analytics-as-a-Service* (**AaaS**) [41.85].

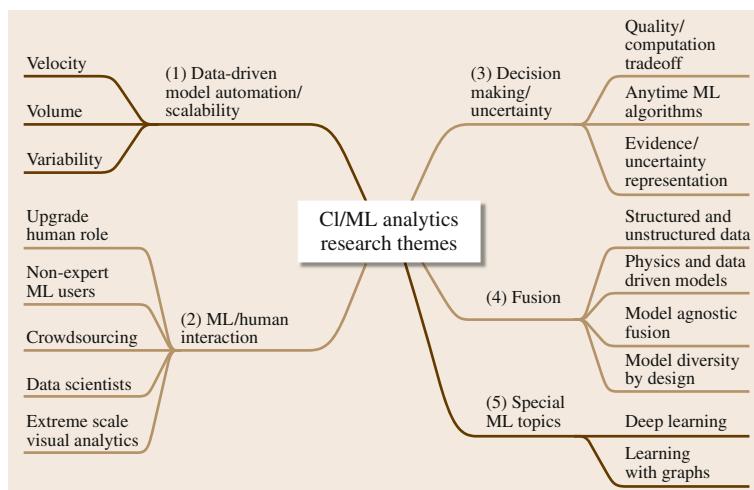

We will conclude this section with a view of five research challenges entailed by this new environment, as illustrated in Fig. 41.16:

#### (1) Data-driven Model Automation and Scalability

- a. *Computation at the edge (velocity)*. When the cost of moving large data set becomes significant, we need to perform analysis while the data are still in memory, via in-situ analytics and in-transit data transformation [41.86]. A variety of

solutions have been proposed, ranging from SW frameworks [41.87] to active Flash [41.88].

- b. *Technology stack for Big Data (volume)*. We need to address scalability issues along many dimensions, such as data size, number of computational nodes over which to distribute the algorithms, number of models to be trained/deployed, etc. Among the research groups addressing this issue, we found the UC Berkeley AMP Lab [41.89] to be among the leaders in this area. The AMP researchers have developed the *Berkeley data analytics stack (BDAS)* [41.90], a technology stack composed of *Shark* (to run structured query language (**SQL**) and complex analytics on large clusters) [41.91, 92], *Spark* (to reuse working set of data across multiple parallel operations, typical of **ML** algorithms) [41.93], and *Mesos* (to share commodity clusters between multiple diverse cluster computing frameworks, such as *Hadoop* and message passing interface (**MPI**)) [41.94].
- c. *Parallelization of ML Algorithms (volume)*. We need to design **ML** algorithms so that their computation can be distributed. Some algorithms are easy to parallelize, like population-based **EAs** (using an island [41.95, 96] or a diffusion grid models to distribute the subpopulations to many computational nodes), or *Random Forest* (growing subsets of trees on different computational nodes) [41.97]. Other algorithms will need to be redesigned for parallelization.
- d. *Multimodal learning (variability)*. As the size of the information grows, its content will become

**Fig. 41.16** Research challenges for **CI/ML** analytics

more heterogeneous. For instance, by navigating through web pages, we encounter information represented as text, images, audio, tables, video, applets, etc. There are preliminary efforts for representing and learning across multiple modalities using graphical approaches [41.98], and kernels [41.99, 100]. However, a comprehensive approach to this issue remains an open problem.

(2) *ML/Human Interactions*

- Upgrade the human role.* We need to remove the human modeler from the most time-consuming, iterative tasks, by automating data scrubbing (outliers removal, de-noising, imputation, or elimination of missing data) and data preparation (multiple sources integration, feature selection, feature generation). As noted in [41.86], while:

*All high performance computing (HPC) components – power, memory, storage, bandwidth, concurrence, etc. – will improve performance by a factor of 3 to 4444 by 2018... human cognitive capability will certainly remain constant.*

We are obviously the bottleneck in any kind of automation process and we need to *upgrade* our role, by interacting with the process at higher levels of model design. For example, in active learning we maximize the information value of each additional question to be answered by a human expert [41.101, 102]. In interactive multi-criteria decision making we can use *progressive preference articulation*. This allows the expert to guide the automated search in the design space, by interactively simplifying the problem, e.g., by transforming an objective into a constraint once the values of most solutions fall within certain ranges for that objective [41.103].

- Non-expert ML users.* For routine modeling task, we need to enable nonexpert users to define analytics in a declarative rather than procedural fashion. In [41.104] we can see an example of this concept, based on the analogy between the *MLbase* language for *ML* and traditional *SQL* languages for *DBs*.
- Integration of crowdsourcing with analytics engines.* Crowdsourcing is an emerging trend that is increasing human capacity in a manner similar to the way cloud computing is increasing computational capacity.

In this analogy, we could think of *Amazon Mechanical Turk* [41.105] as the dual of *Amazon Elastic Cloud Computing* [41.106]. Originated from the concept of *Wisdom of Crowds* [41.107], crowdsourcing has shown a tremendous growth [41.108]. According to Malone et al. [41.109], the crowd's contribution to the solution of a problem/task can be done via *collection*, *competition*, or *collaboration*.

- Collection* is used when the task can be decomposed into independent micro-tasks that are then executed by a large crowd to generate, edit, or augment information. An example of this case is the labeling of videos or images to create a training set for supervised learning [41.110]. The annotation of galaxy morphologies or lunar craters done at *Zooniverse* [41.111] is another example of this case.
- Competition* is used when a single individual in the crowd can provide the complete solution to the task. An example of this case is the creation of data-driven models via contest hosted by sites such as *Kaggle* [41.80] or *CrowdANALYTICS* [41.81].
- Collaboration* is used when single individuals in the crowd cannot provide a complete solution and the task cannot be decomposed into independent subtasks. This situation requires individuals to collaborate toward the generation of the solution. Examples of this case are usually large projects, such as the development of *Linux* or *Wikipedia*.

Additional crowdsourcing systems are surveyed in [41.112]. We are interested in the intersection of crowdsourcing with machine learning and big data, which is also the focus of UCB AMPLab [41.89]. Among the research trends in this area, we find the impact of crowdsourcing in *DBs* queries, such as changing the closed-world assumption of *DB* queries [41.113], monitoring queries progress when crowdsourced inputs are expected [41.114], and using the crowd to interpret queries [41.115]. Furthermore, we can also apply *ML* techniques to improve the quality of the crowd-generated outputs, reducing variability in annotation tasks [41.116], and performing bias removal from the outputs [41.117]. In the future, we expect many more opportunities for *CI/ML* to leverage crowdsourcing and enhance the quality of its outputs.

d. *New generations of Data Scientists.* There is a severe skill gap, which we will need to overcome if we want to accelerate the applicability of ML to a broader set of problems. We need to train a new generation of data scientists, with skills in data flow (collection, storage, access, and mobility), data curation (preservation, publication, security, description, and cleanings), and basic analytics skills (applied statistics, MI/CI). Several universities are creating a customized curriculum to address this need. The National Consortium for Data Science is an illustrative example of this emerging trend [41.118].

e. *Extreme scale visual analytics.* We can cope with increases in data volume/velocity, and analysis complexity because we have benefited from similar increases in computing capacity. Unfortunately, as aptly noted in [41.86], ... there is no Moore's law for human cognitive abilities. So, we face many challenges, described in the same reference, when we want to present/visualize the results of the complex analytics to the user (as in the case of multilevel hierarchies, time-dependent data, etc.) There are situations in which the user can select data with certain characteristics to be used in the analysis and steer data summarization and triage performed by the ML algorithms [41.86]. This will also overlap with the previous category of upgrading the human role.

### (3) Decision Making and Uncertainty

a. *Quality/Computation tradeoff.* When faced with massively large data sets, we need to distribute data and models over multiple nodes. Often we also need to subsample the data sets while training the models. This might introduce biases and increase variances in the models results. The use of the *Bag of Little Bootstrap* [41.72] allows us to extend bootstrap (Sect. 41.5.3) to large data sets. However, not all queries or functions will work with bootstrap. *BlinkDB* is a useful tool to address this problem, as it allows us to understand if additional resources will actually improve the quality of the answer. *BlinkDB* is a [41.119]:

... massively parallel, sampling-based approximate query engine for running ad-hoc, interactive SQL queries on large volumes of data. It allows to trade-off query accuracy for response

time, enabling interactive queries over massive data by running queries on data samples and presenting results annotated with meaningful error bars....

- b. *Anytime ML Algorithms.* Anytime algorithms are especially needed for online ML applications in which models need to produce results within a given real-time constraints [41.120]. In [41.121] the authors propose a method for determining when to terminate the learning phase of an algorithm (for a sequence of iid tasks) to optimize the expected average reward per unit time. In simpler situations, we want to be able to interrupt the algorithm and use its most recent cached answer. This idea is related to the quality/computation tradeoff of point (3.a), as we expect the quality of the answer to increase if we allow more computational resources. For example, in EAs, under convergence assumptions, we expect further generations to have a better fitness than the current one. At any time we can stop the EA and fetch the answer for the current population.
- c. *Evidence and Uncertainty Representation.* This is one of the extreme-scale visual analytics challenges covered in [41.86]. In two previous points, we noted that as the data size increases we would need to perform data subsampling to meet real-time constraints. This subsampling will introduce even greater uncertainty in the process. We need better ways to quantify and visualize such uncertainty and provide the end-user with intuitive views of the information and its underlying risk.

### (4) Model Ensemble/Fusion

- a. *Integration of structured and unstructured data.* The simplest case is the integration of time dependent text (e.g., news, reports, logs) with time series data, e.g., text as a sensor. This topic is related to the multimodal learning discussion illustrated in (1.d). Alternatively, instead of learning across multiple data formats, we can use an ensemble of modality-specific learners and fuse their outputs. An example of this approach can be found in [41.122]
- b. *Integration of physics-based and data-driven models.* There are at least two ways to perform such integration: using the models in parallel or serially. The simplest integration is based on a parallel architecture, in which both mod-

- els are used simultaneously, yet separately. This case covers the use of data-driven models applied to the residuals between expected values (generated by physics-based models) and actual values (measured by sensors). This was illustrated in the first case study (Sect. 41.3.1). Another example of parallel integration is the use of an ensemble of physics-based and data-driven models, followed by an agnostic fusion mechanism (Sect. 41.5.4). A different type is the *serial integration*, in which one model is used to initialize the other one. An example of such integration is the use of data-driven models to generate estimates of parameters and initial conditions of physics based models. For instance, we could use data-driven RUL predictive models to estimate the current degree of degradation of key components in an electro-mechanical system. Then, we could run a physics-based model of the system, using these estimates as initial conditions, to determine the impact of future load scenarios to the RUL predictions. Another example of serial integration is the use of physics-based models to generate (offline) a large data set, usually following a Design of Experiment methodology. This data set becomes the training set for a data-driven model that will functionally approximate the physics-based model. Typically, a second data-driven model, frequently retrained with real-time data feeds, will be used to correct the outputs of the static approximation [41.123].
- c. *Model-agnostic fusion.* In Sect. 41.5.4 we covered the concept of model-agnostic fusion to be deployed when predictive models are created by a variety of sources (such as crowdsourcing via competition or cloud-based genetic programming). We showed that this type of fusion is a meta model that leverages each predictive model's meta-data, defining its region of applicability and relative level of performance [41.82]. Additional research is needed to prevent over-fitting of the meta models and to extend this concept to classification problems.
  - d. *Model diversity by design.* By leveraging the almost infinite computational capacity of the cloud, we should be able to construct model ensembles that are diverse by design. There are many techniques used to inject diversity in the models design, as described in Sect. 41.5.3. One of the most promising techniques con-

sists in evolving a large population of symbolic regression models by distributing genetic programming algorithms using an island approach [41.95, 96]. Random feature subsets can be assigned to each island, which also differ from the other islands through the use of distinct grammars, fitness functions, and functions sets. Additional information on this approach can be found in [41.79, 124, 125].

#### (5) Special Topics in Machine Learning

- a. *Deep Learning.* Originally proposed by Fukushima [41.126], deep learning (DL) gained acceptance when Hinton's showed that DL training was decomposable [41.127, 128]. Hinton showed that each of the layers in the neural network could be pretrained one at a time, as an unsupervised *Restricted Boltzmann Machine*, and then fine-tuned using supervised backpropagation. This discovery allows us to use large (mostly unlabeled) data sets available from Big Data applications to train DL networks.
- b. *Learning with Graphs.* There are many applications of Recommender Systems in social networks and targeted advertising. Typically these systems select information using collaborative filtering (CF), a technique based on collaboration among multiple agents, viewpoints, and data sources. Researchers have proposed various solutions to overcome some of the intrinsic challenges caused by data sparsity and network scalability. Among the most notable approaches we have:
  - (1) *Pregel* [41.129]: a synchronous message passing abstraction in which all vertex programs run simultaneously in a sequence of super steps.
  - (2) *GraphLab* [41.130]: an asynchronous distributed, shared-memory abstraction, designed to leverage attributes typical of ML algorithms, such as sparse data with local dependences, iterative algorithms, and potentially asynchronous execution.
  - (3) *PowerGraph* [41.131] and its Spark implementation *GraphX* [41.132]: an abstraction combining the best features of *Pregel* and *GraphLab*, better suited for natural graphs applications with large neighborhoods and high degree vertices.

The above examples are just a sample of specialized ML algorithms and architectures for niche opportu-

nities, exploiting the characteristic of their respective problems.

In conclusion, we need to shape CI research to address these new challenges. To remain a vital discipline during the next decade, we need to leverage the almost infinite capacity provided by cloud computing and

crowdsourcing, understand the tradeoffs between solution quality and computational resource allocation, design fusion mechanisms for model ensembles derived from heterogeneous data, and create specialized architectures and algorithms to exploit problems characteristics.

# Genetic Algorithms

Jonathan E. Rowe

While much has been discovered about the properties of simple evolutionary algorithms (EAs), based on evolving a single individual, there is very little work touching on the properties of population-based systems. We highlight some of the work that does exist in this chapter.

Genetic algorithms (GA) are a particular class of evolutionary computation method often used for optimization problems. They were originally introduced by Holland [42.1] at around the same time when other evolutionary methods were being developed, and popularized by Goldberg's much-cited book [42.2]. They are characterized by the maintenance of a *population* of search points, rather than a single point, and the evolution of the system involves comparisons and interaction between the points in the population. They are usually used for combinatorial optimization problems, that is where the search space is a finite set (typically with some structure). The most common examples use fixed-length binary strings to represent possible solutions, though this is by no means always the case – the search space representation should be chosen to suit the particular problem class of interest. Members of the search space are then evaluated via a *fitness function*, which determines how well they solve the particular problem instance. This is, of course, by analogy with natural selection in which the fittest survives and evolves to

produce better and better solutions. Notice that the efficiency of a genetic algorithm is therefore measured in terms of the number of evaluations of the fitness function required to solve the problem (rather than a more direct measure of the computational complexity). For any well-defined problem class, the maximum number of function evaluations required by an algorithm to solve a problem instance is called the *black box* complexity of the algorithm for that problem class. The black box complexity of a problem class is defined to be the maximum number of function evaluations required by the best possible black box algorithm. This is a research topic in its own right [42.3].

As an example, consider the subset sum problem, in which a set of  $n$  integers is given, along with a target integer  $T$ , and we have to find a subset whose sum is as close to  $T$  as possible. We can represent subsets as binary strings of length  $n$ , in which a 1 indicates that an element is in the subset and a 0 that it is excluded. The binary string forms the analog of the DNA (deoxyribonucleic acid) of the corresponding individual

solution. Its fitness would then be given by the corresponding sum – which we are trying to minimize.

For a different example, consider the traveling salesman problem, in which there are a number of cities to be visited. We have to plan a route to visit each city once and return home, while minimizing the distance traveled. A potential solution here could be expressed as a permutation of the list of cities (acting as the [DNA](#)), with the fitness given by the corresponding distance.

A genetic algorithm maintains a population of such solutions and their corresponding fitnesses. By focusing on the better members of the population and introduc-

ing small variations (or mutations), we hope that the population will evolve good, or even optimal, solutions in a reasonable time.

A popular general introduction to the field can be found in *Mitchell's* book [42.4]. Much of what is known about the theory of genetic algorithms was developed by *Vose* and colleagues [42.5], which centers around a description of the changing population as a dynamical system. A gentle overview of this theory can be found in [42.6]. More recently, there has been a stronger emphasis on understanding the algorithmic aspects, with a particular focus on run-time analysis for optimization problems [42.7–9].

## 42.1 Algorithmic Framework

The genetic algorithm works by updating the population in discrete iterations, called *generations*. We begin with an initial, randomly generated, population. This acts as a set of *parents* from which a number of *offspring* are produced, from which the next generation is created. There are two basic schemes for doing this: the generational method and the steady-state method.

The generational approach is to repeatedly produce offspring from the parent population, until there are enough to fill up a whole new population. One generation, in this case, corresponds to the creation of all of these offspring. The steady-state approach, by contrast, produces a single offspring from the current parents, and then inserting it into the population, replacing some individual. Here, a generation consists of creating one new individual solution.

In either case, the population size stays fixed at its initial size, which is a parameter of the algorithm. There exists some theoretical work investigating a good choice of population size in different situations, but there are few general principles [42.10]. The correct size will depend on the problem to be optimized, and the particular details of the rest of the algorithm. It should be noted, however, that in a number of cases it can be shown that smaller population sizes are preferable and, indeed, in some cases a *population* of size one is sufficient.

The overall structure of the generational genetic algorithm is as follows:

1. Initialize population of size  $\mu$  randomly with points from the search space.
2. Repeat until stopping criterion is satisfied:
  - a) Repeat  $\mu$  times:

- i. Choose a point from the population.
- ii. Modify the point with *mutation* and *crossover*.
- iii. Place resulting offspring in the new population.

3. Stop.

The critical points are therefore the selection method, used to choose points from the current population, and the mutation and crossover methods used to modify the chosen points. The idea is that selection will favor better solutions (in the sense that they provide better solutions to the optimization problem at hand), that mutation will introduce slight variations in the current chosen solutions, and that crossover will combine together parts of different good solutions to, hopefully, form a better combination. We will look at different schemes for selection, mutation, and crossover in detail later, in Sects. 42.2, 42.4, and 42.6.

The overall structure of the steady-state genetic algorithm is as follows:

1. Initialize population of size  $\mu$  randomly with points from the search space.
2. Repeat until stopping criterion is satisfied:
  - a) Choose a point from the population.
  - b) Modify the point with *mutation* and *crossover*.
  - c) Choose an existing member of the population.
  - d) Replace that member with the new offspring.
3. Stop.

It can be seen that, in addition to selection, mutation and crossover, the steady-state genetic algorithm also requires us to specify a means for choosing an individual to be replaced. Suitable replacement strategies will

be discussed later in Sect. 42.3, but for now we make a few general observations.

It is clear that in the generational genetic algorithm, progress is driven by the selection method. In this step of the algorithm, we choose to keep those solutions which we prefer, by dint of the degree to which they optimize the problem we are trying to solve. For the steady-state genetic algorithm, progress can also be maintained by the replacement strategy, if this is designed so as to affect the replacement of poorly performing individuals. In fact, it is possible to put the whole burden of evolution on the replacement step, for example, by always replacing the worst member of the population, and allowing the selection step to choose any individual uniformly at random. Conversely, one may use a stronger selection method and replace individuals randomly (or, of course, some combination of the two approaches). The steady-state algorithm therefore allows the user finer tuning of the strength of selective pressure.

In addition, the steady-state approach allows the user to guarantee that good individuals are never lost, by choosing a replacement strategy that protects such individuals. For example, replacing the worst individual each time ensures that copies of the best individual always remain. Any EA that has the property of preserving the best individual is called *elitist*. This would seem to be a desirable property as otherwise progress toward the optimum can be lost due to mutation and selection (Sect. 42.5). The generational framework, as it stands, offers no such guarantee. Indeed, depending on the method chose, the best individual may not even be selected, let alone preserved! It is quite a common strategy, therefore, to add elitism to the generational framework, for example, by making sure at least one copy of the best individual is copied across to the next generation each time.

The generational approach, without elitism explicitly added, is referred to as a *comma* strategy. In particular, it is a  $(\mu, \mu)$  EA. This means that the population has size  $\mu$ , and a further  $\mu$  offspring are created, which becomes the next generation population. More generally, we could have  $(\mu, \lambda)$  algorithms, where  $\lambda \geq \mu$ , in which  $\lambda$  offspring are created and the best  $\mu$  are taken to be the next generation. If  $\lambda$  is sufficiently large with respect to  $\mu$ , then the probability of not selecting the best individual gets rather small. If, in addition, there is a reasonable chance that mutation and crossover do not make any changes, we get an approximation of elitism.

The steady-state algorithm, in which one replaces the worst individual, is referred to as a *plus* strategy.

In particular, it is a  $(\mu + 1)$  EA. This means that one offspring is created from a population of size  $\mu$ , and then the best  $\mu$  are kept from the pool of parents plus offspring. More generally, we could have  $(\mu + \lambda)$  algorithms, in which  $\lambda$  offspring are created and the best  $\mu$  from the collection of parents and offspring are kept to be the next generation. *Plus* strategies are, of course, elitist.

Another advantage of the steady-state genetic algorithm is that progress can be immediately exploited. As soon as an improving individual is found, it is inserted into the population, and may be selected for further evolution. The generational algorithm, in contrast, has to produce a full set of offspring before any good discoveries can be built on. This overhead can be minimized by taking the population to be as small as possible, although one then risks losing good individuals in the selection process, unless some form of elitism is explicitly implemented.

A further extension often made to either scheme is to implement a mechanism for maintaining a level of diversity in the population. Clearly, a potential advantage of having a population is that it can cover a broad area of the search space and allow for more effective searching than if a single individual were used. Any such advantage would be lost, however, if the members of the population end up identical or very similar. In particular, the effectiveness of crossover is reduced, or even eliminated, if the population members are too similar. Some of the methods employed for maintaining diversity will be discussed in detail in Sect. 42.7.

Before we move on to details, it is worth asking whether or not maintaining a population is an effective approach to optimization. Indeed, such a question should be asked seriously whenever one attempts to use EAs for such problems. For certain classes of problem, it may well be the case that a simple local search strategy (that is, a  $(1 + 1)$  evolutionary algorithm (EA)) may be as effective or better. For example, for some problems (such as OneMax, which simply totals the bit values in a string), the  $(1 + 1)$ -EA is provably optimal amongst evolutionary algorithms that only use standard bitwise mutation [42.11]. There is a small, but limited, amount of theoretical work on this issue to guide us [42.10]. In the first place, if the search space comprises islands of good solutions with small gaps containing poor solutions, then a population might provide an effective way to jump across the gaps. This is because the poorer offspring are not so readily rejected (especially with a generational approach), and

may persist long enough for a lucky mutation to move into a neighboring good region. One might therefore also expect a population-based approach to be effective generally on highly multimodal problems but, unfortunately, there is very little analysis on this situation. If crossover is thought to be effective for your problem (Sect. 42.6), then a population is required, as we need to choose pairs of parents – although again, it might be the case that very small populations are sufficient. It certainly seems to be the case that for any such advantage, it is necessary to maintain a reasonable level of diversity, or the point of the population is lost [42.12].

One situation in particular, where a genetic algorithm may be helpful, is if the potential solutions to a problem are represented by the population as a whole. That is, one tries to find an optimal set of things, and we can use the population to represent that set. This is the case, for example, in *multiobjective* optimization, where one tries to determine the Pareto set of dominant solutions [42.13]. For single objective problems, it may be possible to represent solutions as a set of objects, each of which can be evaluated according to its contribution to the overall solution. There has been some recent progress on problems of this type [42.14] and will consider this case in Sect. 42.9.

## 42.2 Selection Methods

The selection method is the primary means a genetic algorithm has of directing the search process toward better solutions. It is usually defined in terms of a *fitness function* which assigns a positive score to each point in the search space, with the optimal solution having the maximum (or minimum) fitness. Often the fitness function is, in fact, just the objective function of the problem to be optimized, however, there are times when this can be modified. This typically happens when the problem involves some constraints, and so account has to be taken as to what extent the constraints are satisfied. There are a number of different ways to approach this situation:

1. Simply discard any illegal solution and try again. That is, if mutating (say) a solution produces an illegal solution, discard it and try mutating the original again, until a legal solution is obtained.
2. Repair the solution. This involves creating a special purpose heuristic which, given any illegal solution, modifies it until it becomes legal.
3. More generally, one can construct modified operators which are guaranteed to produce legal solutions. The above two methods are specific ways one might achieve this.
4. Adapt the fitness function by adding penalty terms.

It is this fourth approach which concerns us here, as it allows illegal solutions to be tolerated, but puts the onus on the selection method to drive the population away from illegal and toward legal solutions. The idea is to create a fitness function which is a weighted sum of the original objective function, and a measure of the extend to which constraints have been broken. That is,

if  $h : X \rightarrow \mathbb{R}$  is the objective function, we might have a fitness function

$$f(x) = w_0 h(x) - \sum_{j=1}^k w_j c_j(x),$$

where  $c_j$  is a measure as to how far constraint  $j$  has been broken. A difficulty with this approach is in specifying the weights, since one would like to allow illegal solutions to be tolerated (at least in the early stages of the search), but do not want good, but illegal solutions to wipe out any legal ones. It is common, then, to try to fix the weights at least so that legal solutions are preferred to illegal ones (however good). This, then, suggests a fourth approach which works particularly well with tournament selection (see below), in which it is only necessary to say which of two solutions is to be preferred. We stipulate that legal solutions are to be preferred to illegal ones that two legal solutions should be compared with the objective function and that two illegal solutions should be compared by the extent of constraint violation.

The degree to which poor, or illegal, solutions are tolerated by a genetic algorithm is determined by the strength of the selection method chosen. A weak selection method will allow poor (that is, low fitness) solutions to be selected with high probability compared to a strong scheme, which will typically select better solutions. It is usual to insist that a selection scheme should have the property that a better solution should have a higher probability of being selected than a weaker one. A number of selection methods have been

proposed, ranging from very weak to very strong, and we will consider them in this order.

### 42.2.1 Random Selection

The weakest selection method is simply to pick a member of the population uniformly at random. Of course, this has no selection strength at all and will not, by itself, guide the search process. It must therefore be combined with some other mechanism to achieve this. Typically, this would be used in a steady-state genetic algorithm, in which the replacement strategy imposes the selection pressure (Sect. 42.3). Another possibility is in a parallel genetic algorithm where offspring may replace parents if they are better, but the selection of partners for crossover is random (Sect. 42.8).

### 42.2.2 Proportional Selection

The fitness proportional selection method comes from taking the analogy of the role of fitness in natural evolution seriously. In biological evolution, fitness is literally a measure of how many offspring an individual expects to have. Within the fixed-sized population of a genetic algorithm, then, we model this by saying that the probability of an individual being selected should be proportional to its fitness within the population. That is, the probability of selecting item  $x$  is given by

$$\frac{f(x)}{\sum_y f(y)},$$

where the sum ranges over all members of the population. This selection method is often implemented by the *roulette wheel* algorithm as follows:

1. Let  $T$  be the total fitness of the population.
2. Let  $R$  be a random number in the range  $0 \leq R < T$ .
3. Let  $c = 0$ . Let  $i = 0$ .
4. While  $c < R$  do
  - a) Let  $c = c + f(i)$
  - b) Let  $i = i + 1$ .
5. Return  $i$ .

where  $f(i)$  is the fitness of the item with index  $i$  in the population.

### 42.2.3 Stochastic Universal Sampling

In a generational genetic algorithm, one needs to select  $\mu$  individuals from the population in order to complete one generation. Using proportional selection to

do this therefore requires  $O(\mu^2)$  time, which can be a significant burden on the running time. An alternative selection algorithm, which still ensures that the expected number of times an individual is selected is proportional to its fitness, is the stochastic universal sampling algorithm [42.15]. If  $T$  is again the total fitness of the population, then let

$$E[i] = \frac{f(i)}{T} \mu,$$

which is the expected number of copies of item  $i$ . The selection algorithm guarantees that either  $\lfloor E[i] \rfloor$  or  $\lceil E[i] \rceil$  copies of  $i$  are selected, for each item  $i$  in the population:

1. Let  $r$  be a random number in the range  $0 \leq r < 1$ .
2. Let  $c = 0$ .
3. For  $i = 0$  to  $\mu - 1$  do
  - a) Let  $c = c + E[i]$ .
  - b) While  $r < c$  do:  $r = r + 1$ ; Select( $i$ ).

By the time the algorithm terminates,  $\mu$  items will have been selected, in  $O(\mu)$  time (for a good introduction to asymptotic notation [42.16]).

### 42.2.4 Scaling Methods

In the early stages of a run of a genetic algorithm, there is usually considerable diversity in the population, and the fitness of the best individuals may be considerably greater than the others. When using fitness proportional selection, this can lead to strong selection of the better individuals. Later on when the algorithm is nearing the optimum, the population is less diverse, and fitnesses may be more or less constant. In this situation, proportional selection is very weak, and does not discriminate.

One idea to combat this problem is to scale the fitness function somehow, so as to adjust the selection strength during the run. Two proposals along these lines are *sigma scaling* and *Boltzmann selection*. Sigma scaling (invented by Stephanie Forrest and described in [42.2] and [42.4]) explicitly takes the diversity of the population into account via the standard deviation  $\sigma$  of the fitness in the population. Given the fitness function  $f : X \rightarrow \mathbb{R}$ , the new scaled fitness is

$$h(x) = 1 + \frac{f(x) - \bar{f}}{2\sigma},$$

where  $\bar{f}$  is the average fitness of the population. A negative value of  $h(x)$  might be clamped at zero or some

small value. The idea behind sigma scaling is that now when there is a lot of diversity,  $\sigma$  is large, and so the best individuals will not dominate the selection process so much. However, when diversity is low, so is  $\sigma$  and the scaled fitness function can still discriminate effectively.

The second proposal, Boltzmann selection, makes use of the idea that the diversity (and therefore strength of selection) is lost over time [42.17]. We therefore seek to scale the fitness using the time (or generation number) as a parameter. This is usually done in the same way as simulated annealing, by controlling a *temperature* parameter  $T$ , which is initially large, but decreases over time. We have a scaled fitness of

$$h(x) = \exp\left(\frac{f(i)}{T}\right).$$

Of course, a difficulty with this approach is to select the appropriate *cooling schedule* by which  $T$  should decrease over time.

### 42.2.5 Rank Selection

We have seen that one of the major drawbacks of the proportional selection method, and stochastic universal sampling, is that the probability of choosing individuals is very sensitive to the relative scale of the fitness function. For example, an item with fitness 2 is twice as likely to be chosen as an item of fitness 1. But an item of fitness 101 is almost as likely to be chosen as one with fitness 100. It is therefore suggested that selection should depend only on the relative strength of the individual within the population. One way to achieve this is to choose an individual depending on its *rank*. That is, we sort the population using the fitness function, but then ascribe a rank to each member, with the best individual getting score  $\mu$  down to 1, for the worst [42.18].

The simplest thing to do then is to choose individuals proportional to rank, using the roulette wheel or stochastic universal sampling algorithms. However, this is then sensitive to the population size. So a common alternative is to linearly scale the rank to achieve a score between two numbers  $a$  and  $b$ . We thus get a function

$$h(i) = \frac{(b-a)r(i) + \mu a - b}{\mu - 1},$$

where  $r(i)$  is the rank of item  $i$  in the population. We then seek to select items in proportion to their  $h$ -value. This can be done with the roulette wheel or stochastic universal sampling method. Notice that since the sum

of ranks is known, so is the sum of  $h$ -values, and so the probability of selecting item  $i$  is

$$\frac{2((b-a)r(i) + \mu a - b)}{\mu(\mu-1)(b+a)}.$$

### 42.2.6 Tournament Selection

A much simpler way to achieve a similar end as rank selection is to use tournament selection. We fix a parameter  $k \leq \mu$ . To select an item from the population we simply do the following:

1. Choose  $k$  items from the population, uniformly at random.
2. Return the *best* item from those chosen;

where *best* refers, of course, to assessment by the fitness function. Perhaps the most common version is binary tournament selection, where  $k = 2$ . In this case, it is not strictly necessary to have a fitness function assign a numerical value to points in the search space. All that is required is a means to compare two points and return the preferred one.

It is straightforward to show that the probability of choosing item  $i$  from the population is

$$\frac{2r(i)-1}{\mu^2},$$

where  $r(i)$  is the rank from 1 (the worst) to  $\mu$  (the best). If one chooses the two items to be compared without replacement, then the probability of choosing item  $i$  becomes

$$\frac{2r(i)-2}{\mu(\mu-1)},$$

which is equivalent to rank selection, linearly scaled with  $a = 0$  and  $b = 1$ .

At the other extreme, if one were to pick the tournament size to be very large (close to  $\mu$ ) then it becomes more and more likely that only the best individuals will be selected. Increasing the tournament size in this way is a good method for controlling the selection strength.

### 42.2.7 Truncation Selection

The strongest selection method of all would be to only select the best individual. Slightly more forgiving is truncation selection, where only individuals within a given fraction of top performers are selected. In a generational genetic algorithm, these must be repeatedly

selected at random. In a steady-state algorithm one simply picks one of them at random. Truncation selection, therefore, introduces a new parameter, which is the fraction of the population available for selection. This may

vary from, say, a half (rather weak) to a tenth (rather strong). Usually, this must be done experimentally, as there is little theoretical analysis of this form of selection for combinatorial problems.

## 42.3 Replacement Methods

The steady-state genetic algorithm requires a method by which a new offspring solution can be placed into the population, replacing one of the existing members. As with selection, there are different approaches, which have different *strengths* in terms of the extent to which it drives the population to retain better solutions. Indeed, most of the methods for replacement are based on those already described for selection (Sect. 42.2).

### 42.3.1 Random Replacement

A simple method commonly found in steady-state genetic algorithms is for the new solution to replace an existing member chosen uniformly at random. If this is done, then the replacement phase does not push the search process in any particular direction and the onus for evolving toward better solutions is on the selection method chosen. Because of this, it is commonly supposed that a steady-state genetic algorithm with random replacement is more or less equivalent to a generational genetic algorithm, using the same selection method. This is not quite true; however, it can be shown theoretically that the long-term behavior of both algorithms will be the same [42.19]. What will not necessarily be the same is the short term, transient behavior and, in particular, the speed with which the algorithms will arrive at their long-term *equilibrium* may well be different.

### 42.3.2 Inverse Selection

Several replacement methods are based directly on selection methods, but changed so that the poorer performing solutions are more likely to be replaced than the better ones. For example, one can construct an *inverse fitness proportional* replacement method, where the probability of being replaced is determined by the fitness. In order to ensure that lower fitness means a higher chance of replacement, the reciprocal of the fitness might be used to determine the probability of replacement. Alternatively, the fitness can be subtracted from that of the global optimum (if known). This would

have the advantage that the optimum, if found, would never be replaced. In this case, the probability that item  $i$  in the population is selected for replacement will be

$$\frac{f^* - f(i)}{\mu f^* - \sum_j f(j)},$$

where  $f^*$  is the optimum fitness value.

Replacement determined by fitness has the same drawbacks as selection done in this way. For example, toward the end of the search all the population members will have similar fitness values. Fitness proportional replacement will then be almost as likely to replace the best individual as the worst. Consequently, an alternative method using scaling or rank might be preferred. The simplest of these ideas is to use a tournament, but this time pick the worst of the sample:

1. Choose  $k$  items from the population, uniformly at random without replacement.
2. Return the worst item from those chosen.

This has the advantage that the best item in the population cannot be replaced.

### 42.3.3 Replace Worst

Perhaps the most common choice of replacement strategy is to simply replace the worst member of the population with the new offspring. This is a relatively strong approach, as it preserves all the better members of the population. Indeed, this strategy can well be combined with the random selection method, and using only replacement as the means of driving the evolution toward better individuals.

An even stronger variant would be to replace the worst member of the population only if the new offspring is better or equal in value. This has the property that the minimum fitness of the population can never decrease, and so we are guaranteed progress throughout the evolution. In some cases, this may lead to much faster evolution. However, it may also happen that for a long time, no new individuals are added to the pop-

ulation. This will be increasingly the case toward the end of a run, when it is increasingly hard to create better individuals. Replacing the worst member, regardless of how good or bad the new offspring, at least keeps adding new search points and creates new possibilities for further exploration, while retaining copies of the better solutions in the population.

#### 42.3.4 Replace Parents

A different idea for choosing which element to replace is for the offspring to replace the parent (or parents). This would have an advantage in maintaining some level of diversity (Sect. 42.7) since the offspring is likely to be similar to the parent. The simplest way to do this, in the case when mutation but not crossover is used is for the offspring to replace the parent if it is better. If the selection process is purely random, then this amounts to running a number of local search algorithms in parallel, as there is no interaction between the individuals in the population.

A variation on this is when there is crossover, which requires the selection of a second parent (Sect. 42.6). In this case, it makes sense for the offspring to replace the worst of the two parents, guaranteeing that the best individual is never replaced. This is the idea behind the so-called *microbial* genetic algorithm [42.20], which is a steady-state genetic algorithm, with random selection, standard crossover, and mutation (Sects. 42.4 and 42.6), with the offspring replacing the worst parent:

1. Generate random population.
2. Repeat until stopping criterion satisfied:

- a) Select two individuals from the population uniformly at random.
- b) Perform crossover and mutation.
- c) Let the new offspring replace the worst of the two parents.

3. Stop.

A further variation possible if crossover is used is to create two offspring and for them to replace both parents under some suitable conditions. Possibilities include:

- If at least one offspring is better than both parents.
- If both offspring are no worse than the worst parent.
- If one offspring is better than both parents and the other is better than one of them.

This is the idea behind the *gene invariant genetic algorithm* [42.21]. It is designed for use on search spaces given by fixed length binary strings. We arrange for the initial population to be constructed such that for every random string generated, we also include its bitwise complement. This ensures an equal number of ones and zeros at each bit position in the population. When crossover takes place between two parents, if we keep both possible offspring, then we maintain the number of ones and zeros. This arrangement naturally maintains a lot of diversity in the population, without even the necessity to include mutation. Early empirical studies suggested that this approach would be very good at avoiding certain kinds of *traps* in the search space. There seems to have been very little work following up this suggestion, however (although [42.22] for the analysis of a (1 + 1) version of the algorithm).

### 42.4 Mutation Methods

Whereas selection and replacement focus the genetic algorithm on a subset of its population, the mutation and crossover operators enable it to sample new points in the search space. The idea behind mutation is that, having selected a good member of the population, we should try to create a variant with the hope that it is even better. To do this, it is often possible to make use of some natural or well-established local search operators for the problem class concerned. For example, for the traveling salesman problem, the well-known 2-opt operator works by reversing a random segment of the selected tour [42.23, 24]. This immediately provides us with a way of mutating solutions for this problem class.

Similarly, when solving the Knapsack problem, it is often helpful to exchange items, and this too gives us a good idea how to mutate.

Generally speaking, mutations are defined by choosing a representation for the points of the search space, and then defining a set of operators to act on that representation. For example, many combinatorial optimization problems concern choosing an optimal subset of some set. We can represent the search space, the collection of all subsets, using binary strings with length equal to the size of the set. Each position corresponds to a set element, and we use 0 and 1 to distinguish whether or not an element is included in a particular subset. We

then define a collection of operators with which to act upon the representation. For example, the action of removing or adding an item to the subset is very natural, and is given by simply flipping the bit at the appropriate position. If there are  $n$  bits in the representation, then this would give us  $n$  corresponding operators. In order to mutate a bitstring, one chooses an operator at random and applies it.

In order to exchange an item in a subset with one that is not, we must simultaneously flip a 1 to a 0 and a 0 to a 1. If the subset has  $k$  elements, then there are  $k(n - k)$  ways to do this, giving us another possible set of operators.

Perhaps the most common choice of mutation for binary strings is to randomly flip each bit independently with a fixed probability  $u$  called the *mutation rate*. This corresponds to flipping a subset of bits of size  $k$  with probability  $u^k(1-u)^{n-k}$ . Very often, the mutation rate is set to  $u = 1/n$ . This is popular because, while it favors single bit mutations, there is a significant probability of flipping two or more bits, enabling exchanges to take place. Notice, however, that there is a probability of  $(1 - 1/n)^n \approx 1/e$  that nothing happens at all. While this clearly slows down evolution by an almost constant factor, it is not necessarily a bad thing to have a significant probability of doing nothing – it can sometimes prevent evolution rushing off down the wrong path (Sect. 42.5).

While the mutation rate  $u = 1/n$  is the most commonly recommended, the best value to choose depends on the details of the problem class, and the rest of the genetic algorithm being used [42.25]. For example, the simple  $(1 + 1)$  EA maintains a single point of the search space which it repeatedly mutates – replacing it only if a better offspring occurs. For linear functions, the choice of  $u = 1/n$  is provably optimal for the class of linear functions [42.26]. However, it can be shown that for the so-called leading ones problem, in which the fitness of a string is simply the position of the first zero, the optimal mutation rate for the  $(1 + 1)$  algorithm is in fact close to  $1.59/n$  [42.27].

For a more general approach to defining a mutation operator, one could assign a probability to each subset of bits, and flip such a subset with the given probability. This corresponds to defining a probability distribution over the set of binary strings  $\pi$ . To mutate a string  $x$ , we

choose another string  $y$  with probability  $\pi(y)$  and return the result  $x \oplus y$ , where the  $\oplus$  symbol represents bitwise exclusive-or [42.28]. This general method has the property that it is invariant with respect to the labels 0 and 1 to represent whether or not an item is in a given subset. One might also wish mutation to be invariant with respect to the ordering of the  $n$  elements of the underlying set, so that the performance of the genetic algorithm is not sensitive to how this order is chosen. To do this requires a much more restricted mutation operator. One must specify a probability distribution over the numbers  $0, 1, \dots, n$  and then, having chosen a number according to this distribution, flip a random subset of bits of this size. Such a mutation is said to be *unbiased* with respect to bit labels (that is, the choice of 0 or 1) and bit ordering [42.29, 30].

Mutating each bit with a fixed rate is an example of an unbiased mutation operator, with the probability of flipping  $k$  bits being

$$\binom{n}{k} u^k (1-u)^{n-k}.$$

The following is an efficient algorithm to choose  $k$  according to this binomial distribution [42.31]:

1. Let  $x = y = 0$ .
2. Let  $c = \log(1 - u)$ .
3. Let  $r$  be a random number from 0 to 1.
4. Let  $y = y + 1 + \lfloor \log(r)/c \rfloor$ .
5. If  $y < n$  then let  $x = x + 1$  and go to 3. Else return  $x$ .

We can use this algorithm to perform mutation by first selecting the number of bits to be flipped and then choosing which particular subset of that size will be mutated. The above algorithm has expected running time of  $O(un)$ . If  $u$  is relatively small, one can then sample the bit positions from  $\{1, \dots, n\}$  repeating if the same index is selected twice (use a hash table to detect the unlikely event of a repeated sample). For the choice  $u = 1/n$  the random selection algorithm runs in constant time, and, for large  $n$ , the probability of having to do a repeat sample tends to zero. Consequently, performing mutation in this way is extremely efficient. An alternative method is to randomly choose the position of the next bit to be flipped [42.32].

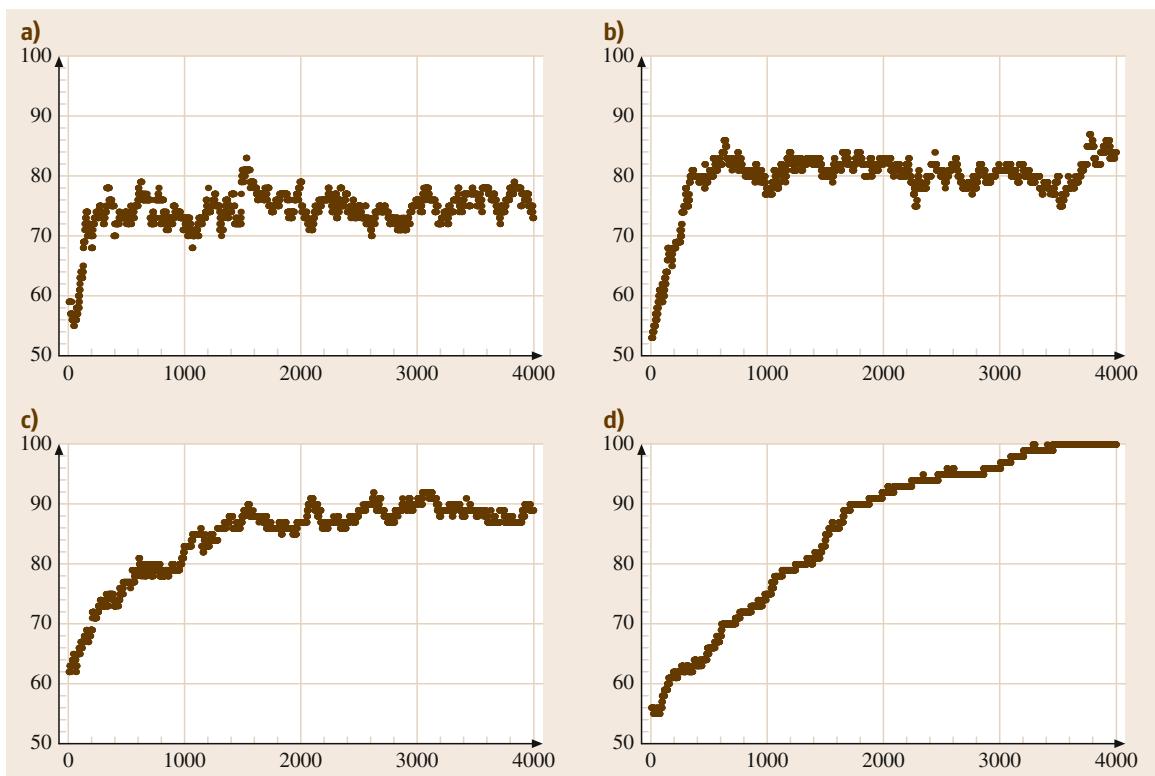

## 42.5 Selection–Mutation Balance

We are now in a position to put together a simple genetic algorithm involving selection, replacement, and mutation. Selection and replacement will focus the search on good solutions, whereas mutation will explore the search space by generating new individuals. We will find that there is a balance between these two forces, but the exact nature of the balance depends on the details of the algorithm, as well as the problem to be solved. To simplify things a little, we will consider the well-known toy problem, OneMax, in which the fitness of a binary string is the sum of its bits. For this problem, there are a number of theoretical results concerning the balance between selection and mutation, for example [42.33, 34]. For a thorough analysis of the selection–mutation balance on a LeadingOnes type problem, [42.35]. Here, we will illustrate the effects with some empirical data.

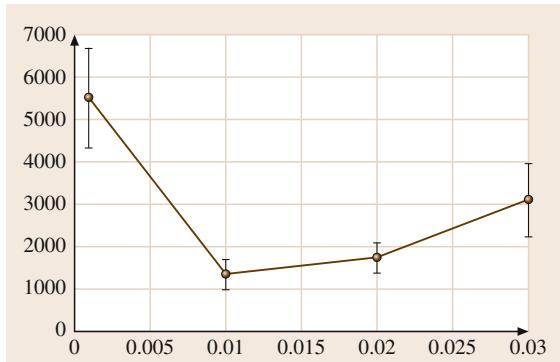

The first algorithm we will look at is the steady state genetic algorithm, using binary tournament selection,

and random replacement. As described above, the long-term behavior will be the same as for a generational genetic algorithm, with the same selection and mutation methods. Specifically, let us consider a population of size 10, fix the string length to 100 bit, and consider the effect of varying the mutation rate. In Fig. 42.1, we show four typical runs at mutation rates 0.03, 0.02, 0.01 and 0.001 respectively. We plot the fitness of the best member of the population at each generation.

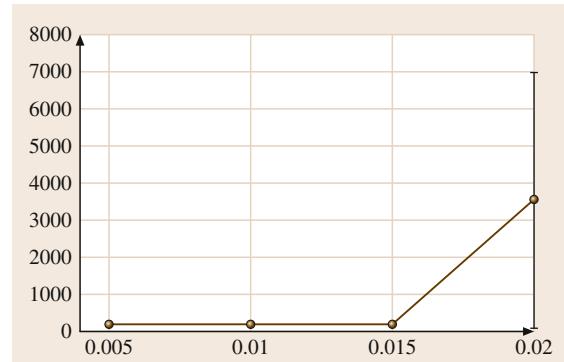

Recall that this algorithm is not elitist. This means that it is possible to lose the best individual, by replacing it with a mutant of the selected individual. It is chosen for replacement with probability of 0.1. Whether it is replaced by something better or worse depends on the mutation rate. A higher mutation rate will tend to be more destructive. We see from the plotted trajectories, that for higher mutation rates, the algorithm converges to a steady state more quickly (around generation 200 in the case of mutation rate of 0.03) but to

**Fig. 42.1a–d** Trajectories of best of population for steady-state GA with random replacement on OneMax problem (100 bit). (a) Mutation rate = 0.03; (b) mutation rate = 0.02, (c) mutation rate = 0.01, (d) mutation rate = 0.001

**Fig. 42.2** Average time taken to optimize OneMax (100 bit) for steady-state GA with worst replacement, with varying mutation rates

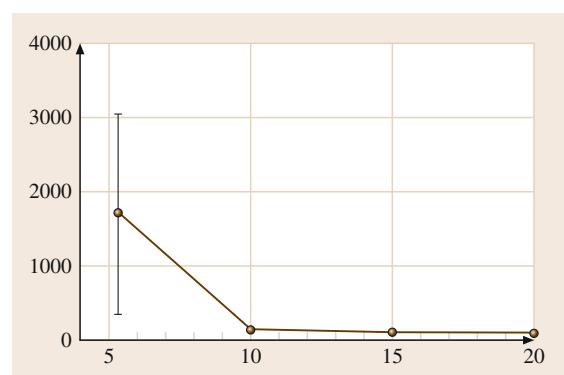

**Fig. 42.3** Average time taken (generations) to optimize OneMax (100 bit) for generational GA with best selection, population size 10, and various mutation rates

a poor quality solution (average fitness around 74). As the mutation rate is reduced, the algorithm takes longer to find the steady state, but it is of higher quality. For the smallest mutation rate shown, 0.001, the run illustrated takes 3500 generations to converge, but this includes the optimal solution.

Since the OneMax problem is simply a matter of hill-climbing, we can improve matters by using an elitist algorithm. So we now consider the steady-state genetic algorithm, again with binary tournament selection, but this time replacing the worst individual in the population. In this setup, we cannot lose the current best solution in the population. We quickly find experimentally that for reasonable mutation rates, we can always find the optimum solution in reasonable time. However, again there is a balance to be struck between selection strength and mutation. If mutation is too high, it is again destructive, which slows down progress. If it is too low, we wait for a long time for progress to be made. There is now an optimal mutation rate to be sought. Figure 42.2 shows the average time to find the optimum for the same four different mutation rates (0.03, 0.02, 0.01, 0.001). The average is taken over 20 runs. We can clearly see that the best tradeoff is obtained with the mutation rate of 0.01 in this case, with an average of around 1400 generations required to find the optimum. This rate equals one divided by the string length, and is a common choice for EAs.

It is not strictly necessary to implement an elitist strategy to obtain reasonable optimisation performance. Consider instead a generational genetic algorithm in which our selection is the strongest possible – we always pick the best in the population. This is not technically elitist, as we apply muta-

**Fig. 42.4** Average time taken (generations) to optimize OneMax (100 bit) for generational GA with best selection, mutation rate 0.01, and various population sizes

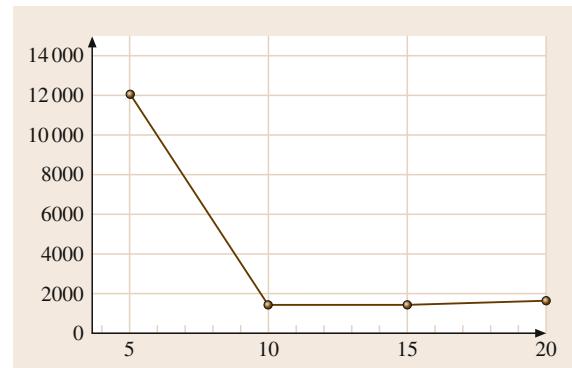

tion to the selected individual, which means there is a chance it is lost. However, if there is a reasonable population size, and the mutation rate is not too large, then there is a good chance that a copy of the best individual will be placed in the next generation. This in effect simulates elitism [42.36]. Yet again there is a balance between selection and mutation, this time depending on the population size. If the mutation rate is high, then we will need a large population to have a good chance of preserving the best individual. Smaller mutation rates will allow smaller populations, but will slow down the evolution.

Consider first a population of size 10, and a range of mutation rates: 0.005, 0.01, 0.015 and 0.02. Figure 42.3 shows the average time to find the optimum for our generational genetic algorithm. We see that it is very

efficient for sufficiently low mutation rates (only 125 generation when the mutation rate is 0.01). However, there is a transition to much longer run times when the mutation rate gets higher (2500 generations when the mutation rate is 0.02).

Conversely, we can consider fixing the mutation rate at 0.01 and varying the population size. Figure 42.4 shows the optimisation time in generations for populations of size 5, 10, 15 and 20. Again we see evidence of a transition from long times (when the population is too small) to very efficient times with larger populations (as low as 80 generations when the population size is 20). However, we have to bear in mind that a generational genetic algorithm has more fitness function evaluations per generation than a steady-state genetic algorithm. Thus we cannot keep increasing the population size indefinitely without cost. Figure 42.5 shows the number of fitness function evaluations required to find the optimum. We see that, of the examples shown, a population of size 10 is best (requiring an average of 1374 evaluations).

The exact tradeoff between mutation rate and population size can be calculated theoretically. If the number of bits is  $n$ , and the mutation rate is  $1/n$ , it can be

**Fig. 42.5** Average time taken (fitness function evaluations) to optimise OneMax (100 bit) for generational GA with best selection, mutation rate 0.01, and various population sizes

shown that there is a transition between exponential and polynomial run time for the OneMax problem when the population size is approximately  $5 \log_{10} n$ . Indeed it can be shown that this is a lower bound on the required population size to efficiently optimize any fitness function with unique global optimum [42.37].

## 42.6 Crossover Methods

Crossover (or recombination) is a method for combining together parts of two different solutions to make a third. The hope is that good parts of each parent solution will combine to make an even better offspring. Of course, we might also be recombining the bad parts of each parent and come up with a worse solution – but then selection and replacement methods will filter these out.

Several methods exist for performing crossover, depending on the representation used. For binary strings, there are three common choices. One-point crossover chooses a bit position at random and combines all the bit values below this position from one parent, with all the remaining bit values from the other. Thus, given the parents

$$\begin{array}{l} 01001101, \\ 11100111 \end{array}$$

if we choose the fifth position for our cut point, we obtain the offspring solution

$$01000111.$$

Similarly, for two-point crossover, we choose two bit positions at random. The bit values between these two cut points come from one parent, and the remaining values come from the other. Thus, with the same two parents, choosing cut positions 2 and 6 produces the offspring

$$01100101.$$

Both one- and two-point crossovers have the property of being biased with respect to the ordering of bits. If the problem representation has been chosen so that this order matters, then such a crossover may confer an advantage as they tend to preserve values that are next to each other. For example, if the problem relates to finding an optimal subset, and the elements of the set have been preordered according to some heuristic (e.g. a greedy algorithm), then one- or two-point crossover may be appropriate. If, however, the order of the bits is arbitrary, then one should choose a method which is unbiased with respect to ordering. The common choice is called uniform crossover, and involves choosing bit values from either parent at random. One way of implementing this would be to generate a random bit

string and let the values in this string (or mask) determine which parents the bit values should come from. For example, using again the two parents above, if we generate the random mask 0 1 0 1 0 1 0 1, we get the offspring

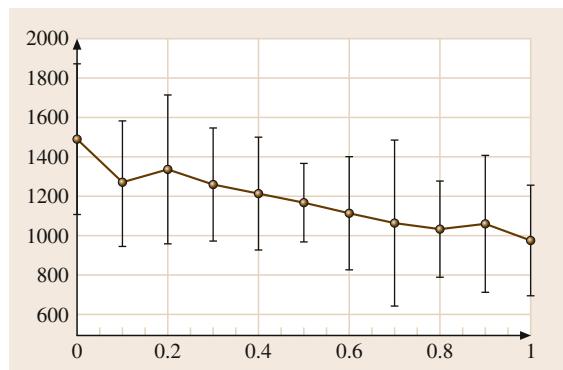

0 1 0 0 1 1 0 1.

This leads to a more general view of crossover: We specify a probability distribution  $\pi$  over the set of binary strings and, to perform crossover, we select a string according to this distribution and use it as a mask [42.5]. Uniform crossover corresponds to a uniform distribution. One-point crossover corresponds to selecting only masks of the form 0 ... 0 1 ... 1. It can be shown that crossover by masks in general is always unbiased with respect to changes in labels of bit values (that is, exchanging ones for zeros). If we also require crossover to be unbiased with respect to bit ordering, then it is necessary and sufficient that masks containing the same number of ones are selected with the equal probability.

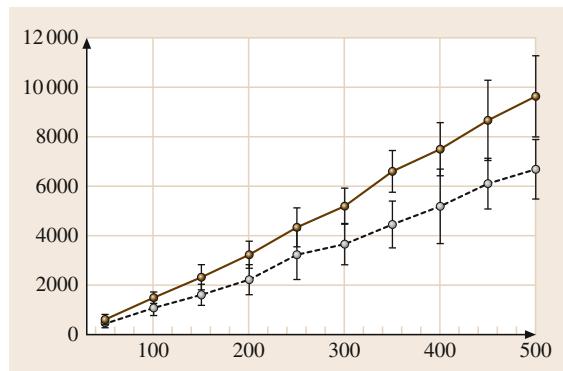

Any crossover by masks also has the nice property that if both parents agree on a bit position, then the offspring will also share the same value at that position. Such crossovers are called respectful, and emphasize the idea that one is trying to preserve structure found in the parents [42.38, 39]. It can be shown that such properties can be understood geometrically [42.40].

Our understanding on when crossover can be helpful is rather limited and there are many open questions. For example, continuing to look at the OneMax problem, we can examine experimentally whether or not crossover helps. Let us keep to the steady-state algorithm with tournament selection and replacement of the worst individual. We modify the algorithm by allowing, with a given probability, crossover to take place between the selected individual and a randomly chosen one. Our algorithm therefore is as follows:

1. Initialize population of size  $\mu$  randomly with points from the search space.
2. Repeat until stopping criterion is satisfied:
  - a) Choose a member of the population using binary tournament selection.
  - b) With probability  $p$ , crossover selected individual with one chosen randomly from the population.
  - c) Modify the result with *mutation* using rate  $1/n$ .
  - d) Replace worst member of population with the new offspring.
3. Stop.

**Fig. 42.6** Average time taken to optimize OneMax (100 bits) for generational GA with tournament selection, mutation rate 0.01, population size 10, and varying crossover probabilities

**Fig. 42.7** Average time taken to optimize OneMax for various string lengths for generational GA with tournament selection, mutation rate  $1/n$ , population size 10. Solid line is with no crossover. Dotted line is with uniform crossover with probability 1

We first consider an experiment on OneMax with  $n = 100$ . We use a population of size 10, and vary the crossover probability between 0 and 1. The results are shown in Fig. 42.6, which shows the average time to find the optimum (averages over 20 runs). It can be seen that there is some improvement as the crossover rate increases, although the results are rather noisy (error bars represent one standard deviation). Examining this case further, we compare the steady-state genetic algorithm with no crossover ( $p = 0$ ) with uniform crossover ( $p = 1$ ) for different string lengths. The results are shown in Fig. 42.7. Here it is clear that there is significant improvement, which appears to be increasing as the string length grows. To date, there

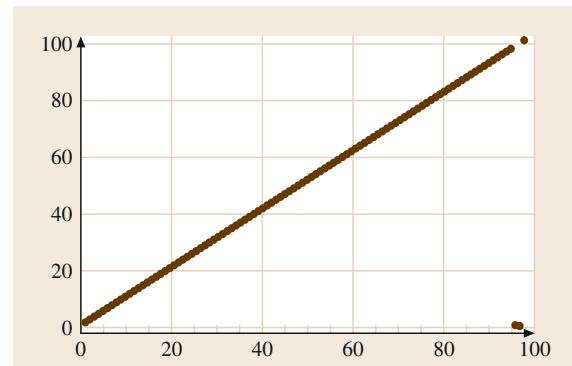

is no theoretical analysis of why this should be the case.

The first example of a problem class for which crossover can provably help is the following [42.12, 41]. We take the OneMax function, and then create a trap just before the optimum

$$\text{jump}(x) = \begin{cases} 0 & \text{if } \theta \leq \|x\| < n, \\ \|x\| & \text{otherwise,} \end{cases}$$

where  $\|x\|$  is the number of ones in  $x$  (Fig. 42.8 for an illustration). The idea is that the population first climbs the hill to the threshold  $\theta$  just before the trap. It is then rather unlikely that a single mutation event will create a string that crosses the gap and finds the global optimum. However, crossing over two strings with just a few zeros in each may have a better chance of jumping the gap, especially if the zeros occur in different places in the two parents. To achieve this, some level of diversity must be maintained in the population – a subject discussed further in Sect. 42.7.

For problem classes in which solutions are not naturally represented by binary strings, one has to think carefully about the best way to design a crossover operator. For example, take the case of the traveling salesman problem, in which a solution is given by a permutation of the cities, indicating the order in which they are to be visited. Over the years, a number of different

**Fig. 42.8** The  $\text{jump}(x)$  function for string length  $n = 100$ , with threshold  $\theta = 98$

crossover methods have been proposed. For the most part, these were designed so as to be respectful of the positions of the cities along the route. That is, if a particular city was visited first by both parents, then it would also be visited first by the offspring. However, a much more effective approach is to try to preserve the *edges* between adjacent cities in a route. That is, if city A is followed immediately by city B by both parents, irrespective of where this takes place in the route, then we should try to ensure that this also happens in the case of offspring. This kind of crossover is called an edge recombination operator [42.42].

## 42.7 Population Diversity

For most forms of crossover, if one crosses an individual with itself, the resulting offspring will again be the same. Crossovers with this property are said to be pure [42.39]. This is certainly a property of one-point, two-point and uniform crossovers for binary strings. There is therefore no point in performing crossover if the population largely comprises copies of the same item. In fact, the whole idea of the population is rather wasted if this is the case. Rather, the hope is to gain advantage by having different members of the population search different parts of the search space. It seems important, therefore, to maintain a level of diversity in the population.

The importance of this can be seen in solving the  $\text{jump}(x)$  problem described earlier in Sect. 42.6. Once the population has arrived at the local optimum, the individuals will typically contain  $\theta - 1$  ones, and the rest zeros. If the zeros tend to fall in the same bit po-

sitions for each member of the population, then it will be impossible for crossover to jump across the gap. For example, crossing

1 1 1 1 1 1 1 0 0 0

and

1 1 1 1 1 1 0 1 0 0

cannot produce the optimum. If, however, we can ensure that diversity in the population, then two members at the local optimum might be

1 1 1 1 1 1 1 0 0 0

and

0 1 1 0 1 1 0 1 1 1 ,

which has a reasonable chance to jump the gap.

Several different mechanisms have been proposed to ensure some diversity is maintained in a population. The simplest way is to enforce it directly by not allowing duplicate individuals in the population [42.43]. So if an offspring is produced which is the same as something already in the population, we just discard it.

A second method is to adjust the replacement method in a steady-state genetic algorithm, by making sure the new offspring replaces something similar to itself. For example, one could have a replacement rule that makes the offspring replace the population member most similar to it (as measured by the Hamming distance). This method, called *crowding* will, of course, destroy the elitism property [42.44]. This can be salvaged by only doing the replacement if the offspring is at least as good as what it replaces.

A third approach to diversity is to explicitly modify the fitness function in such a way that individuals receive a penalty for being too similar to other population members [42.45]. This idea is called fitness sharing. We think of the fitness function as specifying a resource available to individuals. Similar individuals are competing for the resource, which has to be shared out between them.

A fourth approach is to limit the choice of the partner for crossover. So far, our algorithms have chosen the crossover partner uniformly at random. One could instead, try to explicitly choose the most different individual in the population [42.46].

We test these various methods using the  $\text{jump}(x)$  problem of the previous section. Recall that for the population to jump across the gap requires a crossover between two diverse individuals. We work with a string length  $n = 100$  and a threshold  $\theta = 98$ . As a baseline, consider the steady-state genetic algorithm, with binary

**Table 42.1** Success of various diversity methods in solving the  $\text{jump}(x)$  problem. Each is tested for 20 trials, to a maximum of 10 000 fitness function evaluations. Mean and standard deviation refer just to successful runs

| Method         | Percentage successful runs (%) | Mean evaluations | Standard deviation |
|----------------|--------------------------------|------------------|--------------------|
| None           | 5                              | 8860             | —                  |
| No duplicates  | 80                             | 3808             | 2728               |
| Crowding       | 100                            | 1320             | 389                |

| Partner choice | 10                             | 688              | 113                |

tournament selection, replacement of the worst, uniform crossover (probability 1) and mutation rate 0.01. In 20 trials on the  $\text{jump}(x)$  function, only once did this algorithm succeed in finding the optimum within 10 000 generations. On that one successful run, it required 8860 evaluations to complete. We compare this result with the same algorithm, modified in each of the four diversity-preserving methods above. In the case of fitness sharing, we simply penalize any individual which has multiple copies in the population by subtracting the number of copies from the fitness (It should be noted that there are different ways of doing this, and the original method is far more complicated.). The results of the experiments are summarized in Table 42.1. The best result is given by the crowding mechanism, but notice that it is essential to preserve elitism here, otherwise the algorithm never solves the problem within 10 000 generations.

A different approach altogether is to structure the population in some way, so as to prevent certain individuals interaction. We take up this idea, in a more general context, in the following section.

## 42.8 Parallel Genetic Algorithms

There have been a number of studies of different ways to parallelize genetic algorithms. There are two basic methods. The first is the *island* model, in which we have several populations evolving in parallel, which occasionally exchange members [42.47]. To specify such an algorithm, one needs to decide on the topology of the network of populations (that is, which populations can exchange members) and the frequency with which migrations can take place. We also need a method to decide on which individuals should be passed, and how they should be incorporated into the new population.

That is, we need a form of selection and replacement for the migration stage.

As an example, consider having several steady-state genetic algorithms operating in parallel. After a certain number of generation, we choose a member of each population to migrate – for example, the best one in each population. We copy this individual to the neighboring populations, according to the chosen topology. To keep things simple, we choose the complete topology, in which every pair of populations is connected. Thus, each population receives a copy of the best from

all the other populations. These now have to be incorporated into the home population somehow. An easy method is to take the best of all the incoming individuals, and use it to replace the worst in the current population. Such an algorithm will look like this:

1. Create  $m$  populations, each of size  $\mu$ .
2. Update each population for  $c$  generations.
3. For each population, replace the worst individual by the best of the remaining populations.
4. Go to 2.

To take an extreme case, if the population size is  $\mu = 1$  and we migrate every generation ( $c = 1$ ), then this is rather similar to a  $(1, m)$  EA.

There are two possible advantages of the island model. Firstly, it is straightforward to distribute it on a genuinely parallel processing architecture, leading to performance gains. Secondly, there may be some problem classes for which the use of different populations can help. The idea is that different populations may explore different parts of the search space, or develop different partial solutions. The parameter  $c$  is chosen large enough to allow some progress to be made. The migration stage then allows efforts in different directions to be shared, and workable partial solutions to be combined. Some recent theoretical progress has been made in analyzing this situation for certain problem classes [42.48].

A particular case of such a model is found in *co-evolutionary* algorithms. These come in two flavors: competitive and co-operative. In a competitive algorithm, we typically have two parallel populations. One represents solutions to a problem, and the other represents problem instances. The idea is that, as the former population is finding better solutions, so the latter is finding harder instances to test these solutions. An early example evolved sorting networks for sorting lists of integers [42.49]. While one population contained different networks, the other contained different lists to be sorted. The fitness of a network was judged by its ability to sort the problem instances. The fitness of a problem instance was its ability to cause trouble for the networks. As the instances get harder, the sorting networks become more sophisticated.

In a co-operative co-evolutionary algorithm, the different populations work together to solve a single problem [42.50]. This is done by dividing the problem into pieces, and letting each population evolve a solution for each piece. The fitness of a piece is judged by combining it with pieces from other populations and evaluating the success of the whole. Theoretical anal-

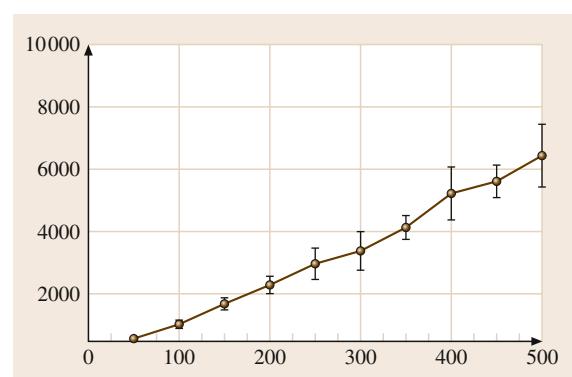

ysis shows that certain types of problems can benefit from this approach by allowing greater levels of exploration than in a single population [42.51].

The second parallel model for genetic algorithms is the *fine grained* model, in which there is a single population, but with the members of the population distributed spatially, typically on a rectangular grid [42.52]. At each time step, each individual is crossed over with a neighbor. The resulting offspring replaces the original if it is better, according to the fitness function. The algorithm looks like this:

1. Create an initial random population of size  $\mu$ .
2. In parallel, for each individual  $x$ :
  - a) Choose a random neighbor  $y$  of  $x$ .
  - b) Cross over  $x$  and  $y$  to form  $z$ .
  - c) Mutate  $z$  to form the offspring.
  - d) Replace  $x$  with the offspring if it is better.
3. Go to 2.

Notice that such an algorithm is generational, but also elitist. There has been very little analysis of this kind of architecture, although there is some empirical evidence that it can be effective, especially for problems with multiple objectives, in which different tradeoffs can emerge in different parts of the population [42.53].

To illustrate the fine-grained parallel genetic algorithm, consider a ring topology, in which the  $k$ th member of the population has as neighbors the  $(k-1)$ th and  $(k+1)$ th member (wrapping round at the ends). We try it on OneMax, with a population of size 10, using uniform crossover and, as usual, a mutation rate of  $1/n$ . The results, for a variety of string lengths, are shown

**Fig. 42.9** The average time (in fitness function evaluations) for the ring-topology parallel genetic algorithm to find the optimum for OneMax for a variety of string lengths. Population size 10, mutation rate =  $1/n$ , uniform crossover

in Fig. 42.9. We can see that the parallel algorithm is competitive with the steady-state genetic algorithm. Note that fitness function evaluations are plotted, and not generations.

The distributed nature of the population should help to maintain a level of diversity. Hence, we would expect a parallel genetic algorithm (with crossover) to perform reasonably well on the  $\text{jump}(x)$  function

of Sect. 42.6. Over 20 trials of our ring-based fine-grained algorithm, on the  $\text{jump}(x)$  function with  $n = 100$  and  $\theta = 98$ , we find that it solves the problem on all trials, requiring an average of 2924 function evaluations (standard deviation is 1483). It is therefore competitive with the simple diversity enforcement method on this problem (compare with results in Table 42.1).

## 42.9 Populations as Solutions

We finish this chapter by considering a genetic algorithm for which the population as a whole represents the solution to the problem, rather than it being a collection of individual solutions. It is therefore an example of cooperative co-evolution taking place within a single population. Moreover, it is one of the very few examples involving a population-based genetic algorithm using crossover, for which a serious theoretical analysis exists. It is one of the highlights of the theory of genetic algorithms to date [42, 14, 54, 55].

The problem we are addressing is the classical All-Pairs Shortest Path problem. We are given a graph with vertex set  $V$  (containing  $n$  vertices) and edge set  $E$  with positive weighted edges. The goal is to determine the shortest path between every pair of vertices in the graph, where length is given by summing the weights along the path.

To clarify what is meant exactly by a path, first consider a sequence of vertices,  $v_1, \dots, v_m$  such that  $(v_k, v_{k+1}) \in E$  for all  $k = 1, \dots, m-1$ . Such a sequence is called a *walk*. A *path* is then a walk with no repeated vertices. Since for any walk between two vertices there is a shorter path (by omitting any loops), we can equivalently consider the problem of finding the shortest walks between any two vertices.

The population will represent a solution to the problem for a given graph, by having each individual representing a walk between two vertices. The problem is solved when the population contains exactly the shortest paths for all of the  $n(n - 1)$  pairs of vertices.

The algorithm will be a steady-state genetic algorithm, with random selection and a replacement method which enforce diversity. For any pair of vertices we will allow at most one walk between them to exist in the population. The outline of the algorithm is as follows:

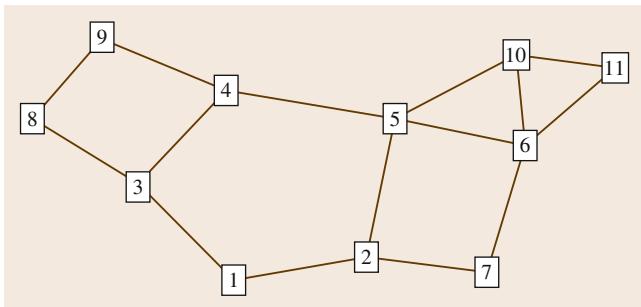

1. Initialize the population to be  $E$ .
2. Select a population member uniformly at random.

3. With probability  $p$  do crossover, else do mutation.
4. If a walk with the same start and end is in population, replace it with offspring, if offspring length is no worse.
5. If a walk with same start and end is not in population, add offspring walk to population.
6. Go to 2.

We can see from line 5 that another unusual feature of the algorithm is that the population size can grow. Indeed, it starts with just the edge set from the graph and has to grow to get the paths between all pairs of vertices.

In line 3, we see there is a choice between mutation and crossover, governed by a parameter  $p$ . Given that our individuals are walks in a graph (rather than binary strings) it is clear that we need to specify some special purpose operators. We define mutation to be a random lengthening or shrinking of a walk as follows. Suppose that the selected walk is  $v_1, v_2, \dots, v_{m-1}, v_m$ . We randomly select a vertex from the neighbors of  $v_1$  and  $v_m$ . If this is neither  $v_2$  nor  $v_{m-1}$  then we append it to the walk. If it is one of  $v_2$  or  $v_{m-1}$  then we truncate the path at that end. This process is repeated a number of times, given by choosing an integer  $s$  according to a Poisson distribution with parameter  $\lambda = 1$ . We then perform  $s + 1$  mutations to generate the offspring walk.

As an example, consider the graph illustrated in Fig. 42.10 (notice that the edge weights are not shown). Suppose we have selected the walk  $(3, 4, 5, 6)$  from the population to mutate. We choose our random Poisson variable  $s$  – let us say it is one. So we have two mutations to apply. We gather the set of vertices connected to the two end points. That is,  $\{1, 4, 8\}$  and  $\{5, 7, 10, 11\}$ , and we pick one of these at random. Let us suppose that 8 is selected. We therefore extend our walk to become  $(8, 3, 4, 5, 6)$ . For the second mutation, we again

**Fig. 42.10** An example graph for the All Pairs Shortest Path problem (edge weights not shown)

collect together the vertices attached to the end points:  $\{3, 9\}$  and  $\{5, 7, 10, 11\}$ . Choosing one at random we select, say, 5. Since this is a vertex in the walk prior to an end point, we truncate to produce the final offspring  $(8, 3, 4, 5)$ . If there is already a walk from 8 to 5 in the population, we replace it with the new one, only if the new one is in fact shorter (that is, the sum of the weights is less). If there is no such walk, then we add the new one to the population.

To perform crossover, we have to be careful to ensure that we end up with a valid walk. Suppose that the individual we have selected is a walk from  $u$  to  $v$ . We consider all the members of the population that start from  $v$ , but exclude the one that goes back to  $u$ . We then choose a member of this set, uniformly at random, and concatenate it to our original walk. This guarantees that the offspring is again a valid walk.

For example, consider again the graph in Fig. 42.10 and the selected walk  $(3, 4, 5, 6)$ . We need to first collect together all the walks in the population that start from vertex 6, excluding the one (if it exists) that goes from

6 to 3. Imagine that we find the following:

$(6, 10, 5, 2)$

$(6, 5, 2, 7)$

$(6, 11, 10)$

and we pick one at random – say, the second one. Concatenating this to the original walk produces the offspring  $(3, 4, 5, 6, 5, 2, 7)$ . Notice that this is a walk, rather than a path, since vertex 5 is repeated. If this is better than any existing walk from vertex 3 to vertex 7, then it replaces it. If there is no such walk in the population, then the new one gets added.

A considerable amount of theoretical analysis have been done for this genetic algorithm on the class of All Pairs Shortest Path problems. If we run the algorithm with no crossover (that is, we set  $p = 0$ ) then it can be shown that it requires  $\mathcal{O}(n^4)$  generations for the population to converge to the optimal set of paths. Adding crossover by choosing  $0 < p < 1$  improves the performance to  $\mathcal{O}(n^3 \log n)$ . Note that the classical approach to solving this problem (the Floyd–Warshall algorithm) requires  $\mathcal{O}(n^3)$  time, which is faster and includes all computations that have to be performed (i. e. this is not just a count of the *black box* function evaluations). Of course, the classical algorithm has full details of the problem instance on which it is working, whereas the genetic algorithm is operating *blind*. Despite this great disadvantage, the genetic algorithm only pays a cost of a factor of  $\log n$  over the classical approach (in addition to any implementation overhead).

This example is one of the only cases where we have a proof that crossover helps for a naturally defined problem class. It is an important open problem to find others.

## 42.10 Conclusions

We have seen that the defining feature of a genetic algorithm is its maintenance of a population, which is used to search for an optimal (or at least sufficiently good) solution to the problem class at hand. For problems where solutions are naturally represented as binary strings, there is an obvious analogy with an evolving population of individuals in nature, with the strings providing the **DNA**. Analogs of mutation and crossover (recombination) are then readily definable and can be used as search operators. The theory that describes the

trajectory of a population under such operators, in general terms, is well developed [42.5].

What is much less clear is the question of when all this is worth doing? That is, if our primary interest is in solving problems efficiently, in what circumstances is a genetic algorithm a good choice? To begin to answer this question requires an in-depth theoretical analysis of algorithms and problem classes. The work on this area has only just begun – most known results relate to the so-called  $(1 + 1)$  **EA** (that is, a *population* of size 1),

and very little work exists on the role of crossover. The All Pairs Shortest Path example represents the current state of the art in this respect.

Having said that, it is clear (at least empirically and anecdotally) that genetic algorithms can be very effective for complex problems, where problem instance

information is limited. Indeed, there are many successful applications of genetic algorithms presented every year at conferences, and they are a well-known tool for optimization in industry. There is, therefore, a desperate need for further theoretical work and understanding in this area.

# Genetic Programming

James McDermott, Una-May O'Reilly

Part E | 43.1

Genetic programming (**GP**) is the subset of evolutionary computation in which the aim is to create executable programs. It is an exciting field with many applications, some immediate and practical, others long-term and visionary. In this chapter, we provide a brief history of the ideas of genetic programming. We give a taxonomy of approaches and place genetic programming in a broader taxonomy of artificial intelligence. We outline some current research topics and point to successful use cases. We conclude with some practical **GP**-related resources including software packages and venues for **GP** publications.

## 43.1 Evolutionary Search for Executable Programs

There have been many attempts to artificially emulate human intelligence, from symbolic artificial intelligence (**AI**) [43.1] to connectionism [43.2, 3], to subcognitive approaches like behavioral **AI** [43.4] and statistical machine learning (**ML**) [43.5], and domain-specific achievements like web search [43.6] and self-driving cars [43.7]. Darwinian evolution [43.8] has a type of distributed intelligence distinct from all of these. It has created lifeforms and ecosystems of amazing diversity, complexity, beauty, facility, and efficiency. It has even created forms of intelligence very different from itself, including our own.

The principles of evolution – fitness biased selection and inheritance with variation – serve as inspiration for the field of evolutionary computation (**EC**) [43.9], an adaptive learning and search approach which is

general-purpose, applicable even with black-box performance feedback, and highly parallel. **EC** is a trial-and-error method: individual solutions are evaluated for fitness, good ones are selected as parents, and new ones are created by inheritance with variation (Fig. 43.1).

**GP** is the subset of **EC** in which the aim is to create executable programs. The search space is a set of programs, such as the space of all possible Lisp programs within a subset of built-in functions and functions composed by a programmer or the space of numerical C functions. The program representation is an encoding of such a search space, for example an abstract syntax tree or a list of instructions. A program's fitness is evaluated by executing it to see what it does. New programs are created by inheritance and variation of material from

**Fig. 43.1** The fundamental loop of EC

parent programs, with constraints to ensure syntactic correctness.

We define a program as a data structure capable of being executed directly by a computer, or of being compiled to a directly executable form by a compiler, or of interpretation, leading to execution of low-level code, by an interpreter. A key feature of some programming languages, such as Lisp, is *homoiconicity*: program code can be viewed as data. This is essential in GP, since when the algorithm operates on existing programs to make new ones, it is regarding them as data; but when they are being executed in order to determine what they do, they are being regarded as the program code. This double meaning echoes that of DNA (deoxyribonucleic acid), which is both data and code in the same sense.

GP exists in many different forms which differ (among other ways) in their executable representation. As in programming *by hand*, GP usually considers and composes programs of varying length. Programs are

also generally hierarchical in some sense, with nesting of statements or control. These representation properties (variable length and hierarchical structure) raise a very different set of technical challenges for GP compared to typical EC.

GP is very promising, because programs are so general. A program can define and operate on any data structure, including numbers, strings, lists, dictionaries, sets, permutations, trees, and graphs [43.10–12]. Via Turing completeness, a program can emulate any model of computation, including Turing machines, cellular automata, neural networks, grammars, and finite-state machines [43.13–18].

A program can be a data regression model [43.19] or a probability distribution. It can express the growth process of a plant [43.20], the gait of a horse [43.21], or the attack strategy of a group of lions [43.22]; it can model behavior in the Prisoner's Dilemma [43.23] or play chess [43.24], Pacman [43.25], or a car-racing game [43.26]. A program can generate designs for physical objects, like a space-going antenna [43.27], or plans for the organization of objects, like the layout of a manufacturing facility [43.28]. A program can implement a rule-based expert system for medicine [43.29], a scheduling strategy for a factory [43.30], or an exam timetable for a university [43.31]. A program can recognize speech [43.32], filter a digital signal [43.33], or process the raw output of a brain-computer interface [43.34]. It can generate a piece of abstract art [43.35], a 3-D (three-dimensional) architectural model [43.36], or a piece of piano music [43.37].

A program can interface with natural or man-made sensors and actuators in the real world, so it can both act and react [43.38]. It can interact with a user or with remote sites over the network [43.39]. It can also introspect and copy or modify itself [43.40]. A program can be nondeterministic [43.41]. If true AI is possible, then a program can be intelligent [43.42].

## 43.2 History

GP has a surprisingly long history, dating back to very shortly after von Neumann's 1945 description of the stored-program architecture [43.43] and the 1946 creation of ENIAC [43.44], sometimes regarded as the first general-purpose computer. In 1948, Turing stated the aim of machine intelligence and recognized that evolution might have something to teach us in this regard [43.45]:

*Further research into intelligence of machinery will probably be very greatly concerned with searches. [...] There is the genetical or evolutionary search by which a combination of genes is looked for, the criterion being survival value. The remarkable success of this search confirms to some extent the idea that intellectual activity consists mainly of various kinds of search.*

However, Turing also went a step further. In 1950, he more explicitly stated the aim of automatic programming (**AP**) and a mapping between biological evolution and program search [43.46]:

*We have [...] divided our problem [automatic programming] into two parts. The child-program [Turing machine] and the education process. These two remain very closely connected. We cannot expect to find a good child-machine at the first attempt. One must experiment with teaching one such machine and see how well it learns. One can then try another and see if it is better or worse. There is an obvious connection between this process and evolution, by the identifications:*

- *Structure of the child machine = Hereditary material*
- *Changes = Mutations*
- *Natural selection = Judgment of the experimenter.*

This is an unmistakeable, if abstract, description of **GP** (though a computational fitness function is not envisaged).

Several other authors expanded on the aims and vision of **AP** and machine intelligence. In 1959 *Samuel* wrote that the aim was to be able to *Tell the computer what to do, not how to do it* [43.47]. An important early attempt at implementation of **AP** was the 1958 *learning machine of Friedberg* [43.48].

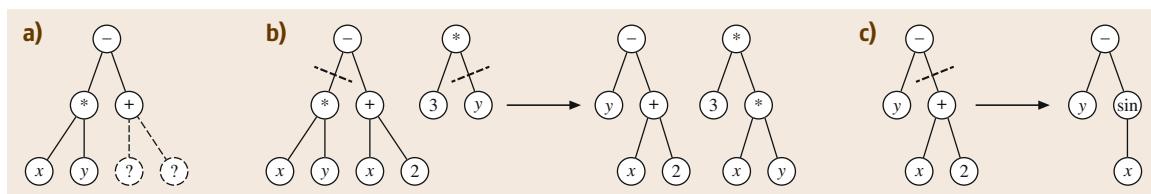

In 1963, *McCarthy* summarized [43.1] several representations with which machine intelligence might be attempted: neural networks, Turing machines, and *calculator programs*. With the latter, *McCarthy* was referring to *Friedberg's* work. *McCarthy* was prescient in identifying important issues such as representations,

operator behavior, density of good programs in the search space, sufficiency of the search space, appropriate fitness evaluation, and self-organized modularity. Many of these remain open issues in **GP** [43.49].

*Fogel et al.'s* 1960s *evolutionary programming* may be the first successful implementation of **GP** [43.50]. It used a finite-state machine representation for programs, with specialized operators to ensure syntactic correctness of offspring. A detailed history is available in *Fogel's* 2006 book [43.51].

In the 1980s, inspired by the success of genetic algorithms (**GAs**) and learning classifier systems (**LCSs**), several authors experimented with hierarchically structured and program-like representations. *Smith* [43.52] proposed a representation of a variable-length list of rules which could be used for program-like behavior such as maze navigation and poker. *Cramer* [43.53] was the first to use a tree-structured representation and appropriate operators. With a simple proof of concept, it successfully evolved a multiplication function in a simple custom language. *Schmidhuber* [43.54] describes a **GP** system with the possibility of Turing completeness, though the focus is on meta-learning aspects. *Fujiki* and *Dickinson* [43.55] generated Lisp code for the prisoner's dilemma, *Bickel* and *Bickel* [43.56] used a **GA** to create variable-length lists of rules, each of which had a tree structure. An artificial life approach using machine-code genomes was used by *Ray* [43.57]. All of these would likely be regarded as on-topic in a modern **GP** conference.

However, the founding of the modern field of **GP**, and the invention of what is now called *standard GP*, are credited to *Koza* [43.19]. In addition to the abstract syntax tree notation (Sect. 43.3.3), the key innovations were subtree crossover (Sect. 43.3.3) and the description and set-up of many test problems. In this and

**Fig. 43.2a–c** The **StdGP** representation is an abstract syntax tree. The expression that will be evaluated in the second tree from left is, in inorder notation,  $(x * y) - (x + 2)$ . In preorder, or the notation of Lisp-style S-expressions, it is  $(- (* x y) (+ x 2))$ . **GP** presumes that the variables  $x$  and  $y$  will be already bound to some value in the execution environment when the expression is evaluated. It also presumes that the operations  $*$  and  $-$ , etc. are also defined. Note that, all interior tree nodes are effectively operators in some computational language. In standard **GP** parlance, these operators are called *functions* and the leaf tree nodes which accept no arguments and typically represent variables bound to data values from the problem domain are referred to as *terminals*.

later research [43.10, 58, 59] symbolic regression of synthetic data and real-world time series, Boolean problems, and simple robot control problems such as the lawnmower problem and the artificial ant with Santa Fe trail were introduced as benchmarks and solved successfully for the first time, demonstrating that **GP** was a potentially powerful and general-purpose method capable of solving machine learning-style problems albeit conventional academic versions of them. Mutation was minimized in order to make it clear that **GP** was different from random search. **GP** took on its modern form in the years following Koza's 1992 book: many researchers took up work in the field, new types of **GP** were developed (Sect. 43.3), successful

applications appeared (Sect. 43.4), key research topics were identified (Sect. 43.5), further books were written, and conferences and journals were established (Sect. 43.6).

Another important milestone in the history of **GP** was the 2004 establishment of the *Humies*, the awards for human-competitive results produced by **EC** methods. The entries are judged for matching or exceeding human-produced solutions to the same or similar problems, and for criteria such as patentability and publishability. The impressive list of human-competitive results [43.60] again helps to demonstrate to researchers and clients outside the field of **GP** that it is powerful and general purpose.

### 43.3 Taxonomy of AI and GP

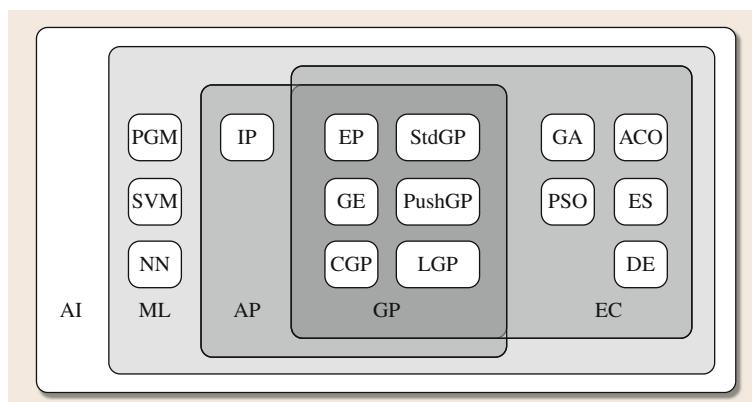

In this section, we present a taxonomy which firstly places **GP** in the context of the broader fields of **EC**, **ML**, and artificial intelligence (**AI**). It then classifies **GP** techniques according to their representations and their population models (Fig. 43.3).

#### 43.3.1 Placing GP in an AI Context

**GP** is a type of **EC**, which is a type of **ML**, which is itself a subset of the broader field of **AI** (Fig. 43.3). Carbonell et al. [43.61] classify **ML** techniques according to the underlying learning strategy, which may be rote learning, learning from instruction, learning by analogy, learning from examples, and learning from observation and discovery. In this classification, **EC** and **GP** fit in the *learning from examples* category, in that an (individual, fitness) pair is an ex-

ample drawn from the search space together with its evaluation.

It is also useful to see **GP** as a subset of another field, **AP**. The term *automatic programming* seems to have had different meanings at different times, from automated card punching, to compilation, to template-driven source generation, then generation techniques such as universal modeling language (**UML**), to the ambitious aim of creating software directly from a natural-language English specification [43.62]. We interpret **AP** to mean creating software by specifying *what to do* rather than *how to do it* [43.47]. **GP** clearly fits into this category. Other nonevolutionary techniques also do so, for example inductive programming (**IP**). The main difference between **GP** and **IP** is that typically **IP** works only with programs which are known to be correct, achieving this using inductive methods over the spec-

**Fig. 43.3** A taxonomy of **AI**, **EC**, and **GP**

ifications, [43.63]. In contrast, **GP** is concerned mostly with programs which are syntactically correct, but behaviorally suboptimal.

### 43.3.2 Taxonomy of GP

It is traditional to divide **EC** into four main subfields: evolution strategies (**ES**) [43.64, 65], evolutionary programming (**EP**) [43.50], **GAs** [43.66], and **GP**. In this view, **ES** is chiefly characterized by real-valued optimization and self-adaptation of algorithm parameters; **EP** by a finite-state machine representation (later generalized) and the absence of crossover; **GA** by the bitstring representation; and **GP** by the abstract syntax tree representation. While historically useful, this classification is not exhaustive: in particular it does not provide a home for the many alternative **GP** representations which now exist. It also separates **EP** and **GP**, though they are both concerned with evolving programs. We prefer to use the term **GP** in a general sense to refer to all types of **EC** which evolve programs. We use the term *standard GP (StdGP)* to mean Koza-style **GP** with a tree representation. With this view, **StdGP** and **EP** are types of **GP**, as are several others discussed below. In the following, we classify **GP** algorithms according to their *representation* and according to their *population model*.

### 43.3.3 Representations

Throughout **EC**, it is useful to contrast *direct* and *indirect* representations. Standard **GP** is direct, in that the genome (the object created and modified by the genetic operators) serves directly as an executable program. Some other **GP** representations are indirect, meaning that the genome must be decoded or translated in some way to give an executable program. An example is grammatical evolution (**GE**, see below), where the genome is an integer array which is used to generate a program. Indirect representations have the advantage that they may allow an easier definition of the genetic operators, since they may allow the genome to exist in a rather simpler space than that of executable programs. Indirect representations also imitate somewhat more closely the mechanism found in nature, a mapping from **DNA** (deoxyribonucleic acid) to **RNA** (ribonucleic acid) to **mRNA** (messenger **RNA**) to codons to proteins and finally to cells. The choice between direct and indirect representations also affects the structure of the fitness landscape (Sect. 43.5.2). In the following, we present a nonexhaustive selection of the main

representations used in **GP**, in each case describing initialization and the two key operators: mutation, and crossover.

#### Standard GP

In Standard **GP (StdGP)**, the representation is an abstract syntax tree, or can be seen as a Lisp-style S-expression. All nodes are functions and all arguments are the same type. A function accepts zero or more arguments and returns a single value. Trees can be initialized by recursive random growth starting from a null node. **StdGP** uses parameterized initialization methods that diversify the size and structure of initial trees. Figure 43.2a shows a tree in the process of initialization.

Trees can be crossed over by cutting and swapping the subtrees rooted at randomly chosen nodes, as shown in Fig. 43.2b. They can be mutated by cutting and regrowing from the subtrees of randomly chosen nodes, as shown in Fig. 43.2c. Another mutation operator, HVL-Prime, is shown later in Fig. 43.11. Note that crossover or mutation creates an offspring of potentially different size and structure, but the offspring remains syntactically valid for evaluation. With these variations, a tree could theoretically grow to infinite size or height. To circumvent this, as a practicality, a hard parameterized threshold for size or height or some other threshold is used. Violations to the threshold are typically rejected. Bias may also be applied in the randomized selection of crossed-over subtree roots. A common variation of **StdGP** is *strongly typed GP (STGP)* [43.67, 68], which supports functions accepting arguments and returning values of specific types by means of specialized mutation and crossover operations that respect these types.

#### Executable Graph Representations

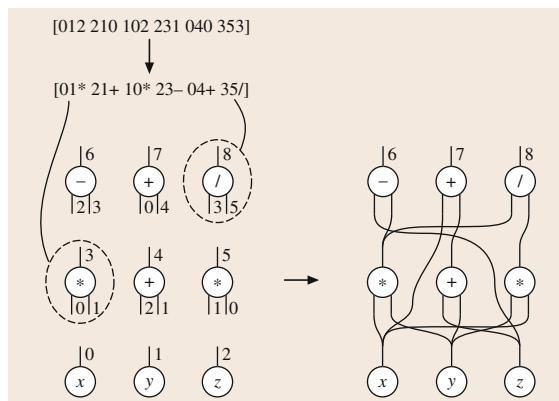

A natural generalization of the executable tree representation of **StdGP** is the executable graph. Neural networks can be seen as executable graphs in which each node calculates a weighted sum of its inputs and outputs the result after a fixed shaping function such as  $\text{tanh}()$ . *Parallel and distributed GP (PDGP)* [43.69] is more closely akin to **StdGP** in that nodes calculate different functions, depending on their labels, and do not perform a weighted sum. It also allows the topology of the graph to vary, unlike the typical neural network. *Cartesian GP (CGP)* [43.70] uses an integer-array genome and a mapping process to produce the graph. Each block of three integer genes codes for a single node in the graph, specifying the indices of

its inputs and the function to be executed by the node (Fig. 43.4).

*Neuro-evolution of augmenting topologies* (NEAT) [43.71] again allows the topology to vary, and allows nodes to be labelled by the functions they perform, but in this case each node does perform a weighted sum of its inputs. Each of these representations uses different operators. For example, CGP uses simple array-oriented (GA-style) initialization, crossover, and mutation operators (subject to some customizations).

### Finite-State Machine Representations

Some GP representations use graphs in a different way: the model of computation is the finite-state machine rather than the executable functional graph (Fig. 43.5). The original incarnation of *evolutionary programming* (EP) [43.72] is an example. In a typical implementation [43.72], five types of mutation are used: adding and deleting states, changing the initial state, changing the output symbol attached to edges, and changing the edges themselves. In this implementation, crossover is not used.

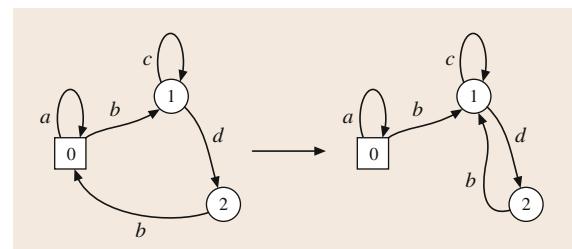

**Fig. 43.4** Cartesian GP. An integer-array genome is divided into blocks: in each block the last integer specifies a function (top-left). Then one node is created for each input variable ( $x, y, z$ ) and for each genome block. Nodes are arranged in a grid and outputs are indexed sequentially (bottom-left). The first elements in each block specify the indices of the incoming links. The final graph is created by connecting each node input to the node output with the same integer label (right). Dataflow in the graph is bottom to top. Multiple outputs can be read from the topmost layer of nodes. In this example node 6 outputs  $xy - z + y$ , node 7 outputs  $x + z + y$ , and node 8 outputs  $xy/xy$ .

### Grammatical GP

In grammatical GP [43.73], the context-free grammar (CFG) is the defining component of the representation. In the most common approach, search takes place in the space defined by a fixed nondeterministic CFG. The aim is to find a good program in that space. Often the CFG defines a useful subset of a programming language such as Lisp, C, or Python. Programs derived from the CFG can then be compiled or interpreted using either standard or special-purpose software. There are several advantages to using a CFG. It allows convenient definition of multiple data-types which are automatically respected by the crossover and mutation operators. It can introduce domain knowledge into the problem representation. For example, if it is known that good programs will consist of a conditional statement inside a loop, it is easy to express this knowledge using a grammar. The grammar can restrict the ways in which program expressions are combined, for example making the system aware of physical units in *dimensionally aware GP* [43.74, 75]. A grammatical GP system can conveniently be applied to new domains, or can incorporate new domain knowledge, through updates to the grammar rather than large-scale reprogramming.

In one early system [43.76], the derivation tree is used as the genome: initial individuals' genomes are randomly generated according to the rules of the grammar. Mutation works by randomly generating a new subtree starting from a randomly chosen internal node in the derivation tree. Crossover is constrained to exchange subtrees whose roots are identical. In this way, new individuals are guaranteed to be valid derivation trees. The executable program is then created from the genome by reading the leaves left to right. A later system, *grammatical evolution* (GEs) [43.77] instead uses an integer-array genome. Initialization, mutation and crossover are defined as simple GA-style array operations. The genome is mapped to an output program by using the successive integers of the genome to choose

**Fig. 43.5** EP representation: finite-state machine. In this example, a mutation changes a state transition

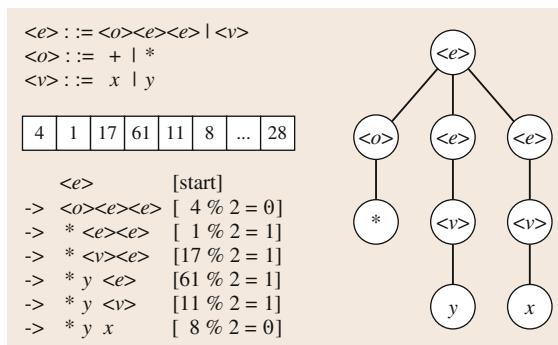

among the applicable production choices at each step of the derivation process. Figure 43.6 shows a simple grammar, integer genome, derivation process, and derivation tree. At each step of the derivation process, the left-most nonterminal in the derivation tree is rewritten. The next integer gene is used to determine, using the *mod rule*, which of the possible productions is chosen. The output program is the final step of the derivation tree.

Although successful and widely used, GE has also been criticized for the disruptive effects of its operators with respect to preserving the modular functionality of parents. Another system, *tree adjoining grammar-guided genetic programming* (TAG3P) has also been used successfully [43.78]. Instead of a string-rewriting CFG, TAG3P uses the tree-rewriting *tree adjoining grammars*. The representation has the advantage, relative to GE, that individuals are valid programs at every step of the derivation process. TAGs also have some context-sensitive properties [43.78]. However, it is a more complex representation.

Another common alternative approach, surveyed by Shan et al. [43.79], uses probabilistic models over grammar-defined spaces, rather than direct evolutionary search.

### Linear GP

In *Linear GP* (LGP), the program is a list of instructions to be interpreted sequentially. In order to achieve complex functionality, a set of registers acting as state or memory are used. Instructions can read from or write to

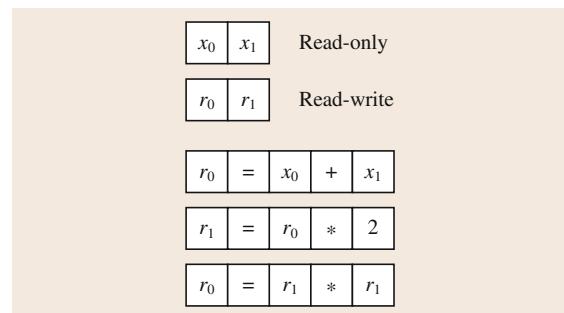

**Fig. 43.6** GE representation. The grammar (top-left) consists of several rules. The genome (center-left) is a variable-length list of integers. At each step of the derivation process (bottom-left), the left-most nonterminal is rewritten as specified by a gene. The resulting derivation tree is shown on the right: reading just the leaves gives the derived program

the registers. Several registers, which may be read-only, are initialized with the values of the input variables. One register is designated as the output: its value at the end of the program is taken as the result of the program. Since a register can be read multiple times after writing, an LGP program can be seen as having a graph structure. A typical implementation is that of [43.80]. It uses instructions of three registers each, which typically calculate a new value as an arithmetic function of some registers and/or constants, and assign it to a register (Fig. 43.7).

It also allows conditional statements and looping. It explicitly recognizes the possibility of nonfunctioning code, or *introns*. Since there are no syntactic constraints on how multiple instructions may be composed together, initialization can be as simple as the random generation of a list of valid instructions. Mutation can change a single instruction to a newly generated instruction, or change just a single element of an instruction. Crossover can be performed over the two parents' list structures, respecting instruction boundaries.

### Stack-Based GP

A variant of linear GP avoids the need for registers by adding a stack. The program is again a list of instructions, each now represented by a single label. In a simple arithmetic implementation, the label may be one of the input variables ( $x_i$ ), a numerical constant, or a function (\*, +, etc.). If it is a variable or constant, the instruction is executed by pushing the value onto the stack. If a function, it is executed by popping the required number of operands from the stack, executing the function on them, and pushing the result back on. The result of the program is the value at the top of

**Fig. 43.7** Linear GP representation. This implementation has four registers in total (top). The representation is a list of register-oriented instructions (bottom). In this example program of three instructions,  $r_0$  is the output register, and the formula  $4(x_0 + x_1)^2$  is calculated

the stack after all instructions have been executed. With the stipulation that stack-popping instructions become no-ops when the stack is empty, one can again implement initialization, mutation, and crossover as simple list-based operations [43.81]. One can also constrain the operations to work on what are effectively subtrees, so that stack-based GP becomes effectively equivalent to a reverse Polish notation implementation of standard GP [43.82]. A more sophisticated type of stack-based GP is *PushGP* [43.83], in which multiple stacks are used. Each stack is used for values of a different type, such as integer, boolean, and float. When a function requires multiple operands of different types, they are taken as required from the appropriate stacks. With the addition of an *exec* stack which stores the program code itself, and the *code* stack which stores items of code, both of which may be both read and written, PushGP gains the ability to evolve programs with self-modification, modularity, control structures, and even self-reproduction.

### Low-Level Programming

Finally, several authors have evolved programs directly in real-world low-level programming languages. Schulte et al. [43.84] automatically repaired programs written in Java byte code and in x86 assembly. Orlov and Sipper [43.85] evolved programs such as trail navigation and image classification *de novo* in Java byte code. This work made use of a specialized crossover operator which performed automated checks for compatibility of the parent programs' stack and control flow state. Nordin [43.86] proposed a machine-code representation for GP. Programs consist of lists of low-level register-oriented instructions which execute directly, rather than in a virtual machine or interpreter. The result is a massive speed-up in execution.

#### 43.3.4 Population Models

It is also useful to classify GP methods according to their population models. In general the population model and the representation can vary independently, and in fact all of the following population can be applied with any EC representation including bitstrings and real-valued vectors, as well as with GP representations.

The simplest possible model, *hill-climbing*, uses just one individual at a time [43.87]. At each iteration, offspring are created until one of them is more highly fit than the current individual, which it then replaces. If at any iteration it becomes impossible to find an improve-

ment, the algorithm has *climbed the hill*, i. e. reached a local optimum, and stops. It is common to use a random restart in this case. The hill-climbing model can be used in combination with any representation. Note that it does not use crossover. Variants include ES-style  $(\mu, \lambda)$  or  $(\mu + \lambda)$  schemes, in which multiple parents each give rise to multiple offspring by mutation.

The most common model is an *evolving population*. Here a large number of individuals (from tens to many thousands) exist in parallel, with new generations being created by crossover and mutation among selected individuals. Variants include the steady-state and the generational models. They differ only in that the steady-state model generates one or a few new individuals at a time, adds them to the existing population and removes some old or weak individuals; whereas the generational model generates an entirely new population all at once and discards the old one.

The *island model* is a further addition, in which multiple populations all evolve in parallel, with infrequent migration between them [43.88].

In *coevolutionary* models, the fitness of an individual cannot be calculated in an endogenous way. Instead it depends on the individual's relationship to other individuals in the population. A typical example is in game-playing applications such as checkers, where the best way to evaluate an individual is to allow it to play against other individuals. Coevolution can also use fitness defined in terms of an individual's relationship to individuals in a population of a different type. A good example is the work of [43.89], which uses a type of *predator-prey* relationship between populations of programs and populations of test cases. The test cases (*predators*) evolve to find bugs in the programs; the programs (*prey*) evolve to fix the bugs being tested for by the test suites.

Another group of highly biologically inspired population models are those of *swarm intelligence*. Here the primary method of learning is not the creation of new individuals by inheritance. Instead, each individual generally lives for the length of the run, but *moves about* in the search space with reference to other individuals and their current fitness values. For example, in particle swarm optimization (PSO) individuals tend to move toward the global best and toward the best point in their own history, but tend to avoid moving too close to other individuals. Although PSO and related methods such as differential evolution (DE) are best applied in real-valued optimization, their population models and operators can be abstracted and applied in GP methods also [43.90, 91].

Finally, we come to *estimation of distribution algorithms* (EDAs). Here the idea is to create a population, select a subsample of the best individuals, model that subsample using a distribution, and then create a new population by sampling the distribution. This approach is particularly common in grammar-based GP [43.73].

though it is also used with other representations [43.92–94]. The modeling-sampling process could be regarded as a type of whole-population crossover. Alternatively one can view EDAs as being quite far from the biological inspiration of most EC, and in a sense they bridge the gap between EC and statistical ML.

## 43.4 Uses of GP

Our introduction (Sect. 43.1) has touched on a wide array of domains in which GP has been applied. In this section, we give more detail on just a few of these.

### 43.4.1 Symbolic Regression

Symbolic regression is one of the most common tasks for which GP is used [43.19, 95, 96]. It is used as a component in techniques like data modeling, clustering, and classification, for example in the modeling application outlined in Sect. 43.4.2. It is named after techniques such as linear or quadratic regression, and can be seen as a generalization of them. Unlike those techniques it does not require a priori specification of the model. The goal is to find a function in symbolic form which models a data set. A typical symbolic regression is implemented as follows.

It begins with a dataset which is to be regressed, in the form of a numerical matrix (Fig. 43.8, left). Each row  $i$  is a data-point consisting of some input (explanatory) variables  $x_i$  and an output (response) variable  $y_i$  to be modeled. The goal is to produce a function  $f(x)$  which models the relationship between  $x$  and  $y$  as closely as possible. Figure 43.8 (right) plots the existing data and one possible function  $f$ .

Typically StdGP is used, with a numerical *language* which includes arithmetic operators, functions like sinusoids and exponentials, numerical constants, and the input variables of the dataset. The internal nodes of each StdGP abstract syntax tree will be operators and functions, and the leaf nodes will be constants and variables.

To calculate the fitness of each model, the explanatory variables of the model are bound to their values at each of the training points  $x_i$  in turn. The model is executed, and the output  $f(x_i)$  is the model's predicted response. This value  $\hat{y}_i$  is then compared to the response of the training point  $y_i$ . The error can be visualized as the dotted lines in Fig. 43.8 (right). Fitness is usually defined as the root-mean-square error of the model's outputs versus the training data. In this formulation,

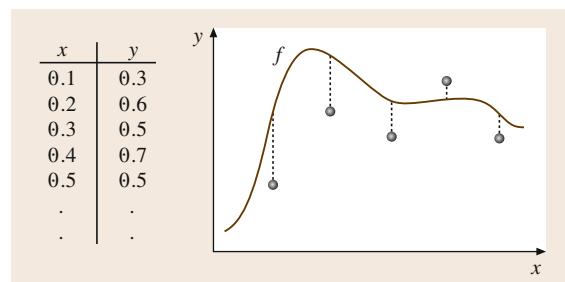

therefore, fitness is to be minimized

$$\text{fitness}(f) = \sqrt{\frac{\sum_{i=1}^n (f(x_i) - y_i)^2}{n}}.$$

Over the course of evolution, the population moves toward better and better models  $f$  of the training data. After the run, a testing data set is used to confirm that the model is capable of generalization to unseen data.

### 43.4.2 Machine Learning

Like other ML methods, GP is successful in quantitative domains where data is available for learning and both approximate solutions and incremental improvements are valued. In modeling or supervised learning, GP is preferable to other ML methods in circumstances where the form of the solution model is unknown a priori because it is capable of searching among possible forms for the model. Symbolic regression can be used as an approach to classification, regression modeling, and clustering. It can also be used to automatically extract influential features, since it is able to pare down the feature set it is given at initialization. GP-derived classifiers have been integrated into ensemble

**Fig. 43.8** Symbolic regression: a matrix of data (left) is to be modeled by a function. It is plotted as dots in the figure on the right. A candidate function  $f$  (solid line) can be plotted, and its errors (dotted lines) can be visualized

learning approaches and **GP** has been used in reinforcement learning (**RL**) contexts. Figure 43.9 shows **GP** as a means of **ML** which allows it to address problems such as planning, forecasting, pattern recognition, and modeling.

For the sensory evaluation problem described in [43.97], the authors use **GP** as the anchor of a **ML** framework (Fig. 43.10). A panel of assessors provides *liking scores* for many different flavors. Each flavor consists of a mixture of ingredients in different proportions. The goals are to discover the dependency of a liking score on the concentration levels of flavors' ingredients, identifying ingredients that drive liking, segmenting the panel into groups with similar liking preferences and optimizing flavors to maximize liking per group. The framework uses symbolic regression and ensemble methods to generate multiple diverse explanations of liking scores, with confidence information. It uses statistical techniques to extrapolate from the genetically evolved model ensembles to unobserved regions of the flavor space. It also segments the assessors into groups which either have the same propensity to like flavors, or whose liking is driven by the same ingredients.

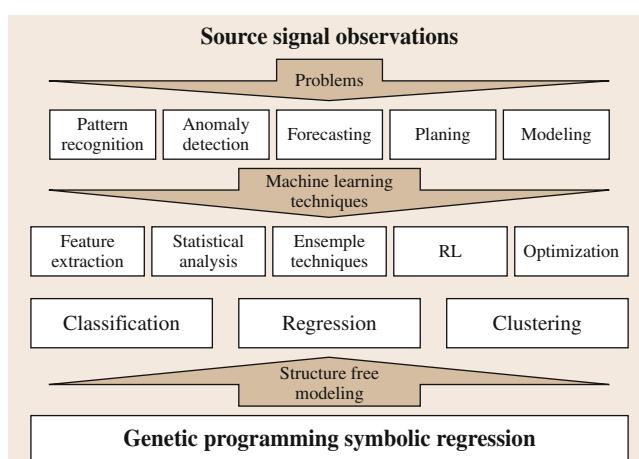

Sensory evaluation data is very sparse and there is large variation among the responses of different assessors. A Pareto-**GP** algorithm (which uses multi-objective techniques to maximise model accuracy and minimise model complexity; [43.98]) was therefore used to evolve an ensemble of models for each assessor and to use this ensemble as a source of robust vari-

able importance estimation. The frequency of variable occurrences in the models of the ensemble was interpreted as information about the ingredients that drive the liking of an assessor. Model ensembles with the same dominance of variable occurrences, and which demonstrate similar effects when the important variables are varied, were grouped together to identify assessors who are driven by the same ingredient set and in the same direction. Varying the input values of the important variables, while using the model ensembles of these panel segments, provided a means of conducting focused sensitivity analysis. Subsequently, the same model ensembles when clustered constitute the *black box* which is used by an evolutionary algorithm in its optimization of flavors that are well liked by assessors who are driven by the same ingredient.

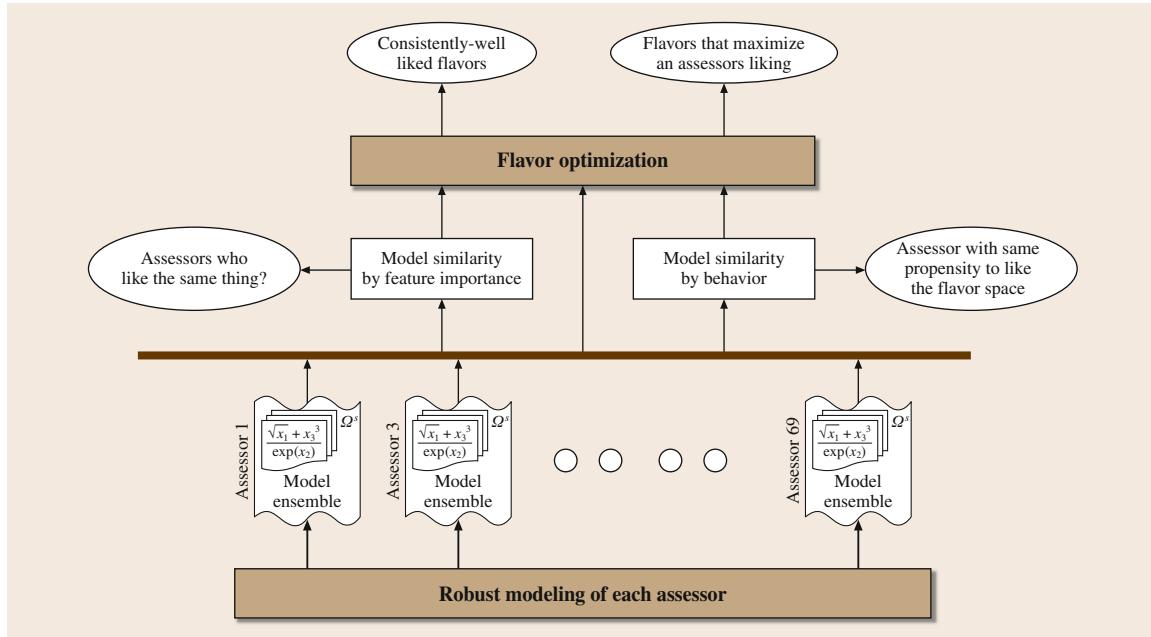

### 43.4.3 Software Engineering

At least three areas of software engineering have been tackled with remarkable success by **GP**: bug-fixing [43.99], parallelization [43.100, 101], and optimization [43.102–104]. These three areas are very different in their aims, scope, and methods; however, they all need to deal with two key problems in this domain: the very large and unconstrained search space, and the problem of program correctness. They therefore do not aim to evolve new functionality from scratch, but instead use existing code as material to be transformed in some way; and they either guarantee correctness of the evolved programs as a result of their representations, or take advantage of existing test suites in order to provide strong evidence of correctness.

*Le Goues et al.* [43.99] show that automatically fixing software bugs is a problem within the reach of **GP**. They describe a system called *GenProg*. It operates on C source code taken from open-source projects. It works by forming an abstract syntax tree from the original source code. The initial population is seeded with variations of the original. Mutations and crossover are constrained to copy or delete complete lines of code, rather than editing subexpressions, and they are constrained to alter only lines which are exercised by the failing test cases. This helps to reduce the search space size. The original test suites are used to give confidence that the program variations have not lost their original functionality. Fixes for several real-world bugs are produced, quickly and with high certainty of success, including bugs in HTTP servers, Unix utilities, and a media player. The fixes can be automatically processed to produce minimal patches. Best of all, the fixes

**Fig. 43.9** **GP** as a component in **ML**. Symbolic regression can be used as an approach to many **ML** tasks, and integrated with other **ML** techniques

**Fig. 43.10** GP symbolic regression is unique and useful as an ML technique because it obviates the need to define the structure of a model prior to training. Here, it is used to form a personalized ensemble model for each assessor in a flavor evaluation panel

are demonstrated to be rather robust: some even generalize to fixing related bugs which were not explicitly encoded in the test suite.

Ryan [43.100] describes a system, *Paragen*, which automatically rewrites serial Fortran programs to parallel versions. In *Paragen I*, the programs are directly varied by the genetic operators, and automated tests are used to reward the preservation of the program's original semantics. The work of Williams [43.101] was in some ways similar to Paragen I. In *Paragen II*, correctness of the new programs is instead guaranteed, using a different approach. The programs to be evolved are sequences of transformations defined over the original serial code. Each transformation is known to preserve semantics. Some transformations however directly transform serial operations to parallel, while other transformations merely enable the first type.

A third goal of software engineering is optimization of existing code. White et al. [43.104] tackle this task using a multiobjective optimization method. Again, an existing program is used as a starting point, and the aim is to evolve a semantically equivalent one with improved characteristics, such as reduced memory usage, execution time, or power consumption. The system is

capable of finding *nonobvious* optimizations, i. e. ones which cannot be found by optimizing compilers. A population of test cases is coevolved with the population of programs. Stephenson et al. [43.102, 103] in the Meta Optimization project improve program execution speed by using GP to refine priority functions within the compiler. The compiler generates better code which executes faster across the input range of one program and across the program range of a benchmark set.

A survey of the broader field of *search-based software engineering* is given by Harman [43.105].

#### 43.4.4 Design

GP has been successfully used in several areas of design. This includes both engineering design, where the aim is to design some hardware or software system to carry out a well-defined task, and aesthetic design, where the aim is to produce art objects with subjective qualities.

##### Engineering Design

One of the first examples of GP design was the synthesis of analog electrical circuits by Koza et al. [43.106]. This work addressed the problem of automatically cre-

ating circuits to perform tasks such as a filter or an amplifier. Eight types of circuit were automatically created, each having certain requirements, such as outputting an amplified copy of the input, and low distortion. These functions were used to define fitness. A complex **GP** representation was used, with both **STGP** (Sect. 43.3.3) and **ADF**'s (Sect. 43.5.3). Execution of the evolved program began with a trivial *embryonic circuit*. **GP** program nodes, when executed, performed actions such as altering the circuit topology or creating a new component. These nodes were parameterized with numerical parameters, also under **GP** control, which could be created by more typical arithmetic **GP** subtrees. The evolved circuits solved significant problems to a human-competitive standard though they were not fabricated.

Another significant success story was the space-going antenna evolved by Hornby et al. [43.27] for the **NASA** (National Aeronautics and Space Administration) Space Technology 5 spacecraft. The task was to design an antenna with certain beamwidth and bandwidth requirements, which could be tested in simulation (thus providing a natural fitness function). **GP** was used to reduce reliance on human labor and limitations on complexity, and to explore areas of the search space which would be rejected as not worthy of exploration by human designers. Both a **GA** and a **GP** representation were used, producing quite similar results. The **GP** representation was in some ways similar to a 3-D turtle graphics system. Commands included *forward* which moved the turtle forward, creating a wire component, and *rotate-x* which changed orientation. Branching of the antenna arms was allowed with special markers similar to those used in turtle graphics programs. The program composed of these primitives, when run, created a wire structure, which was rotated and copied four times to produce a symmetric result for simulation and evaluation.

### Aesthetic Design

There have also been successes in the fields of graphical art, 3-D aesthetic design, and music. Given the aesthetic nature of these fields, **GP** fitness is often replaced by an interactive approach where the user performs *direct selection* on the population. This approach dates back to Dawkins' seminal *Biomorphs* [43.107] and has been used in other forms of **EC** also [43.108]. Early successes were those of Todd and Latham [43.109], who created pseudo-organic forms, and Sims [43.35] who created abstract art. An overview of evolutionary art is provided by Lewis [43.110].

A key aim throughout aesthetic design is to avoid the many random-seeming designs which tend to be created by typical representations. For example, a naive representation for music might encode each quarter-note as an integer in a genome whose length is the length of the eventual piece. Such a representation will be capable of representing some good pieces of music, but it will have several significant problems. The vast majority of pieces will be very poor and random sounding. Small mutations will tend to gradually degrade pieces, rather than causing large-scale and semantically sensible transformations [43.111].

As a result, many authors have tried to use representations which take advantage of forms of *reuse*. Although reuse is also an aim in nonaesthetic **GP** (Sect. 43.5.3), the hypothesis that good solutions will tend to involve reuse, even on new, unknown problems, is more easily motivated in the context of aesthetic design.

In one strand of research, the time or space to be occupied by the work is predefined, and divided into a grid of 1, 2, or 3 dimensions. A **GP** function of 1, 2 or 3 arguments is then evolved, and applied to each point in the grid with the coordinates of the point passed as arguments to the function. The result is that the function is reused many times, and all parts of the work are felt to be coherent. The earliest example of such work was that of Sims [43.35], who created fascinating graphical art (a 2-D grid) and some animations (a 3-D grid of two spatial dimensions and 1 time dimension). The paradigm was later brought to a high degree of artistry by Hart [43.112]. The same generative idea, now with a 1-D grid representing time, was used by Hoover et al. [43.113], Shao et al. [43.114] and McDermott and O'Reilly [43.115] to produce music as a function of time, and with a 3-D grid by Clune and Lipson [43.116] to produce 3-D sculptures.

Other successful work has used different approaches to reuse. *L-systems* are grammars in which symbols are recursively expanded in parallel: after several expansions (a *growth process*), the string will be highly patterned, with multiple copies of some substrings. Interpreting this string as a program can then yield highly patterned graphics [43.117], artificial creatures [43.118], and music [43.119]. Grammars have also been used in 3-D and architectural design, both in a modified L-system form [43.36] and in the standard **GE** form [43.120]. The *Ossia* system of Dahlstedt [43.37] uses **GP** trees with recursive pointers to impose reuse and a natural, *gestural* quality on short pieces of art music.

## 43.5 Research Topics

Many research topics of interest to GP practitioners are also of broader interest. For example, the self-adaptation of algorithm parameters is a topic of interest throughout EC. We have chosen to focus on four research topics of specific interest in GP: bloat, GP theory, modularity, and open-ended evolution.

### 43.5.1 Bloat

Most GP-type problems naturally require variable-length representations. It might be expected that selection pressure would effectively guide the population toward program sizes appropriate to the problem, and indeed this is sometimes the case. However, it has been observed that for many different representations [43.121] and problems, programs grow over time *without* apparent fitness improvements. This phenomenon is called *bloat*. Since the time complexity for the evaluation of a GP program is generally proportional to its size, this greatly slows the GP run down. There are also other drawbacks. The eventual solution may be so large and complex that is unreadable, negating a key advantage of symbolic methods like GP. Overly large programs tend to generalize less well than parsimonious ones. Bloat may negatively impact the rate of fitness improvement. Since bloat is a significant obstacle to successful GP, it is an important topic of research, with differing viewpoints both on the causes of bloat and the best solutions.

The competing theories of the causes of bloat are summarized by Luke and Panait [43.122] and Silva et al. [43.123]. A fundamental idea is that adding material rather than removing material from a GP tree is more likely to lead to a fitness improvement. The *hitchhiking* theory is that noneffective code is carried along by virtue of being attached to useful code. *Defense against crossover* suggests that large amounts of noneffective code give a selection advantage later in GP runs when crossover is likely to highly destructive of good, fragile programs. *Removal bias* is the idea that it is harder for GP operators to remove exactly the right (i. e., noneffective) code than it is to add more. The *fitness causes bloat* theory suggests that fitness-neutral changes tend to increase program size just because there are many more programs with the same functionality at larger sizes than at smaller [43.124]. The *modification point depth* theory suggests that children formed by tree crossover at deep crossover points are likely to have fitness similar to their parents and thus

more likely to survive than the more radically different children formed at shallow crossover points. Because larger trees have more very deep potential crossover points, there is a selection pressure toward growth. Finally, the *crossover bias* theory [43.125] suggests that after many crossovers, a population will tend toward a limiting distribution of tree sizes [43.126] such that small trees are more common than large ones – note that this is the opposite of the effect that might be expected as the basis of a theory of bloat. However, when selection is considered, the majority of the small programs cannot compete with the larger ones, and so the distribution is now skewed in favour of larger programs.

Many different solutions to the problem of bloat have been proposed, many with some success. One simple method is *depth limiting*, imposing a fixed limit on the tree depth that can be produced by the variation operators [43.19].

Another simple but effective method is *Tarpeian bloat control* [43.127]. Individuals which are larger than average receive, with a certain probability, a constant punitively bad fitness. The advantage is that these individuals are not evaluated, and so a huge amount of time can be saved and devoted to running more generations (as in [43.122]). The Tarpeian method does allow the population to grow beyond its initial size, since the punishment is only applied to a proportion of individuals – typically around 1 in 3. This value can also be set adaptively [43.127].

The *parsimony pressure* method evaluates all individuals, but imposes a fitness penalty on overly large individuals. This assumes that fitness is commensurable with size: the magnitude of the punishment establishes a *de facto exchange rate* between the two. Luke and Panait [43.122] found that parsimony pressure was effective across problems and across a wide range of exchange rates.

The choice of an exchange rate can be avoided using multiobjective methods, such as Pareto-GP [43.128], where one of the objectives is fitness and the other program length or complexity. The correct definition for complexity in this context is itself an interesting research topic [43.96, 129]. Alternatively, the pressure against bloat can be moved from the fitness evaluation phase to the the selection phase of the algorithm, using the *double tournament* method [43.122]. Here individuals must compete in one fitness-based tournament and one size-based one. Another approach

is to incorporate tree size directly into fitness evaluation using a minimum description length principle [43.130].

Another technique is called *operator length equalization*. A histogram of program sizes is maintained throughout the run and is used to set the population's capacity for programs of different sizes. A newly created program which would cause the population's capacity to be exceeded is rejected, unless exceptionally fit. A *mutation-based* variation of the method instead mutates the overly large individuals using directed mutation to become smaller or larger as needed.

Some authors have argued that the choice of **GP** representation can avoid the issue of bloat [43.131]. Some aim to avoid the problem of bloat by speeding up fitness evaluation [43.82, 132] or avoiding wasted effort in evaluation [43.133, 134]. Sometimes **GP** techniques are introduced with other motivations but have the side-effect of reducing bloat [43.135].

In summary, researchers including *Luke* and *Panait* [43.122], *Poli* et al. [43.127], *Miller* [43.131], and *Silva* et al. [43.123] have effectively *declared victory* in the fight against bloat. However, their techniques have not yet become standard for new **GP** research and benchmark experiments.

### 43.5.2 GP Theory

Theoretical research in **GP** seeks to answer a variety of questions, for example: What are the drivers of population fitness convergence? How does the behavior of an operator influence the progress of the algorithm? How does the combination of different algorithmic mechanisms steer **GP** toward fitter solutions? What mechanisms cause bloat to arise? What problems are difficult for **GP**? How diverse is a **GP** population? Theoretical methodologies are based in mathematics and exploit formalisms, theorems, and proofs for rigor. While **GP** may appear simple, beyond its stochastic nature which it shares with all other evolutionary algorithms, its variety of representations each impose specific requirements for theoretical treatment. All **GP** representations share two common traits which greatly contribute to the difficulty it poses for theoretical analysis. First, the representations have no fixed size, implying a complex search space. Second, **GP** representations do not imply that parents will be equal in size and shape. While crossover accommodates this lack of synchronization, it generally allows the exchange of content from *anywhere* in one parent to *anywhere* in the other parent's

tree. This implies combinatorial outcomes and *likes not switching with likes*. This functionality contributes to complicated algorithmic behavior which is challenging to analyze.

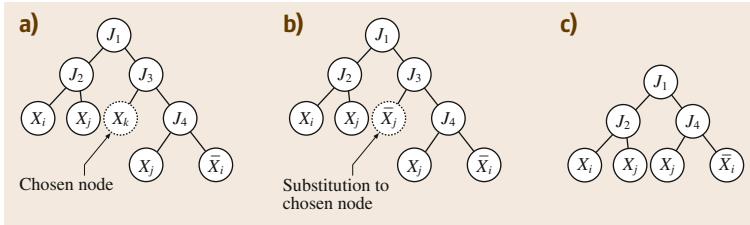

Here, we select several influential methods of theoretical analysis and very briefly describe them and their results: schema-based analysis, Markov chain modeling, runtime complexity, and problem difficulty. We also introduce the No Free Lunch Theorem and describe its implications for **GP**.

#### Schema-Based Analysis

In schema-based analysis, the search space is conceptually partitioned into hyperplanes (also known as schemas) which represent sets of partial solutions. There are numerous ways to do this and, as a consequence, multiple schema definitions have been proposed [43.136–139]. The fitness of a schema is estimated as the average fitness of all programs in the sample of its hyperplane, given a population. The processes of fitness-based selection and crossover are formalized in a recurrence equation which describes the expected number of programs sampling a schema from the current population to the next. Exact formulations have been derived for most types of crossover [43.140, 141]. These alternatively depend on making explicit the effects and the mechanisms of schema creation. This leads to insight; however, tracking schema equations in actual **GP** population dynamics is infeasible. Also, while schema theorems predict changes from one generation to the next, they cannot predict further into the future to predict the long-term dynamics that **GP** practitioners care about.

#### Markov Chain Analysis

Markov chain models are one means of describing such long-term **GP** dynamics. They take advantage of the Markovian property observed in a **GP** algorithm: the composition of one generation's population relies only upon that of the previous generation. Markov chains describe the probabilistic movement of a particular population (state) to others using a probabilistic transition matrix. In evolutionary algorithms, the transition matrix must express the effects of any selection and variation operators. The transition matrix, when multiplied by itself  $k$  times, indicates which new populations can be reached in  $k$  generations. This, in principle, allows a calculation of the probability that a population with a solution can be reached. To date a Markov chain for a simplified **GP** crossover operator has been derived, see [43.142]. Another interesting Markov chain-based

**Fig. 43.11a–c** HVL-prime mutation: substitution and deletion **(a)** Original parse tree, **(b)** Result of substitution **(c)** Result of deletion

result has revealed that the *distribution of functionality of non-Turing complete programs approaches a limit as length increases*. Markov chain analysis has also been the means of describing what happens with **GP** semantics rather than syntax. The influence of subtree crossover is studied in a semantic building block analysis by [43.143]. Markov chains, unfortunately, combinatorially explode with even simple extensions of algorithm dynamics or, in GP's case, its theoretically infinite search space. Thus, while they can support further analysis, ultimately this complexity is unwieldy to work with.

### Runtime Complexity

Due to stochasticity, it is arguably impossible in most cases to make formal guarantees about the number of fitness evaluations needed for a **GP** algorithm to find an optimal solution. However, initial steps in the runtime complexity analysis of genetic programming have been made in [43.144]. The authors study the runtime of hill climbing **GP** algorithms which use a mutation operator called HVL-Prime (Figs. 43.11 and 43.12). Several of these simplified **GP** algorithms were analyzed on two separable model problems, Order and Majority introduced in [43.145]. Order and Majority each have an independent, additive fitness structure. They each admit multiple solutions based on their objective function, so they exhibit a key property of all real **GP** problems. They each capture a different relevant facet of typical **GP** problems. Order represents problems, such as classification problems, where the operators include conditional functions such as an IF-THEN-ELSE. These functions give rise to conditional execution paths which have implications for evolvability and the effectiveness of crossover. Majority is a **GP** equivalent of the **GA** OneMax problem [43.146]. It reflects a general (and thus weak) property required of **GP** solutions: a solution must have correct functionality (by evolving an aggregation of subsolutions) and no incorrect functionality. The analyses highlighted, in particular, the impact of accepting or rejecting neutral moves and the impor-

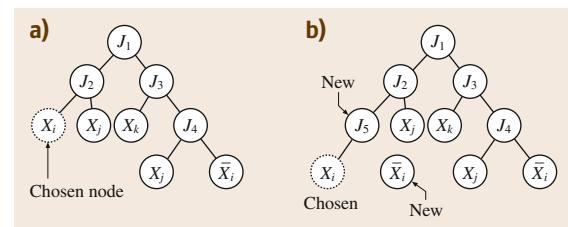

tance of a local mutation operator. A similar finding, [43.147], regarding mutation arose from the analysis of the Max problem [43.148] and hillclimbing. For a search process bounded by a maximally sized tree of  $n$  nodes, the time complexity of the simple **GP** mutation-based hillclimbing algorithms using HVL-Prime for the entire range of MAX variants are  $O(n \log^2 n)$  when one mutation operation precedes each fitness evaluation. When multiple mutations are successively applied before each fitness evaluation, the time complexity is  $O(n^2)$ . This complexity can be reduced to  $O(n \log n)$  if the mutations are biased to replace a random leaf with distance  $d$  from the root with probability  $2^{-d}$ .

Runtime analyses have also considered parsimony pressure and multiobjective **GP** algorithms for generalizations of Order and Majority [43.149].

**GP** algorithms have also been studied in the **PAC** learning framework [43.150].

### Problem Difficulty

Problem difficulty is the study of the differences between algorithms and problems which lead to differences in performance. Stated simply, the goal is to understand why some problems are easy and some are hard, and why some algorithms perform well on certain problems and others do not. Problem difficulty work in the field of **GP** has much in common with similar work in the broader field of **EC**. Problem difficulty is naturally related to the size of the search space; smaller spaces are easier to search, as are spaces in which

**Fig. 43.12a,b** HVL-prime mutation: insertion **(a)** Original parse tree, **(b)** Result of insertion

the solution is *over-represented* [43.151]. Difficulty is also related to the *fitness landscape* [43.152], which in turn depends on both the problem and the algorithm and representation chosen to solve it. Landscapes with few local optima (visualized in the fitness landscape as peaks which are not as high as that of the global optimum) are easier to search. *Locality*, that is the property that small changes to a program lead to small changes in fitness, implies a smooth, easily searchable landscape [43.151, 153].

However, more precise statements concerning problem difficulty are usually desired. One important line of research was carried out by Vanneschi et al. [43.154–156]. This involved calculating various measures of the *correlation* of the fitness landscape, that is the relationship between distance in the landscape and fitness difference. The measures include the *fitness distance correlation* and the *negative slope coefficient*. These measures require the definition of a distance measure on the search space, which in the case of standard GP means a distance between pairs of trees. Various tree distance measures have been proposed and used for this purpose [43.157–160]. However, the reliable prediction of performance based purely on landscape analysis remains a distant goal in GP as it does in the broader field of EC.

#### No Free Lunch

In a nutshell, the No Free Lunch Theorem [43.161] proves that, averaged over all problem instances, no algorithm outperforms another. Follow-up NFL analysis [43.162, 163] yields a similar result for problems where the set of fitness functions are closed under permutation. One question is whether the NFL theorem applies to GP algorithms: for some problem class, is it worth developing a better GP algorithm, or will this effort offer no extra value when all instances of the problem are considered? Research has revealed two conditions under which the NFL breaks down for GP because the set of fitness functions is not closed under permutation. First, GP has a many-to-one syntax tree to program output mapping because many different programs have the same functionality while program output functionality is not uniformly distributed across syntax trees. Second, a geometric argument has shown [43.164], that many *realistic* situations exist where a set of GP problems is provably not closed under permutation. The implication of a contradiction to the No Free Lunch theorem is that it is worthwhile investing effort in improving a GP algorithm for a class of problems.

### 43.5.3 Modularity

*Modularity* in GP is the ability of a representation to evolve good building blocks and then encapsulate and reuse them. This can be expected to make complex programs far easier to find, since good building blocks needed in multiple places in the program not be laboriously re-evolved each time. One of the best-known approaches to modularity is *automatically defined functions* (ADFs), where the building blocks are implemented as functions which are defined in one part of the evolving program and then invoked from another part [43.58]. This work was followed by automatically defined macros which are more powerful than ADFs and allow control of program flow [43.165]; automatically defined iteration, recursion, and memory stores [43.10]; modularity in other representations [43.166]; and demonstrations of the power of reuse, [43.167].

### 43.5.4 Open-Ended Evolution and GP

Biological evolution is a long-running exploration of the enormously varied and indefinitely sized DNA search space. There is no hint that a limit on new areas of the space to be explored will ever be reached. In contrast, EC algorithms often operate in search spaces which are finite and highly simplified in comparison to biology. Although GP itself can be used for a wide variety of tasks (Sect. 43.1), each specific instance of the GP algorithm is capable of solving only a very narrow problem. In contrast, some researchers see biological evolution as pointing the way to a more ambitious vision of the possibilities for GP [43.168]. In this vision, an evolutionary run would continue for an indefinite length of time, always exploring new areas of an indefinitely sized search space; always responding to changes in the environment; and always reshaping the search space itself. This vision is particularly well suited to GP, as opposed to GAs and similar algorithms, because GP already works in search spaces which are infinite in theory, if not in practice.

To make this type of GP possible, it is necessary to prevent convergence of the population on a narrow area of the search space. Diversity preservation [43.169], periodic injection of new random material [43.170], and island-structured population models [43.88] can help in this regard.

Open-ended evolution would also be facilitated by complexity and nonstationarity in the algorithm's evo-

lutionary *ecosystem*. If fitness criteria are dynamic or coevolutionary [43.171–173], there may be no natural

end-point to evolution, and so continued exploration under different criteria can lead to unlimited new results.

## 43.6 Practicalities

### 43.6.1 Conferences and Journals

Several conferences provide venues for the publication of new **GP** research results. The ACM *Genetic and Evolutionary Computation Conference* (**GECCO**) alternates annually between North America and the rest of the world and includes a **GP** track. *EuroGP* is held annually in Europe as the main event of *Evo\**, and focuses only on **GP**. The IEEE *Congress on Evolutionary Computation* is a larger event with broad coverage of **EC** in general. *Genetic Programming Theory and Practice* is held annually in Ann Arbor, MI, USA and provides a focused forum for **GP** discussion. *Parallel Problem Solving from Nature* is one of the older, general **EC** conferences, held biennially in Europe. It alternates with the *Evolution Artificielle* conference. Finally, *Foundations of Genetic Algorithms* is a smaller, theory-focused conference.

The journal most specialized to the field is probably *Genetic Programming and Evolvable Machines* (published by Springer). The September 2010, 10-year anniversary issue included several review articles on **GP**. *Evolutionary Computation* (MIT Press) and the IEEE *Transactions on Evolutionary Computation* also publish important **GP** material. Other on-topic journals with a broader focus include *Applied Soft Computing* and *Natural Computing*.

### 43.6.2 Software

A great variety of **GP** software is available. We will mention only a few packages – further options can be found online.

One of the well-known Java systems is **ECJ** [43.174, 175]. It is a general-purpose system with support for many representations, problems, and methods, both within **GP** and in the wider field of **EC**. It has a helpful mailing list. **Watchmaker** [43.176] is another general-purpose system with excellent out-of-the-box examples. **GEVA** [43.177, 178] is another Java-based package, this time with support only for **GE**.

For users of C++ there are also several options. Some popular packages include *Evolutionary*

*Objects* [43.179], **μGP** [43.180–182], and *OpenBeagle* [43.183, 184]. Matlab users may be interested in **GPLab** [43.185], which implements standard **GP**, while **DEAP** [43.186] provides implementations of several algorithms in Python. **PushGP** [43.187] is available in many languages.

Two more systems are worth mentioning for their deliberate focus on simplicity and understandability. **TinyGP** [43.188] and **PonyGE** [43.189] implement standard **GP** and **GE** respectively, each in a single, readable source file.

Moving on from open source, Michael Schmidt and Hod Lipson's **Eureqa** [43.190] is a free-to-use tool with a focus on symbolic regression of numerical data and the built-in ability to use cloud resources.

Finally, the authors are aware of two commercially available **GP** tools, each fast and industrial-strength. They have more automation and *it just works* functionality, relative to most free and open-source tools. Free trials are available. **DataModeler** (Evolved Analytics LLC) [43.191] is a notebook in Mathematica. It employs the ParetoGP method [43.128] which gives the ability to trade program fitness off against complexity, and to form ensembles of programs. It also exploits complex population archiving and archive-based selection. It offers means of dealing with ill-conditioned data and extracting information on variable importance from evolved models. **Discipulus** (Register Machine Learning Technologies, Inc.) [43.192] evolves machine code based on the ideas of **Nordin** et al. [43.193]. It runs on Windows only. The machine code representation allows very fast fitness evaluation and low memory usage, hence large populations. In addition to typical **GP** features, it can: use an **ES** to optimise numerical constants; automatically construct ensembles; preprocess data; extract variable importance after runs; automatically simplify results; and save them to high-level languages.

### 43.6.3 Resources and Further Reading

Another useful resource for **GP** research is the **GP Bibliography** [43.194]. In addition to its huge, regularly updated collection of BibTeX-formatted citations,

it has lists of researchers' homepages [43.195] and co-authorship graphs. The *GP mailing list* [43.196] is one well-known forum for discussion.

Many of the traditional GP benchmark problems have been criticized for being unrealistic in various ways. The lack of standardization of benchmark problems also allows the possibility of cherry-picking of benchmarks. Effort is underway to bring some standardization to the choice of GP benchmarks [43.197, 198].

Those wishing to read further have many good options. The *Field Guide to GP* is a good introduction, walking the reader through simple examples,

scanning large amounts of the literature, and offering practical advice [43.199]. *Luke's Essentials of Metaheuristics* [43.200] also has an introductory style, but is broader in scope. Both are free to download. Other broad and introductory books include those by Fogel [43.51] and Banzhaf et al. [43.201]. More specialized books include those by Langdon and Poli [43.202] (coverage of theoretical topics), Langdon [43.11] (narrower coverage of GP with data structures), O'Neill and Ryan [43.77] (GE), Iba et al. [43.203] (GP-style ML), and Sipper [43.204] (games). *Advances in Genetic Programming*, a series of four volumes, contains important foundational work from the 1990s.

# Evolution Strategies

Nikolaus Hansen, Dirk V. Arnold, Anne Auger

Part E | 44.1

Evolution strategies (ES) are evolutionary algorithms that date back to the 1960s and that are most commonly applied to black-box optimization problems in continuous search spaces. Inspired by biological evolution, their original formulation is based on the application of mutation, recombination and selection in populations of candidate solutions. From the algorithmic viewpoint, ES are optimization methods that sample new candidate solutions stochastically, most commonly from a multivariate normal probability distribution. Their two most prominent design principles are unbiasedness and adaptive control of parameters of the sample distribution. In this overview, the important concepts of success based step-size control, self-adaptation, and derandomization are covered, as well as more recent developments such as covariance matrix adaptation and natural ES. The latter give new insights into the fundamental mathematical rationale behind ES. A broad discussion of theoretical results includes progress rate results on various function classes and convergence proofs for evolution strategies.

## 44.1 Overview

*Evolution strategies* [44.1–4], sometimes also referred to as evolutionary strategies, and *evolutionary programming* [44.5] are search paradigms inspired by the principles of biological evolution. They belong to the family of evolutionary algorithms that address optimization problems by implementing a repeated process of (small) stochastic variations followed by selection. In each generation (or iteration), new offspring (or candidate solutions) are generated from their parents (candidate solutions already visited), their fitness is

|                                                                                 |     |

evaluated, and the better offspring are selected to become the parents for the next generation.

ES most commonly address the problem of *continuous black-box optimization*. The search space is the continuous domain,  $\mathbb{R}^n$ , and solutions in search space are  $n$ -dimensional vectors, denoted as  $x$ . We consider an objective or fitness function  $f : \mathbb{R}^n \rightarrow \mathbb{R}, x \mapsto f(x)$  to be minimized. We make no specific assumptions on  $f$ , other than that  $f$  can be evaluated for each  $x$ , and refer to this search problem as *black-box optimization*.

The objective is, loosely speaking, to generate solutions ( $\mathbf{x}$ -vectors) with small  $f$ -values while using a small number of  $f$ -evaluations. Formally, we like to *converge* to an essential global optimum of  $f$ , in the sense that the best  $f(\mathbf{x})$  value gets arbitrarily close to the *essential infimum* of  $f$  (i. e., the smallest  $f$ -value for which all larger, i. e., worse  $f$ -values have sublevel sets with positive volume).

In this context, we present an overview of methods that sample new offspring, or candidate solutions, from normal distributions. Naturally, such an overview is biased by the authors' viewpoints, and our emphasis will be on important design principles and on contemporary **ES** that we consider as most relevant in practice or future research. More comprehensive historical overviews can be found elsewhere [44.6, 7].

In the next section, the main principles are introduced and two *algorithm templates* for an evolution strategy are presented. Section 44.3 presents six **ES** that mark important conceptual and algorithmic developments. Section 44.4 summarizes important theoretical results.

#### 44.1.1 Symbols and Abbreviations

Throughout this chapter, vectors like  $\mathbf{z} \in \mathbb{R}^n$  are column vectors, their transpose is denoted as  $\mathbf{z}^T$ , and transformations like  $\exp(\mathbf{z})$ ,  $\mathbf{z}^2$ , or  $|\mathbf{z}|$  are applied component-wise. Further symbols are:

- $|\mathbf{z}| = (|z_1|, |z_2|, \dots)^T$  absolute value taken component wise
- $\|\mathbf{z}\| = \sqrt{\sum_i z_i^2}$  Euclidean length of a vector
- $\sim$  equality in distribution
- $\propto$  in the limit proportional to
- $\circ$  binary operator giving the component-wise product of two vectors or matrices (Hadamard product), such that for  $\mathbf{a}, \mathbf{b} \in \mathbb{R}^n$  we have  $\mathbf{a} \circ \mathbf{b} \in \mathbb{R}^n$  and  $(\mathbf{a} \circ \mathbf{b})_i = a_i b_i$ .
- $\mathbb{1}_\alpha$  the indicator function,  $\mathbb{1}_\alpha = 0$  if  $\alpha$  is false or 0 or empty, and  $\mathbb{1}_\alpha = 1$  otherwise.
- $\lambda \in \mathbb{N}$  number of offspring, offspring population size
- $\mu \in \mathbb{N}$  number of parents, parental population size
- $\mu_w = (\sum_{k=1}^\mu |w_k|)^2 / \sum_{k=1}^\mu w_k^2$ , the variance effective selection mass or *effective number of parents*, where always  $\mu_w \leq \mu$  and  $\mu_w = \mu$  if all recombination weights  $w_k$  are equal in absolute value
- (1 + 1) elitist selection scheme with one parent and one offspring, see Sect. 44.2.5
- $(\mu + \lambda)$ , e.g., (1+1) or (1,  $\lambda$ ), selection schemes, see Sect. 44.2.5
- $(\mu/\rho, \lambda)$  selection scheme with recombination (if  $\rho > 1$ ), see Sect. 44.2.5
- $\rho \in \mathbb{N}$  number of parents for recombination
- $\sigma > 0$  a step-size and/or standard deviation
- $\sigma \in \mathbb{R}_+^n$  a vector of step-sizes and/or standard deviations
- $\varphi \in \mathbb{R}$  a progress measure, see Definition 44.2 and Sect. 44.4.2
- $c_{\mu/\mu, \lambda}$  the progress coefficient for the  $(\mu/\mu, \lambda)$ -**ES** [44.8] equals the expected value of the average of the largest  $\mu$  order statistics of  $\lambda$  independent standard normally distributed random numbers and is of the order of  $\sqrt{2 \log(\lambda/\mu)}$ .
- $\mathbf{C} \in \mathbb{R}^{n \times n}$  a (symmetric and positive definite) covariance matrix
- $\mathbf{C}^{\frac{1}{2}} \in \mathbb{R}^{n \times n}$  a matrix that satisfies  $\mathbf{C}^{\frac{1}{2}} \mathbf{C}^{\frac{1}{2}}^T = \mathbf{C}$  and is symmetric if not stated otherwise. If  $\mathbf{C}^{\frac{1}{2}}$  is symmetric, the eigendecomposition  $\mathbf{C}^{\frac{1}{2}} = \mathbf{B} \mathbf{A} \mathbf{B}^T$  with  $\mathbf{B} \mathbf{B}^T = \mathbf{I}$  and the diagonal matrix  $\mathbf{A}$  exists and we find  $\mathbf{C} = \mathbf{C}^{\frac{1}{2}} \mathbf{C}^{\frac{1}{2}} = \mathbf{B} \mathbf{A}^2 \mathbf{B}^T$  as eigendecomposition of  $\mathbf{C}$ .
- $e_i$  the  $i$ -th canonical basis vector
- $f : \mathbb{R}^n \rightarrow \mathbb{R}$  fitness or objective function to be minimized
- $\mathbf{I} \in \mathbb{R}^{n \times n}$  the identity matrix (identity transformation)
- **i.i.d.** independent and identically distributed
- $\mathcal{N}(\mathbf{x}, \mathbf{C})$  a multivariate normal distribution with expectation and modal value  $\mathbf{x}$  and covariance matrix  $\mathbf{C}$ , see Sect. 44.2.8.
- $n \in \mathbb{N}$  search space dimension
- $\mathcal{P}$  a multiset of individuals, a population
- $s, s_\sigma, s_c < \in \mathbb{R}^n$  a search path or evolution path
- $s, s_k$  endogenous strategy parameters (also known as control parameters) of a single parent or the  $k$ -th offspring; they typically parametrize the mutation, for example with a step-size  $\sigma$  or a covariance matrix  $\mathbf{C}$
- $t \in \mathbb{N}$  time or iteration index
- $w_k \in \mathbb{R}$  recombination weights
- $\mathbf{x}, \mathbf{x}^{(t)}, \mathbf{x}_k \in \mathbb{R}^n$  solution or object parameter vector of a single parent (at iteration  $t$ ) or of the  $k$ -th offspring; an element of the search space  $\mathbb{R}^n$  that serves as argument to the fitness function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ .
- $\text{diag} : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times n}$  the diagonal matrix from a vector
- $\exp^\alpha : \mathbb{R}^{n \times n} \rightarrow \mathbb{R}^{n \times n}, \mathbf{A} \mapsto \sum_{i=0}^\infty (\alpha \mathbf{A})^i / i!$  is the matrix exponential for  $n > 1$ , otherwise

the exponential function. If  $\mathbf{A}$  is symmetric and  $\mathbf{B}\Lambda\mathbf{B}^T = \mathbf{A}$  is the eigendecomposition of  $\mathbf{A}$  with  $\mathbf{B}\mathbf{B}^T = \mathbf{I}$  and  $\Lambda$  diagonal, we have  $\exp(\mathbf{A}) =$

$\mathbf{B}\exp(\Lambda)\mathbf{B}^T = \mathbf{B}(\sum_{i=0}^{\infty} \Lambda^i / i!) \mathbf{B}^T = \mathbf{I} + \mathbf{B}\Lambda\mathbf{B}^T + \mathbf{B}\Lambda^2\mathbf{B}^T/2 + \dots$ . Furthermore, we have  $\exp^\alpha(\mathbf{A}) = \exp(\mathbf{A})^\alpha = \exp(\alpha\mathbf{A})$  and  $\exp^\alpha(x) = (e^\alpha)^x = e^{\alpha x}$ .

## 44.2 Main Principles

ES derive inspiration from principles of biological evolution. We assume a *population*,  $\mathcal{P}$ , of so-called *individuals*. Each individual consists of a solution or object parameter vector  $\mathbf{x} \in \mathbb{R}^n$  (the visible traits) and further endogenous parameters,  $s$  (the hidden traits), and an associated fitness value,  $f(\mathbf{x})$ . In some cases, the population contains only one individual. Individuals are also denoted as *parents* or *offspring*, depending on the context. In a generational procedure:

1. One or several parents are picked from the population (mating selection) and new offspring are generated by duplication and recombination of these parents.
2. The new offspring undergo mutation and become new members of the population.
3. Environmental selection reduces the population to its original size.

Within this procedure, ES employ the following main principles that are specified and applied in the operators and algorithms further below.

### 44.2.1 Environmental Selection

Environmental selection is applied as so-called *truncation selection*. Based on the individuals' fitnesses,  $f(\mathbf{x})$ , only the  $\mu$  best individuals from the population survive. In contrast to roulette wheel selection in *genetic algorithms* [44.9], only fitness ranks are used. In evolution strategies, environmental selection is deterministic. In evolutionary programming, like in many other evolutionary algorithms, environmental selection has a stochastic component. Environmental selection can also remove *overaged* individuals first.

### 44.2.2 Mating Selection and Recombination

Mating selection picks individuals from the population to become new parents. Recombination generates a single new offspring from these parents. Specifically, we

differentiate two common scenarios for mating selection and recombination:

- *Fitness-independent* mating selection and recombination do not depend on the fitness values of the individuals and can be either deterministic or stochastic. *Environmental* selection is then essential to drive the evolution toward better solutions.
- *Fitness-based* mating selection and recombination, where the recombination operator utilizes the fitness ranking of the parents (in a deterministic way). *Environmental* selection can potentially be omitted in this case.

### 44.2.3 Mutation and Parameter Control

Mutation introduces small, random, and unbiased changes to an individual. These changes typically affect all variables. The average size of these changes depends on endogenous parameters that change over time. These parameters are also called control parameters, or *endogenous strategy parameters*, and define the notion of *small*, for example, via the *step-size*  $\sigma$ . In contrast, *exogenous strategy parameters* are fixed once and for all, for example, parent number  $\mu$ . Parameter control is not always directly inspired by biological evolution, but is an indispensable and central feature of evolution strategies.

### 44.2.4 Unbiasedness

Unbiasedness is a generic design principle of evolution strategies. Variation resulting from mutation or recombination is designed to introduce new, unbiased *information*. Selection, on the other hand biases this information toward solutions with better fitness. Under neutral selection (i.e., fitness independent mating and environmental selection), all variation operators are desired to be unbiased. Maximum exploration and unbiasedness are in accord. ES are unbiased in the following respects:

- The type of mutation distribution, the Gaussian or normal distribution, is chosen in order to have rotational symmetry and maximum entropy (maximum exploration) under the given variances. Decreasing the entropy would introduce prior information and therefore a bias.
- Object parameters and endogenous strategy parameters are unbiased under recombination and unbiased under mutation. Typically, mutation has expectation zero.
- Invariance properties avoid a bias toward a specific representation of the fitness function, e.g., representation in a specific coordinate system or using specific fitness values (invariance to strictly monotonic transformations of the fitness values can be achieved). Parameter control in evolution strategies strives for invariance properties [44.10].

#### 44.2.5 $(\mu/\rho + \lambda)$ Notation for Selection and Recombination

An evolution strategy is an iterative (generational) procedure. In each generation new individuals (offspring) are created from existing individuals (parents). A mnemonic notation is commonly used to describe some aspects of this iteration. The  $(\mu/\rho + \lambda)$ -ES, where  $\mu$ ,  $\rho$  and  $\lambda$  are positive integers, also frequently denoted as  $(\mu + \lambda)$ -ES (where  $\rho$  remains unspecified) describes the following:

- The parent population contains  $\mu$  individuals.
- For recombination,  $\rho$  (out of  $\mu$ ) parent individuals are used. We have therefore  $\rho \leq \mu$ .
- $\lambda$  denotes the number of offspring generated in each iteration.
- $+$  describes whether or not selection is additionally based on the individuals' age. An evolution strategy applies *either plus- or comma-selection*. In *plus-selection*, age is not taken into account and the  $\mu$  best of  $\mu + \lambda$  individuals are chosen. Selection is elitist and, in effect, the parents are the  $\mu$  all-time best individuals. In *comma-selection*, individuals die out after one iteration step and only the offspring (the youngest individuals) survive to the next generation. In that case, environmental selection chooses  $\mu$  parents from  $\lambda$  offspring.

In a  $(\mu, \lambda)$ -ES,  $\lambda \geq \mu$  must hold and the case  $\lambda = \mu$  requires *fitness-based* mating selection or recombination. In a  $(\mu + \lambda)$ -ES,  $\lambda = 1$  is possible and known as *steady-state* scenario.

Occasionally, a subscript to  $\rho$  is used in order to denote the type of recombination, e.g.,  $\rho_I$  or  $\rho_W$  for intermediate or weighted recombination, respectively. Without a subscript, we tacitly assume intermediate recombination, if not stated otherwise. The notation has also been expanded to include the maximum age,  $\kappa$ , of individuals as  $(\mu, \kappa, \lambda)$ -ES [44.11], where *plus-selection* corresponds to  $\kappa = \infty$  and *comma-selection* corresponds to  $\kappa = 1$ .

#### 44.2.6 Two Algorithm Templates

Algorithm 44.1 gives pseudocode for the evolution strategy.

##### Algorithm 44.1 The $(\mu/\rho + \lambda)$ -ES

```

1: given  $n, \rho, \mu, \lambda \in \mathbb{N}_+$ 
2: initialize  $\mathcal{P} = \{(x_k, s_k, f(x_k)) \mid 1 \leq k \leq \mu\}$ 
3: while not happy
4:   for  $k \in \{1, \dots, \lambda\}$ 
5:      $(x_k, s_k) = \text{recombine}(\text{select\_mates}(\rho, \mathcal{P}))$ 
6:      $s_k \leftarrow \text{mutate\_s}(s_k)$ 
7:      $x_k \leftarrow \text{mutate\_x}(s_k, x_k) \in \mathbb{R}^n$ 
8:    $\mathcal{P} \leftarrow \mathcal{P} \cup \{(x_k, s_k, f(x_k)) \mid 1 \leq k \leq \lambda\}$ 
9:    $\mathcal{P} \leftarrow \text{select\_by\_age}(\mathcal{P})$  // identity for '+'
10:   $\mathcal{P} \leftarrow \text{select\_mu\_best}(\mu, \mathcal{P})$  // by  $f$ -ranking

```

Given is a population,  $\mathcal{P}$ , of at least  $\mu$  individuals  $(x_k, s_k, f(x_k))$ ,  $k = 1, \dots, \mu$ . Vector  $x_k \in \mathbb{R}^n$  is a solution vector and  $s_k$  contains the control or endogenous strategy parameters, for example, a success counter or a step-size that primarily serves to control the mutation of  $x$  (in Line 7). The values of  $s_k$  may be identical for all  $k$ . In each generation, first  $\lambda$  offspring are generated (Lines 4–7), each by recombination of  $\rho \leq \mu$  individuals from  $\mathcal{P}$  (Line 2), followed by mutation of  $s$  (Line 6) and of  $x$  (Line 7). The new offspring are added to  $\mathcal{P}$  (Line 8). Overaged individuals are removed from  $\mathcal{P}$  (Line 9), where individuals from the same generation have, by definition, the same age. Finally, the best  $\mu$  individuals are retained in  $\mathcal{P}$  (Line 10).

The mutation of the  $x$ -vector in Line 7 always involves a stochastic component. Lines 5 and 6 may have stochastic components as well.

When `select_mates` in Line 5 selects  $\rho = \mu$  individuals from  $\mathcal{P}$ , it reduces to the identity. If  $\rho = \mu$  and recombination is deterministic, as is commonly the case, the result of `recombine` is the same *parental centroid* for all offspring. The computation of the parental centroid can be done once before the `for` loop or as the

last step of the **while** loop, simplifying the initialization of the algorithm. Algorithm 44.2 shows the pseudocode in this case.

#### Algorithm 44.2 The $(\mu/\mu + \lambda)$ -ES

```

1: given  $n, \lambda \in \mathbb{N}_+$ 
2: initialize  $\mathbf{x} \in \mathbb{R}^n, s, \mathcal{P} = \{\}$ 
3: while not happy
4:   for  $k \in \{1, \dots, \lambda\}$ 
5:      $s_k = \text{mutate\_s}(s)$ 
6:      $\mathbf{x}_k = \text{mutate\_x}(s_k, \mathbf{x})$ 
7:      $\mathcal{P} \leftarrow \mathcal{P} \cup \{(\mathbf{x}_k, s_k, f(\mathbf{x}_k))\}$ 
8:    $\mathcal{P} \leftarrow \text{select\_by\_age}(\mathcal{P})$  // identity for '+'
9:    $(\mathbf{x}, s) \leftarrow \text{recombine}(\mathcal{P}, \mathbf{x}, s)$ 
```

In Algorithm 44.2, only a single parental centroid  $(\mathbf{x}, s)$  is initialized. Mutation takes this parental centroid as input (notice that  $s_k$  and  $\mathbf{x}_k$  in Lines 5 and 6 are now *assigned* rather than *updated*) and *recombination* is postponed to the end of the loop, computing in Line 9 the new parental centroid. While  $(\mathbf{x}_k, s_k)$  can contain all necessary information for this computation, it is often more transparent to use  $\mathbf{x}$  and  $s$  as additional arguments in Line 9. Selection based on  $f$ -values is now limited to mating selection in procedure *recombine* (that is, procedure *select\_mu\_best* is omitted and  $\mu$  is the number of individuals in  $\mathcal{P}$  that are actually used by *recombine*).

Using a single parental centroid has become the most popular approach, because such algorithms are simpler to formalize, easier to analyze, and even perform better in various circumstances as they allow for maximum genetic repair (see in the following). All instances of **ES** given in Sect. 44.3 are based on Algorithm 44.2.

#### 44.2.7 Recombination Operators

In **ES**, *recombination* combines information from several parents to generate a *single* new offspring. Often, *multirecombination* is used, where more than two parents are recombined ( $\rho > 2$ ). In contrast, in *genetic algorithms* often *two* offspring are generated from the recombination of two parents. In evolutionary programming, recombination is generally not used. The most important recombination operators used in evolution strategies are the following:

- *Discrete* or dominant recombination, denoted by  $(\mu/\rho_D + \lambda)$ , is also known as *uniform crossover* in genetic algorithms. For each variable (component

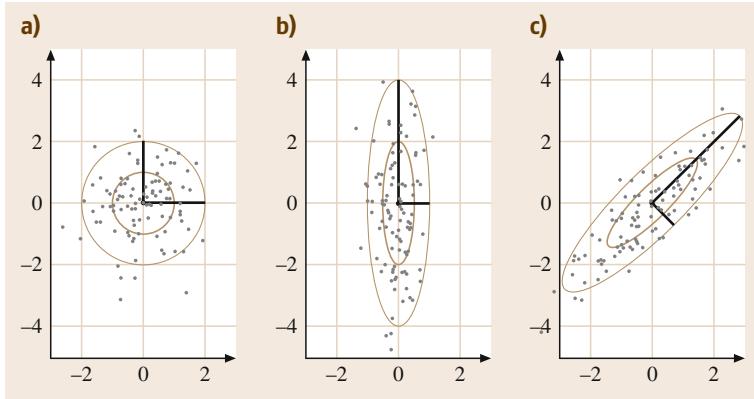

of the  $\mathbf{x}$ -vector), a single parent is drawn uniformly from all  $\rho$  parents to inherit the variable value. For  $\rho$  parents that all differ in each variable value, the result is uniformly distributed across  $\rho^n$  different  $\mathbf{x}$ -values. The result of discrete recombination depends on the given coordinate system.

- *Intermediate* recombination, denoted by  $(\mu/\rho_I + \lambda)$ , takes the average value of all  $\rho$  parents (computes the center of mass, the centroid).
- *Weighted* multirecombination [44.10, 12, 13], denoted by  $(\mu/\rho_W + \lambda)$ , is a generalization of intermediate recombination, usually with  $\rho = \mu$ . It takes a weighted average of all  $\rho$  parents. The weight values depend on the fitness ranking, in that better parents never get smaller weights than inferior ones. With equal weights, intermediate recombination is recovered. By using comma selection and  $\rho = \mu = \lambda$ , where some of the weights may be zero, weighted recombination can take over the role of fitness-based environmental selection and *negative* weights become a feasible option [44.12, 13]. The sum of weights must be either one or zero, or recombination must be applied to the vectors  $\mathbf{x}_k - \mathbf{x}$  and the result added to  $\mathbf{x}$ .

In principle, recombination operators from genetic algorithms, like one-point and two-point crossover or line recombination [44.14] can alternatively be used. However, they have been rarely applied in **ES**.

In **ES**, the result of selection and recombination is often deterministic (namely, if  $\rho = \mu$  and recombination is intermediate or weighted). This means that eventually all offspring are generated by mutation from the same single solution vector (the parental centroid) as in Algorithm 44.2. This leads, for given variances, to maximum entropy because all offspring are independently drawn from the same normal distribution. With discrete recombination, the offspring distribution is generated from a mixture of normal distributions with different mean values. The resulting distribution has lower entropy unless it has a larger overall variance.

The role of recombination, in general, is to keep the variation in a population high. Discrete recombination directly introduces variation by generating different solutions. Their distance resembles the distance between the parents. However, discrete recombination, as it depends on the given coordinate system, relies on separability: it can introduce variation *successfully* only if values of disrupted variables do not strongly depend on each other. Solutions resulting from discrete

**Fig. 44.1a–c** Three two-dimensional multivariate normal distributions  $\mathcal{N}(\mathbf{0}, \mathbf{C}) \sim \mathbf{C}^{\frac{1}{2}} \mathcal{N}(\mathbf{0}, \mathbf{I})$ . The covariance matrix  $\mathbf{C}$  of the distribution is, from left to right, the identity  $\mathbf{I}$  (isotropic distribution), the diagonal matrix  $\begin{pmatrix} 1/4 & 0 \\ 0 & 4 \end{pmatrix}$  (axis-parallel distribution) and  $\begin{pmatrix} 2.125 & 1.875 \\ 1.875 & 2.125 \end{pmatrix}$  with the same eigenvalues  $(1/4, 4)$  as the diagonal matrix. Shown are in each subfigure the mean at  $\mathbf{0}$  as small black dot (a different mean solely changes the axis annotations), two eigenvectors of  $\mathbf{C}$  along the principal axes of the ellipsoids (thin black lines), two ellipsoids reflecting the set of points  $\{\mathbf{x} : (\mathbf{x} - \mathbf{0})^T \mathbf{C}^{-1} (\mathbf{x} - \mathbf{0}) \in \{1, 4\}\}$  that represent the  $1\sigma$  and  $2\sigma$  lines of equal density, and 100 sampled points (however, a few of them are likely to be outside of the area shown)

recombination lie on the vertices of an *axis-parallel* box.

Intermediate and weighted multirecombination do not lead to variation within the new population as they result in the same single point for all offspring. However, they do allow the mutation operator to introduce *additional* variation by means of genetic repair [44.15]. Recombinative averaging reduces the effective step length taken in unfavorable directions by a factor of  $\sqrt{\mu}$  (or  $\sqrt{\mu_w}$  in the case of weighted recombination), but leaves the step length in favorable directions essentially unchanged, see also Sect. 44.4.2. This may allow increased variation by enlarging mutations by a factor of about  $\mu$  (or  $\mu_w$ ) as revealed in (44.16), to achieve maximal progress.

#### 44.2.8 Mutation Operators

The mutation operator introduces (*small*) variations by adding a point symmetric perturbation to the result of recombination, say a solution vector  $\mathbf{x} \in \mathbb{R}^n$ . This perturbation is drawn from a multivariate normal distribution,  $\mathcal{N}(\mathbf{0}, \mathbf{C})$ , with zero mean (expected value) and covariance matrix  $\mathbf{C} \in \mathbb{R}^{n \times n}$ . Besides normally distributed mutations, Cauchy mutations [44.16–18] have also been proposed in the context of ES and evolutionary programming. We have  $\mathbf{x} + \mathcal{N}(\mathbf{0}, \mathbf{C}) \sim \mathcal{N}(\mathbf{x}, \mathbf{C})$ , meaning that  $\mathbf{x}$  determines the expected value of the new offspring individual. We also have  $\mathbf{x} + \mathcal{N}(\mathbf{0}, \mathbf{C}) \sim$

$\mathbf{x} + \mathbf{C}^{\frac{1}{2}} \mathcal{N}(\mathbf{0}, \mathbf{I})$ , meaning that the linear transformation  $\mathbf{C}^{\frac{1}{2}}$  generates the desired distribution from the vector  $\mathcal{N}(\mathbf{0}, \mathbf{I})$  that has i.i.d.  $\mathcal{N}(0, 1)$  components. (Using the normal distribution has several advantages. The  $\mathcal{N}(\mathbf{0}, \mathbf{I})$  distribution is the most convenient way to implement an *isotropic* perturbation. The normal distribution is stable: sums of independent normally distributed random variables are again normally distributed. This facilitates the design and analysis of algorithms remarkably. Furthermore, the normal distribution has maximum entropy under the given variances.)

Figure 44.1 shows different normal distributions in dimension  $n = 2$ . Their lines of equal density are ellipsoids. Any straight section through the two-dimensional density recovers a two-dimensional Gaussian bell. Based on multivariate normal distributions, three different mutation operators can be distinguished:

- *Spherical/isotropic* (Fig. 44.1a) where the covariance matrix is proportional to the identity, i.e., the mutation distribution follows  $\sigma \mathcal{N}(\mathbf{0}, \mathbf{I})$  with step-size  $\sigma > 0$ . The distribution is spherical and invariant under rotations about its mean. In the following, Algorithm 44.3 uses this kind of mutation.
- *Axis-parallel* (Fig. 44.1b) where the covariance matrix is a diagonal matrix, i.e., the mutation distribution follows  $\mathcal{N}(\mathbf{0}, \text{diag}(\sigma)^2)$ , where  $\sigma$  is a vector of coordinate-wise standard deviations and the di-

agonal matrix  $\text{diag}(\sigma)^2$  has eigenvalues  $\sigma_i^2$  with eigenvectors  $e_i$ . The principal axes of the ellipsoid are parallel to the coordinate axes. This case includes the previous isotropic case. Below, Algorithms 44.4–44.6 implement this kind of mutation distribution.

- *General* (Fig. 44.1c) where the covariance matrix is symmetric and positive definite (i.e.,  $x^T C x > 0$  for all  $x \neq 0$ ), generally nondiagonal and has  $(n^2 + n)/2$  degrees of freedom (control parameters). The general case includes the previous axis-parallel and spherical cases. Below, Algorithms 44.7 and 44.8 implement general multivariate normally distributed mutations.

In the first and the second cases, the variations of variables are independent of each other, they are uncorrelated. This limits the usefulness of the operator in practice. The third case is *incompatible* with discrete recombination: for a narrow, diagonally oriented ellipsoid (not to be confused with a diagonal covariance matrix), a point resulting from selection and *discrete* recombination lies within this ellipsoid only if each

coordinate is taken from the same parent (which happens with probability  $1/\rho^{n-1}$ ) or from a parent with a very similar value in this coordinate. The narrower the ellipsoid the more similar (i.e., correlated) the value needs to be. As another illustration consider sampling, neutral selection and discrete recombination based on Fig. 44.1c): after discrete recombination the points  $(-2, 2)$  and  $(2, -2)$  outside the ellipsoid have the same probability as the points  $(2, 2)$  and  $(-2, -2)$  inside the ellipsoid.

The mutation operators introduced are *unbiased* in several ways. They are all point symmetrical and have expectation zero. Therefore, mutation alone will almost certainly not lead to better fitness values *in expectation*. The isotropic mutation operator features the same distribution along any direction. The general mutation operator is, as long as  $C$  remains unspecified, unbiased toward the choice of a Cartesian coordinate system, i.e. unbiased toward the representation of solutions  $x$ , which has also been referred to as invariance to affine coordinate system transformations [44.10]. This however depends on the way how  $C$  is adapted (see the following).

## 44.3 Parameter Control

Controlling the parameters of the mutation operator is key to the design of **ES**. Consider the isotropic operator (Fig. 44.1a), where the step-size  $\sigma$  is a scaling factor for the random vector perturbation. The step-size controls to a large extent the convergence speed. In situations where larger step-sizes lead to larger expected improvements, a step-size control technique should aim at increasing the step-size (and decreasing it in the opposite scenario).

The importance of step-size control is illustrated with a simple experiment. Consider a spherical function  $f(x) = \|x\|^\alpha$ ,  $\alpha > 0$ , and a (1+1)-**ES** with constant step-size equal to  $\sigma = 10^{-2}$ , i.e., with mutations drawn from  $10^{-2}\mathcal{N}(0, I)$ . The convergence of the algorithm is depicted in Fig 44.2 (constant  $\sigma$  graphs).

We observe, roughly speaking, three stages: up to 600 function evaluations, progress toward the optimum is slow. At this stage, the fixed step-size is too small. Between 700 and 800 evaluations, fast progress toward the optimum is observed. At this stage, the step-size is close to optimal. Afterward, the progress decreases and approaches the rate of the pure random search algorithm, well illustrated on the bottom subfigure. At this

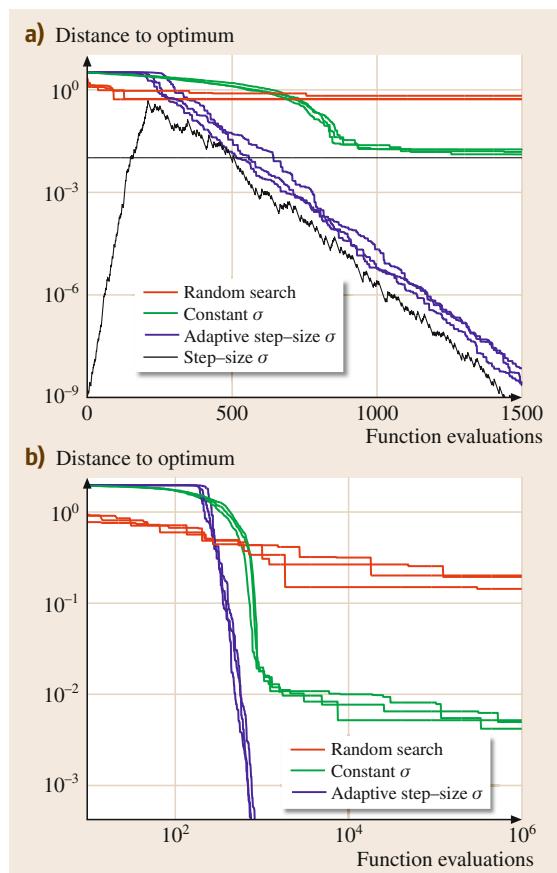

stage the fixed step-size is too large and the probability to sample better offspring becomes very small.

The figure also shows runs of the (1+1)-**ES** with 1/5th success rule step-size control (as described in Sect. 44.3.1) and the step-size evolution associated to one of these runs. The initial step-size is far too small and we observe that the adaptation technique increases the step-size in the first iterations. Afterward, step-size is kept roughly proportional to the distance to the optimum, which is in fact optimal and leads to linear convergence on the top subfigure.

Generally, the goal of parameter control is to drive the endogenous strategy parameters close to their optimal values. These optimal values, as we have seen for the step-size in Fig. 44.2, can significantly change over time or depending on the position in search space. In the most general case, the mutation operator has  $(n^2 + n)/2$  degrees of freedom (Sect. 44.2.8). The conjecture is that in the desired scenario lines of equal density of the mutation operator resemble locally the lines of equal fitness [44.4, pp. 242f.]. In the case of convex-quadratic fitness functions this resemblance can be perfect and, apart from the step-size, optimal param-

eters do not change over time (as illustrated in Fig. 44.3 below).

Control parameters like the step-size can be stored on different *levels*. Each individual can have its own

**Fig. 44.2a,b** Runs of the (1+1)-ES with constant step-size, of pure random search (uniform in  $[-0.2, 1]^{10}$ ), and of the (1+1)-ES with 1/5th success rule (Algorithm 44.3) on a spherical function  $f(\mathbf{x}) = \|\mathbf{x}\|^\alpha$ ,  $\alpha > 0$  (because of invariance to monotonic  $f$ -transformation the same graph is observed for any  $\alpha > 0$ ). For each algorithm, there are three runs in (a) and (b). The  $x$ -axis is linear in (a) and in log-scale in (b). For the (1+1)-ES with constant step-size,  $\sigma$  equals  $10^{-2}$ . For the (1+1)-ES with 1/5th success rule, the initial step-size is chosen very small to  $10^{-9}$  and the parameter  $d$  equals  $1 + 10/3$ . In (a) also the evolution of the step-size of one of the runs of the (1+1)-ES with 1/5th success rule is shown. All algorithms are initialized at 1. Eventually, the (1+1)-ES with 1/5th success rule reveals linear behavior (a), while the other two algorithms reveal eventually linear behavior in (b)

step-size value (like in Algorithms 44.4 and 44.5), or a single step-size is stored and applied to all individuals in the population. In the latter case, sometimes different populations with different parameter values are run in parallel [44.19].

In the following, six specific ES are outlined, each of them representing an important achievement in parameter control.

#### 44.3.1 The 1/5th Success Rule

The 1/5th success rule for step-size control is based on an important discovery made very early in the research of evolution strategies [44.1]. A similar rule had also been found independently before in [44.20]. As a control mechanism in practice, the 1/5th success rule has been mostly superseded by more sophisticated methods. However, its conceptual insight remains remarkably valuable.

Consider a linear fitness function, for example,  $f : \mathbf{x} \mapsto x_1$  or  $f : \mathbf{x} \mapsto \sum_i x_i$ . In this case, any point symmetrical mutation operator has a success probability of  $1/2$ : in one-half of the cases, the perturbation will improve the original solution, in one half of the cases the solution will deteriorate. Following the Taylor's formula, we know that smooth functions with decreasing neighborhood size become more and more linear. Therefore, the success probability becomes  $1/2$  for step-size  $\sigma \rightarrow 0$ . On most nonlinear functions, the success rate is indeed a monotonously decreasing function in  $\sigma$  and goes to zero for  $\sigma \rightarrow \infty$ . This suggests to control the step-size by increasing it for large success rates and decreasing it for small ones. This mechanism can drive the step-size close to the optimal value.

Rechenberg [44.1] investigated two simple but quite different functions, the corridor function

$$f : \mathbf{x} \mapsto \begin{cases} x_1 & \text{if } |x_i| \leq 1 \text{ for } i = 2, \dots, n \\ \infty & \text{otherwise,} \end{cases}$$

and the sphere function

$$f : \mathbf{x} \mapsto \sum x_i^2.$$

He found optimal success rates for the (1+1)-ES with isotropic mutation to be  $\approx 0.184 > 1/6$  and  $\approx 0.270 < 1/3$ , respectively (for  $n \rightarrow \infty$ ) [44.1]. Optimality here means to achieve the largest expected approach of the optimum in a single generation. This leads to approximately  $1/5$  as being the success value where to switch between decreasing and increasing the step-size.

**Algorithm 44.3** The (1+1)-ES with 1/5th Rule

```

1: given  $n \in \mathbb{N}_+$ ,  $d \approx \sqrt{n+1}$ 
2: initialize  $\mathbf{x} \in \mathbb{R}^n$ ,  $\sigma > 0$ 
3: while not happy
4:    $\mathbf{x}_1 = \mathbf{x} + \sigma \times \mathcal{N}(\mathbf{0}, \mathbf{I})$            // mutation
5:    $\sigma \leftarrow \sigma \times \exp^{1/d}(\mathbb{E}_{f(x_1) \leq f(x)} - 1/5)$ 
6:   if  $f(\mathbf{x}_1) \leq f(\mathbf{x})$                          // select if better
7:      $\mathbf{x} = \mathbf{x}_1$                                 //  $\mathbf{x}$ -value of new parent

```

Algorithm 44.3 implements the (1+1)-ES with 1/5th success rule in a simple and effective way [44.21]. Lines 5–7 implement Line 9 from Algorithm 44.2, including selection in Line 8. Line 5 in Algorithm 44.3 updates the step-size  $\sigma$  of the single parent. The step-size does not change if and only if the argument of  $\exp$  is zero. While this cannot happen in a single generation, we still can find a stationary point for  $\sigma$ :  $\log \sigma$  is unbiased if and only if the expected value of the argument of  $\exp$  is zero. This is the case if  $\mathbb{E}_{f(x_1) \leq f(x)} = 1/5$ , in other words, if the probability of an improvement with  $f(\mathbf{x}_1) \leq f(\mathbf{x})$  is 20%. Otherwise,  $\log \sigma$  increases in expectation if the success probability is larger than 1/5 and decreases if the success probability is smaller than 1/5. Hence, Algorithm 44.3 indeed implements the 1/5th success rule.

**44.3.2 Self-Adaptation**

A seminal idea in the domain of ES is parameter control via *self-adaptation* [44.3]. In self-adaptation, new control parameter settings are generated similar to new  $\mathbf{x}$ -vectors by recombination and mutation. Algorithm 44.4 presents an example with adaptation of  $n$  coordinate-wise standard deviations (individual step-sizes).

**Algorithm 44.4** The  $(\mu/\mu, \lambda)$ - $\sigma$  SA-ES

```

1: given  $n \in \mathbb{N}_+$ ,  $\lambda \geq 5n$ ,  $\mu \approx \lambda/4 \in \mathbb{N}$ ,  $\tau \approx 1/\sqrt{n}$ ,
    $\tau_i \approx 1/n^{1/4}$ 
2: initialize  $\mathbf{x} \in \mathbb{R}^n$ ,  $\sigma \in \mathbb{R}_+^n$ 
3: while not happy
4:   for  $k \in \{1, \dots, \lambda\}$ 
     // random numbers i.i.d. for all  $k$ 
5:      $\xi_k = \tau \mathcal{N}(0, 1)$            // global step-size
6:      $\hat{\xi}_k = \tau_i \mathcal{N}(\mathbf{0}, \mathbf{I})$       // coordinate-wise  $\sigma$ 
7:      $z_k = \mathcal{N}(\mathbf{0}, \mathbf{I})$           //  $\mathbf{x}$ -vector change
     // mutation
8:      $\sigma_k = \sigma \circ \exp(\xi_k) \times \exp(\hat{\xi}_k)$ 
9:      $\mathbf{x}_k = \mathbf{x} + \sigma_k \circ z_k$ 
10:     $\mathcal{P} = \text{sel\_}\mu\text{-best}(\{(\mathbf{x}_k, \sigma_k, f(\mathbf{x}_k)) \mid 1 \leq k \leq \lambda\})$ 
     // recombination

```

$$\begin{aligned} 11: \quad \sigma &= \frac{1}{\mu} \sum_{\sigma_k \in \mathcal{P}} \sigma_k \\ 12: \quad \mathbf{x} &= \frac{1}{\mu} \sum_{x_k \in \mathcal{P}} \mathbf{x}_k \end{aligned}$$

First, for conducting the mutation, random events are drawn in Lines 5–7. In Line 8, the step-size vector for each individual undergoes (i) a mutation common for all components,  $\exp(\xi_k)$ , and (ii) a component-wise mutation with  $\exp(\hat{\xi}_k)$ . These mutations are unbiased, in that  $\mathbb{E} \log \sigma_k = \log \sigma$ . The mutation of  $\mathbf{x}$  in Line 9 uses the mutated vector  $\sigma_k$ . After selection in Line 10, intermediate recombination is applied to compute  $\mathbf{x}$  and  $\sigma$  for the next generation. By taking the average over  $\sigma_k$  we have  $\mathbb{E}\sigma = \mathbb{E}\sigma_k$  in Line 11. However, the application of mutation *and* recombination on  $\sigma$  introduces a moderate bias such that  $\sigma$  tends to increase under neutral selection [44.22].

In order to achieve stable behavior of  $\sigma$ , the number of parents  $\mu$  must be large enough, which is reflected in the setting of  $\lambda$ . A setting of  $\tau \approx 1/4$  has been proposed in combination with  $\xi_k$  being uniformly distributed across the two values in  $\{-1, 1\}$  [44.2].

**44.3.3 Derandomized Self-Adaptation**

Derandomized self-adaptation [44.23] addresses the problem of selection noise that occurs with self-adaptation of  $\sigma$  as outlined in Algorithm 44.4. Selection noise refers to the possibility that very good offspring may be generated with poor strategy parameter settings and vice versa. The problem occurs frequently and has two origins:

- A small/large component in  $|\sigma_k \circ z_k|$  (Line 9 in Algorithm 44.4) does not necessarily imply that the respective component of  $\sigma_k$  is small/large. Selection of  $\sigma$  is disturbed by the respective realizations of  $z$ .
- Selection of a small/large component of  $|\sigma_k \circ z_k|$  does not imply that this is necessarily a favorable setting: more often than not, the sign of a component is more important than its size and all other components influence the selection as well.

Due to selection noise, poor values are frequently inherited and we observe stochastic fluctuations of  $\sigma$ . Such fluctuations can in particular lead to very small values (very large values are removed by selection more quickly). The overall magnitude of these fluctuations can be implicitly controlled via the parent number  $\mu$ ,

because intermediate recombination (Line 11 in Algorithm 44.4) effectively reduces the magnitude of  $\sigma$ -changes and biases  $\log \sigma$  to larger values.

For  $\mu \ll n$ , the stochastic fluctuations become prohibitive and therefore  $\mu \approx \lambda/4 \geq 1.25n$  is chosen to make  $\sigma$ -self-adaptation reliable.

Derandomization addresses the problem of selection noise on  $\sigma$  directly without resorting to a large parent number. The derandomized  $(1, \lambda)$ - $\sigma$ SA-ES is outlined in Algorithm 44.5 and addresses selection noise twofold.

#### Algorithm 44.5 Derandomized $(1, \lambda)$ - $\sigma$ SA-ES

```

1: given  $n \in \mathbb{N}_+$ ,  $\lambda \approx 10$ ,  $\tau \approx 1/3$ ,  $d \approx \sqrt{n}$ ,  $d_i \approx n$ 
2: initialize  $\mathbf{x} \in \mathbb{R}^n$ ,  $\sigma \in \mathbb{R}_+^n$ 
3: while not happy
4:   for  $k \in \{1, \dots, \lambda\}$ 
      // random numbers i.i.d. for all  $k$ 
5:      $\xi_k = \tau \mathcal{N}(0, 1)$ 
6:      $\mathbf{z}_k = \mathcal{N}(\mathbf{0}, \mathbf{I})$ 
      // mutation, re-using random events
7:      $\mathbf{x}_k = \mathbf{x} + \exp(\xi_k) \times \sigma \circ \mathbf{z}_k$ 
8:      $\sigma_k = \sigma \circ \exp^{1/d_i} \left( \frac{|\mathbf{z}_k|}{\mathbb{E}|\mathcal{N}(0, 1)|} - 1 \right)$ 
       $\times \exp^{1/d}(\xi_k)$ 
9:      $(\mathbf{x}_1, \sigma_1, f(\mathbf{x}_1)) \leftarrow \text{select\_single\_best}($ 
       $\{(\mathbf{x}_k, \sigma_k, f(\mathbf{x}_k)) \mid 1 \leq k \leq \lambda\})$ 
      // assign new parent
10:     $\sigma = \sigma_1$ 
11:     $\mathbf{x} = \mathbf{x}_1$ 
```

Instead of introducing new variations in  $\sigma$  by means of  $\exp(\xi_k)$ , the variations from  $\mathbf{z}_k$  are directly used for the mutation of  $\sigma$  in Line 8. The variations are damped compared to their use in the mutation of  $\mathbf{x}$  (Line 7) via  $d$  and  $d_i$ , thereby mimicking the effect of intermediate recombination on  $\sigma$  [44.23, 24]. The order of the two mutation equations becomes irrelevant.

For Algorithm 44.5 also a  $(\mu/\mu, \lambda)$  variant with recombination is feasible. However, in particular in the  $(\mu/\mu_I, \lambda)$ -ES,  $\sigma$ -self-adaptation tends to generate too small step-sizes. A remedy for this problem is to use nonlocal information for step-size control.

#### 44.3.4 Nonlocal Derandomized Step-Size Control (CSA)

When using self-adaptation, step-sizes are associated with individuals and selected based on the fitness of each individual. However, step-sizes that serve indi-

viduals well by giving them a high likelihood to be selected are generally not step-sizes that maximize the progress of the entire population or the parental centroid  $\mathbf{x}$ . We will see later that, for example, the optimal step-size may increase linearly with  $\mu$  (Sect. 44.4.2 and (44.16)). With self-adaptation on the other hand, the step-size of the  $\mu$ -th best offspring is typically even smaller than the step-size of the best offspring. Consequently, Algorithm 44.5 assumes often too small step-sizes and can be considerably improved by using nonlocal information about the evolution of the population. Instead of single (local) mutation steps  $\mathbf{z}$ , an exponentially fading record,  $s_\sigma$ , of mutation steps is taken. This record, referred to as *search path* or *evolution path*, can be pictured as a sequence or sum of consecutive successful  $\mathbf{z}$ -steps that is nonlocal in time and space. A search path carries information about the interrelation between single steps. This information can improve the adaptation and search procedure remarkably. Algorithm 44.6 outlines the  $(\mu/\mu, \lambda)$ -ES with *cumulative path length control*, also denoted as *cumulative step-size adaptation* (CSA), and additionally with nonlocal *individual* step-size adaptation [44.25, 26].

#### Algorithm 44.6 The $(\mu/\mu, \lambda)$ -ES with Search Path

```

1: given  $n \in \mathbb{N}_+$ ,  $\lambda \in \mathbb{N}$ ,  $\mu \approx \lambda/4 \in \mathbb{N}$ ,
    $c_\sigma \approx \sqrt{\mu/(n+\mu)}$ ,  $d \approx 1 + \sqrt{\mu/n}$ ,  $d_i \approx 3n$ 
2: initialize  $\mathbf{x} \in \mathbb{R}^n$ ,  $\sigma \in \mathbb{R}_+^n$ ,  $s_\sigma = \mathbf{0}$ 
3: while not happy
4:   for  $k \in \{1, \dots, \lambda\}$ 
      // i.i.d. for each  $k$ 
5:      $\mathbf{z}_k = \mathcal{N}(\mathbf{0}, \mathbf{I})$ 
6:      $\mathbf{x}_k = \mathbf{x} + \sigma \circ \mathbf{z}_k$ 
7:      $\mathcal{P} \leftarrow \text{sel\_}\mu\text{-best}(\{(\mathbf{x}_k, \mathbf{z}_k, f(\mathbf{x}_k)) \mid 1 \leq k \leq \lambda\})$ 
      // recombination and parent update
8:      $s_\sigma \leftarrow (1 - c_\sigma) s_\sigma +$ 
       $\sqrt{c_\sigma (2 - c_\sigma)} \frac{\sqrt{\mu}}{\mu} \sum_{\mathbf{z}_k \in \mathcal{P}} \mathbf{z}_k$ 
9:      $\sigma \leftarrow \sigma \circ \exp^{1/d_i} \left( \frac{|s_\sigma|}{\mathbb{E}|\mathcal{N}(0, 1)|} - 1 \right)$ 
10:     $\times \exp^{c_\sigma/d} \left( \frac{\|s_\sigma\|}{\mathbb{E}\|\mathcal{N}(\mathbf{0}, \mathbf{I})\|} - 1 \right)$ 
11:     $\mathbf{x} = \frac{1}{\mu} \sum_{\mathbf{x}_k \in \mathcal{P}} \mathbf{x}_k$ 
```

In the  $(\mu/\mu, \lambda)$ -ES with search path, Algorithm 44.6, the factor  $\xi_k$  for changing the overall step-size has disappeared (compared to Algorithm 44.5) and the update of  $\sigma$  is postponed until after the *for* loop.

Instead of the additional random variate  $\xi_k$ , the length of the search path  $\|s_\sigma\|$  determines the global step-size change in Line 9. For the individual step-size change,  $|z_k|$  is replaced by  $|s_\sigma|$ .

Using a search path is justified in two ways. First, it implements a low-pass filter for selected  $z$ -steps, removing high-frequency (most likely noisy) information. Second, and more importantly, it utilizes information that is otherwise lost: even if all single steps have the same length, the length of  $s_\sigma$  can vary, because it depends on the correlation between the directions of  $z$ -steps. If single steps point into similar directions, the path will be up to almost  $\sqrt{2/c_\sigma}$  times longer than a single step and the step-size will increase. If they oppose each other the path will be up to almost  $\sqrt{c_\sigma/2}$  times shorter and the step-size will decrease. The same is true for single components of  $s_\sigma$ .

The factors  $\sqrt{c_\sigma(2-c_\sigma)}$  and  $\sqrt{\mu}$  in Line 8 guarantee unbiasedness of  $s_\sigma$  under neutral selection, as usual.

All **ES** described so far are of somewhat limited value, because they feature only isotropic or axis-parallel mutation operators. In the remainder we consider methods that entertain not only an  $n$ -dimensional step-size vector  $\sigma$ , but also correlations between variables for the mutation of  $x$ .

#### 44.3.5 Addressing Dependencies Between Variables

The **ES** presented so far sample the mutation distribution independently in each component of *the given* coordinate system. The lines of equal density are either spherical or axis-parallel ellipsoids (compare Fig. 44.1). This is a major drawback, because it allows to solve problems with a long or elongated valley efficiently only if the valley is aligned with the coordinate system. In this section, we discuss **ES** that allow us to traverse nonaxis-parallel valleys efficiently by sampling distributions with correlations.

## Full Covariance Matrix

Algorithms that adapt the complete covariance matrix of the mutation distribution (compare Sect. 44.2.8) are *correlated mutations* [44.3], the *generating set adaptation* [44.26], the *covariance matrix adaptation (CMA)* [44.27], a mutative invariant adaptation [44.28], and some instances of *natural evolution strategies (NES)* [44.29–31]. Correlated mutations and some natural ES are however not invariant under changes of the

coordinate system [44, 10, 31, 32]. In the next sections, we outline two **ES** that adapt the full covariance matrix reliably and are invariant under coordinate system changes: the covariance matrix adaptation evolution strategy (**CMA-ES**) and the exponential natural evolution strategy (**xNES**).

## Restricted Covariance Matrix

Algorithms that adapt nondiagonal covariance matrices, but are restricted to certain matrices, are the *momentum adaptation* [44.33], *direction adaptation* [44.26], *main vector adaptation* [44.34], and *limited memory CMA-ES* [44.35]. These variants are limited in their capability to shape the mutation distribution, but they might be advantageous for larger dimensional problems, say larger than a 100.

#### 44.3.6 Covariance Matrix Adaptation (CMA)

The **CMA-ES** [44.10, 27, 36] is a de facto standard in continuous domain evolutionary computation. The **CMA-ES** is a natural generalization of Algorithm 44.6 in that the mutation ellipsoids are not constrained to be axis-parallel, but can take on a general orientation. The **CMA-ES** is also a direct successor of the *generating set adaptation* [44.26], replacing self-adaptation to control the overall step-size with cumulative step-size adaptation [44.37].

The  $(\mu/\mu_W, \lambda)$ -CMA-ES is outlined in Algorithm 44.7.

---

**Algorithm 44.7** The  $(\mu/\mu_W, \lambda)$ -CMA-ES

```

9:    $s_c \leftarrow (1 - c_e) s_c + h_\sigma \sqrt{c_e (2 - c_e)} \sqrt{\mu_w} \sum_{z_k \in \mathcal{P}} w_k \mathbf{C}^{\frac{1}{2}} z_k$  // search path for  $\mathbf{C}$ 
10:   $x \leftarrow x + c_m \sigma \mathbf{C}^{\frac{1}{2}} \sum_{z_k \in \mathcal{P}} w_k z_k$ 
11:   $\sigma \leftarrow \sigma \exp^{c_\sigma/d} \left( \frac{\|s_\sigma\|}{\mathbb{E}[\|\mathcal{N}(\mathbf{0}, \mathbf{I})\|]} - 1 \right)$ 
12:   $\mathbf{C} \leftarrow (1 - c_1 + c_h - c_\mu) \mathbf{C} + c_1 s_c s_c^T + c_\mu \sum_{z_k \in \mathcal{P}} w_k \mathbf{C}^{\frac{1}{2}} z_k (\mathbf{C}^{\frac{1}{2}} z_k)^T$ 

```

where  $h_\sigma = \mathbb{1}_{\|s_\sigma\|^2/n < 2+4/(n+1)}$ ,  $c_h = c_1(1 - h_\sigma^2)c_e(2 - c_e)$ , and  $\mathbf{C}^{\frac{1}{2}}$  is the unique symmetric positive definite matrix obeying  $\mathbf{C}^{\frac{1}{2}} \times \mathbf{C}^{\frac{1}{2}} = \mathbf{C}$ . All  $c$ -coefficients are  $\leq 1$ .

Two search paths are maintained,  $s_\sigma$  and  $s_c$ . The first path,  $s_\sigma$ , accumulates steps in the coordinate system where the mutation distribution is isotropic and which can be derived by scaling in the principal axes of the mutation ellipsoid only. The path generalizes  $s_\sigma$  from Algorithm 44.6 to nondiagonal covariance matrices and is used to implement cumulative step-size adaptation, CSA, in Line 10 (resembling Line 9 in Algorithm 44.6). Under neutral selection,  $s_\sigma \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$  and  $\log \sigma$  is unbiased.

The second path,  $s_c$ , accumulates steps, disregarding  $\sigma$ , in the given coordinate system. Whenever  $s_\sigma$  is large and therefore  $\sigma$  is increasing fast, the coefficient  $h_\sigma$  prevents  $s_c$  from getting large and quickly changing the distribution shape via  $\mathbf{C}$ . Given  $h_\sigma \equiv 1$ , under neutral selection  $s_c \sim \mathcal{N}(\mathbf{0}, \mathbf{C})$ . The coefficient  $c_h$  in Line 12 corrects for the bias on  $s_c$  introduced by events  $h_\sigma = 0$ . The covariance matrix update consists of a rank-1 update, based on the search path  $s_c$ , and a rank- $\mu$  update with  $\mu$  nonzero recombination weights  $w_k$ . Under neutral selection, the expected covariance matrix equals the covariance matrix before the update.

The updates of  $x$  and  $\mathbf{C}$  follow a common principle. The mean  $x$  is updated such that the likelihood of successful offspring to be sampled again is maximized (or increased if  $c_m < 1$ ). The covariance matrix  $\mathbf{C}$  is updated such that the likelihood of successful steps  $(x_k - x)/\sigma$  to appear again, or the likelihood to sample (in the direction of) the path  $s_c$ , is increased. A more fundamental principle for the equations is given in the next section.

Using not only the  $\mu$  best but all  $\lambda$  offspring can be particularly useful for the rank- $\mu$  update of  $\mathbf{C}$  in

Line 12, where negative weights  $w_k$  for inferior offspring are advisable. Such an update has been introduced as *active CMA* [44.38].

The factor  $c_m$  in Line 10 can be equally written as a mutation scaling factor  $\kappa = 1/c_m$  in Line 6, compare [44.39]. This means that the actual mutation steps are larger than the inherited ones, resembling the derandomization technique of damping step-size changes to address selection noise as described in Sect. 44.3.3.

An elegant way to replace Line 10 is

$$\sigma \leftarrow \sigma \exp^{(c_\sigma/d)/2} \left( \frac{\|s_\sigma\|^2}{n} - 1 \right), \quad (44.1)$$

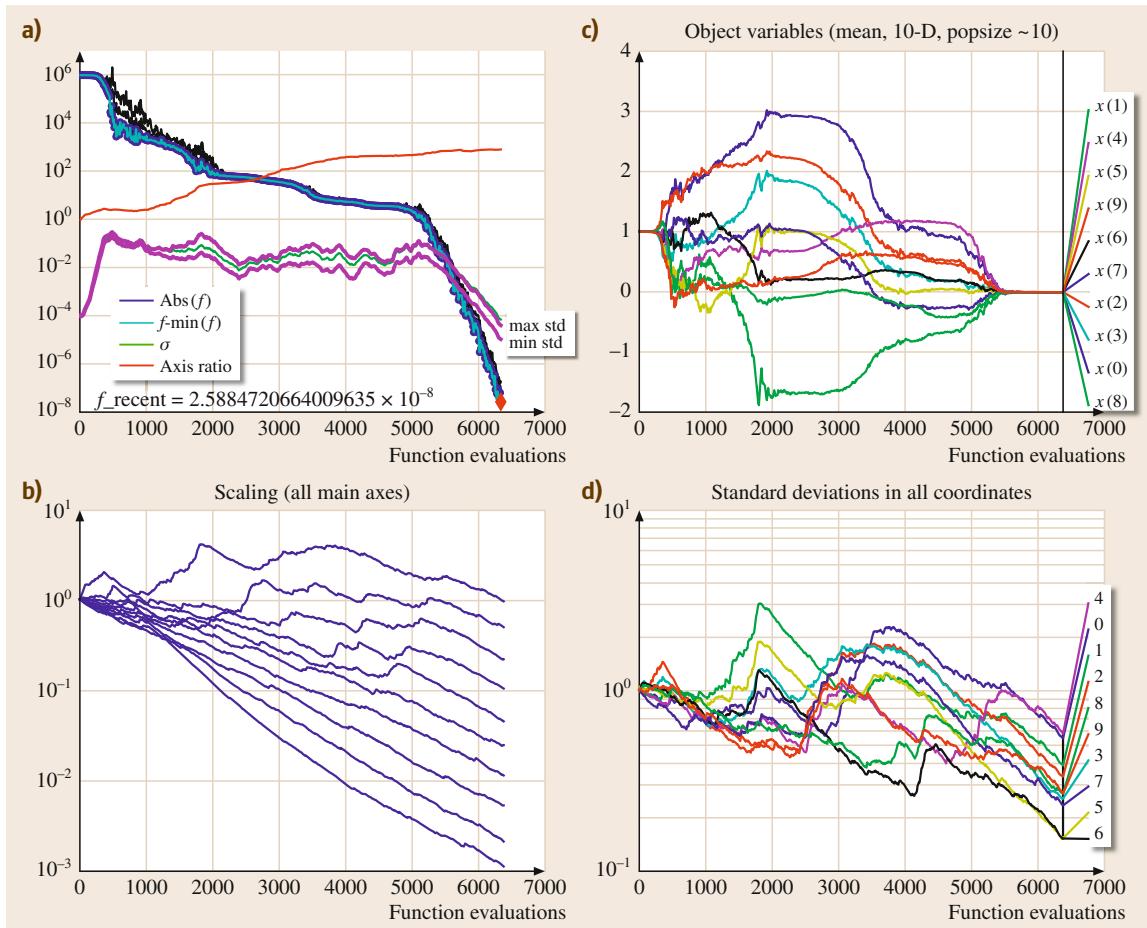

and often used in theoretical investigations of this update as those presented in Sect. 44.4.2.

A single run of the  $(5/5_W, 10)$ -CMA-ES on a convex-quadratic function is shown in Fig. 44.3. For the sake of demonstration, the initial step-size is chosen far too small (a situation that should be avoided in practice) and increases quickly for the first 400  $f$ -evaluations. After no more than 5500  $f$ -evaluations the adaptation of  $\mathbf{C}$  is accomplished. Then the eigenvalues of  $\mathbf{C}$  (square roots of which are shown in the lower left) reflect the underlying convex-quadratic function and the convergence speed is the same as on the sphere function and about 60% of the speed of the  $(1+1)$ -ES as observed in Fig. 44.2. The resulting convergence speed is about 10 000 times faster than without adaptation of  $\mathbf{C}$  and at least 1000 times faster compared to any of the algorithms from the previous sections.

#### 44.3.7 Natural Evolution Strategies

The idea of using natural gradient learning [44.40] in ES has been proposed in [44.29] and further pursued in [44.31, 41]. *Natural evolution strategies* (NES) put forward the idea that the update of all distribution parameters can be based on the same fundamental principle. NES have been proposed as a more principled alternative to CMA-ES and characterized by operating on Cholesky factors of a covariance matrix. Only later was it discovered that also CMA-ES implements the underlying NES principle of natural gradient learning [44.31, 42].

For simplicity, let the vector  $\theta$  represents all parameters of the distribution to sample new offspring. In the case of a multivariate normal distribution as above, we have a bijective transformation between  $\theta$  and mean and covariance matrix of the distribution,  $\theta \leftrightarrow (x, \sigma^2 \mathbf{C})$ .

**Fig. 44.3a-d** A single run of the (5/5<sub>w</sub>, 10)-CMA-ES on the rotated ellipsoid function  $\mathbf{x} \mapsto \sum_{i=1}^n \alpha_i^2 y_i^2$  with  $\alpha_i = 10^{3(i-1)/(n-1)}$ ,  $\mathbf{y} = \mathbf{R}\mathbf{x}$ , where  $\mathbf{R}$  is a random matrix with  $\mathbf{R}^T \mathbf{R} = \mathbf{I}$ , for  $n = 10$ . Shown is the evolution of various parameters against the number of function evaluations. (a) best (gray), median and worst fitness value that reveal the final convergence phase after about 5500 function evaluations where the ellipsoid function has been reduced to the simple sphere; minimal and maximal coordinate-wise standard deviation of the mutation distribution and in between (mostly hidden) the step-size  $\sigma$  that is initialized far too small and increases quickly in the beginning, that increases afterward several times again by up to one order of magnitude and decreases with maximal rate during the last 1000 f-evaluations; axis ratio of the mutation ellipsoid (square root of the condition number of  $\mathbf{C}$ ) that increases from 1 to 1000 where the latter corresponds to  $\alpha_n/\alpha_1$ . (b) sorted principal axis lengths of the mutation ellipsoid disregarding  $\sigma$  (square roots of the sorted eigenvalues of  $\mathbf{C}$ , see also Fig. 44.1) that adapt to the (local) structure of the underlying optimization problem; they finally reflect almost perfectly the factors  $\alpha_i^{-1}$  up to a constant factor. (c)  $\mathbf{x}$  (distribution mean) that is initialized with all ones and converges to the global optimum in zero while correlated movements of the variables can be observed. (d) standard deviations in the coordinates disregarding  $\sigma$  (square roots of diagonal elements of  $\mathbf{C}$ ) showing the  $\mathbf{R}$ -dependent projections of the principal axis lengths into the given coordinate system. The straight lines to the right of the vertical line at about 6300 only annotate the coordinates and do not reflect measured data

We consider a probability density  $p(\cdot|\theta)$  over  $\mathbb{R}^n$  parametrized by  $\theta$  and a nonincreasing function  $W_\theta^f: \mathbb{R} \rightarrow \mathbb{R}$ . More specifically,  $W_\theta^f: y \mapsto w(\Pr_{z \sim p(\cdot|\theta)}(f(z) \leq y))$  computes the  $p_\theta$ -quantile, or cumulative distribution function, of  $f(z)$  with  $z \sim p(\cdot|\theta)$  at point  $y$ , composed with a nonincreasing predefined weight function  $w: [0, 1] \rightarrow \mathbb{R}$  (where  $w(0) > w(1/2) = 0$  is advisable). The value of  $W_\theta^f(f(x))$  is invariant under strictly monotonous transformations of  $f$ . For  $x \sim p(\cdot|\theta)$  the distribution of  $W_\theta^f(f(x)) \sim w(\mathcal{U}[0, 1])$  depends only on the predefined  $w$ ; it is independent of  $\theta$  and  $f$  and therefore also (time-)invariant under  $\theta$ -updates. Given  $\lambda$  samples  $x_k$ , we have the rank-based consistent estimator

$$W_\theta^f(f(x_k)) \approx w\left(\frac{\text{rank}(f(x_k)) - 1/2}{\lambda}\right).$$

We consider the expected  $W_\theta^f p$ -transformed fitness [44.43]

$$\begin{aligned} J(\theta) &= \mathbb{E}(W_\theta^f p(f(x))) \quad x \sim p(\cdot|\theta) \\ &= \int W_\theta^f p(f(x)) p(x|\theta) dx, \end{aligned} \quad (44.2)$$

where the expectation is taken under the given sample distribution. The maximizer of  $J$  w.r.t.  $p(\cdot|\theta)$  is, for any fixed  $W_\theta^f p$ , a Dirac distribution concentrated on the minimizer of  $f$ . A natural way to update  $\theta$  is therefore a gradient ascent step in the  $\nabla_\theta J$  direction. However, the *vanilla* gradient  $\nabla_\theta J$  depends on the specific parametrization chosen in  $\theta$ . In contrast, the natural gradient, denoted by  $\widetilde{\nabla}_\theta$ , is associated to the Fisher metric that is intrinsic to  $p$  and independent of the chosen  $\theta$ -parametrization. Developing  $\widetilde{\nabla}_\theta J(\theta)$  under mild assumptions on  $f$  and  $p(\cdot|\theta)$  by exchanging differentiation and integration, recognizing that the gradient  $\widetilde{\nabla}_\theta$  does not act on  $W_\theta^f p$ , using the log-likelihood trick  $\widetilde{\nabla}_\theta p(\cdot|\theta) = p(\cdot|\theta) \widetilde{\nabla}_\theta \ln p(\cdot|\theta)$  and finally setting  $\theta' = \theta$  yields

$$\widetilde{\nabla}_\theta J(\theta) = \mathbb{E}\left(W_\theta^f(f(x)) \widetilde{\nabla}_\theta \ln p(x|\theta)\right). \quad (44.3)$$

We set  $\theta' = \theta$  because we will estimate  $W_{\theta'}$  using the current samples that are distributed according to  $p(\cdot|\theta)$ . A Monte Carlo approximation of the expected value by the average finally yields the comparatively simple expression

$$\widetilde{\nabla}_\theta J(\theta) \approx \frac{1}{\lambda} \sum_{k=1}^{\lambda} \underbrace{W_\theta^f(f(x_k))}_{\text{intrinsic candidate direction}} \underbrace{\widetilde{\nabla}_\theta \ln p(x_k|\theta)}_{\text{preference weight}} \quad (44.4)$$

for a natural gradient update of  $\theta$ , where  $x_k \sim p(\cdot|\theta)$  is sampled from the current distribution. The natural gradient can be computed as  $\widetilde{\nabla}_\theta = \mathbf{F}_\theta^{-1} \nabla_\theta$ , where  $\mathbf{F}_\theta$  is the Fisher information matrix expressed in  $\theta$ -coordinates. For the multivariate Gaussian distribution,  $\widetilde{\nabla}_\theta \ln p(x_k|\theta)$  can indeed be easily expressed and computed efficiently. We find that in CMA-ES (Algorithm 44.7), the rank- $\mu$  update (Line 12 with  $c_1 = 0$ ) and the update in Line 10 are natural gradient updates of  $\mathbf{C}$  and  $\mathbf{x}$ , respectively [44.31, 42], where the  $k$ -th largest  $w_k$  is a consistent estimator for the  $k$ -th largest  $W_\theta^f(f(x_k))$  [44.43].

While the natural gradient does not depend on the parametrization of the distribution, a finite step taken in the natural gradient direction does. This becomes relevant for the covariance matrix update, where natural ES take a different parametrization than CMA-ES. Starting from Line 12 in Algorithm 44.7, we find for  $c_1 = c_h = 0$

$$\begin{aligned} \mathbf{C} &\leftarrow (1 - c_\mu) \mathbf{C} + c_\mu \sum_{z_k \in \mathcal{P}} w_k \mathbf{C}^{\frac{1}{2}} z_k (\mathbf{C}^{\frac{1}{2}} z_k)^T \\ &= \mathbf{C}^{\frac{1}{2}} \left( (1 - c_\mu) \mathbf{I} + c_\mu \sum_{z_k \in \mathcal{P}} w_k z_k z_k^T \right) \mathbf{C}^{\frac{1}{2}} \\ &\stackrel{w_k=1}{=} \mathbf{C}^{\frac{1}{2}} \left( \mathbf{I} + c_\mu \sum_{z_k \in \mathcal{P}} w_k (z_k z_k^T - \mathbf{I}) \right) \mathbf{C}^{\frac{1}{2}} \\ &\stackrel{c_\mu \ll 1}{\approx} \mathbf{C}^{\frac{1}{2}} \exp^{c_\mu} \left( \sum_{z_k \in \mathcal{P}} w_k (z_k z_k^T - \mathbf{I}) \right) \mathbf{C}^{\frac{1}{2}}. \end{aligned} \quad (44.5)$$

The term bracketed between the matrices  $\mathbf{C}^{\frac{1}{2}}$  in the lower three lines is a multiplicative covariance matrix update expressed in the natural coordinates, where the covariance matrix is the identity and  $\mathbf{C}^{\frac{1}{2}}$  serves as coordinate system transformation into the given coordinate system. Only the lower two lines of (44.5) do not rely on the constraint  $\sum_k w_k = 1$  in order to satisfy a stationarity condition on  $\mathbf{C}$ . For a given  $\mathbf{C}$  on the right-hand side of (44.5), we have under neutral selection the stationarity condition  $\mathbb{E}(\mathbf{C}_{\text{new}}) = \mathbf{C}$  for the first three lines and  $\mathbb{E}(\log(\mathbf{C}_{\text{new}})) = \log(\mathbf{C})$  for the last line, where  $\log$  is the inverse of the matrix exponential  $\exp$ . The last line of (44.5) is used in the *exponential natural evolution strategy*, xNES [44.31] and guarantees positive definiteness of  $\mathbf{C}$  even with negative weights, independent of  $c_\mu$  and of the data  $z_k$ . The xNES is depicted in Algorithm 44.8.

**Algorithm 44.8 The Exponential NES (xNES)**

```

1: given  $n \in \mathbb{N}_+$ ,  $\lambda \geq 5$ ,  $w_k = w'(k) / \sum_k |w'(k)|$ ,  

    $w'(k) \approx \log(\lambda/2 + 1/2) - \log \text{rank}(f(x_k))$ ,  

    $\eta_c \approx (5 + \lambda)/(5n^{1.5}) \leq 1$ ,  $\eta_\sigma \approx \eta_c$ ,  $\eta_x \approx 1$   

2: initialize  $\mathbf{C}^{\frac{1}{2}} = \mathbf{I}$ ,  $\sigma \in \mathbb{R}_+$ ,  $\mathbf{x} \in \mathbb{R}^n$   

3: while not happy  

4:   for  $k \in \{1, \dots, \lambda\}$   

5:      $\mathbf{z}_k = \mathcal{N}(\mathbf{0}, \mathbf{I})$  // i.i.d. for all  $k$   

6:      $\mathbf{x}_k = \mathbf{x} + \sigma \mathbf{C}^{\frac{1}{2}} \times \mathbf{z}_k$   

7:      $\mathcal{P} = \{(\mathbf{z}_k, f(\mathbf{x}_k)) \mid 1 \leq k \leq \lambda\}$   

8:      $\mathbf{x} \leftarrow \mathbf{x} + \eta_x \sigma \mathbf{C}^{\frac{1}{2}} \sum_{\mathbf{z}_k \in \mathcal{P}} w_k \mathbf{z}_k$   

9:      $\sigma \leftarrow \sigma \exp^{\eta_\sigma/2} \left( \sum_{\mathbf{z}_k \in \mathcal{P}} w_k \left( \frac{\|\mathbf{z}_k\|^2}{n} - 1 \right) \right)$   

10:     $\mathbf{C}^{\frac{1}{2}} \leftarrow \mathbf{C}^{\frac{1}{2}} \times \exp^{\eta_c/2} \left( \sum_{\mathbf{z}_k \in \mathcal{P}} w_k \left( \mathbf{z}_k \mathbf{z}_k^T - \frac{\|\mathbf{z}_k\|^2}{n} \mathbf{I} \right) \right)$ 

```

In xNES, sampling is identical to CMA-ES and environmental selection is omitted entirely. Line 9 resembles the step-size update in (44.1). Comparing the updates more closely, with  $c_\sigma = 1$  (44.1) uses

$$\frac{\mu_w \|\sum_k w_k \mathbf{z}_k\|^2}{n} - 1$$

whereas xNES uses

$$\sum_k w_k \left( \frac{\|\mathbf{z}_k\|^2}{n} - 1 \right)$$

for updating  $\sigma$ . For  $\mu = 1$  the updates are the same. For  $\mu > 1$ , the latter only depends on the lengths of the  $\mathbf{z}_k$ , while the former depends on their lengths and directions. Finally, xNES expresses the update (44.5) in Line 10 on the Cholesky factor  $\mathbf{C}^{\frac{1}{2}}$ , which does not remain symmetric in this case ( $\mathbf{C} = \mathbf{C}^{\frac{1}{2}} \times \mathbf{C}^{\frac{1}{2}T}$  still holds). The term  $-\|\mathbf{z}_k\|^2/n$  keeps the determinant of  $\mathbf{C}^{\frac{1}{2}}$  (and thus the trace of  $\log \mathbf{C}^{\frac{1}{2}}$ ) constant and is of rather cosmetic nature. Omitting the term is equivalent to using  $\eta_\sigma + \eta_c$  instead of  $\eta_\sigma$  in Line 9.

The exponential natural evolution strategy is a very elegant algorithm. Like CMA-ES it can be interpreted as an incremental estimation of distribution algorithm [44.44]. However, it performs generally inferior compared to CMA-ES because it does not use search paths for updating  $\sigma$  and  $\mathbf{C}$ .

**44.3.8 Further Aspects****Internal Parameters**

Adaptation and self-adaptation address the control of the most important internal parameters in ES. Yet, all algorithms presented have hidden and exposed parameters in their implementation. Many of them can be set to reasonable and robust default values. The population size parameters  $\mu$  and  $\lambda$  however change the search characteristics of an evolution strategy significantly. Larger values, in particular for parent number  $\mu$ , often help address highly multimodal or noisy problems successfully.

In practice, several experiments or restarts are advisable, where different initial conditions for  $\mathbf{x}$  and  $\sigma$  can be employed. For exploring different population sizes, a schedule with increasing population size (IPOP) is advantageous [44.45–47], because runs with larger populations take typically more function evaluations. Preceding long runs (large  $\mu$  and  $\lambda$ ) with short runs (small  $\mu$  and  $\lambda$ ) leads to a smaller (relative) impairment of the later runs than vice versa.

**Internal Computational Complexity**

Algorithms presented in Sects. 44.3.1–44.3.4 that sample isotropic or axis-parallel mutation distributions have an internal computational complexity linear in the dimension. The internal computational complexity of CMA-ES and xNES is, for constant population size, cubic in the dimension due to the update of  $\mathbf{C}^{\frac{1}{2}}$ . Typical implementations of the CMA-ES however have quadratic complexity, as they implement a lazy update scheme for  $\mathbf{C}^{\frac{1}{2}}$ , where  $\mathbf{C}$  is decomposed into  $\mathbf{C}^{\frac{1}{2}} \mathbf{C}^{\frac{1}{2}T}$  only after about  $n/\lambda$  iterations. An exact quadratic update for CMA-ES has also been proposed [44.48]. While never considered in the literature, a lazy update for xNES to achieve quadratic complexity seems feasible as well.

**Invariance**

Selection and recombination in ES are based solely on the ranks of offspring and parent individuals. As a consequence, the behavior of ES is invariant under order-preserving (strictly monotonous) transformations of the fitness function value. In particular, all spherical unimodal functions belong to the same function class, which the convex-quadratic sphere function is the most pronounced member of. This function is more thoroughly investigated in Sect. 44.4.

All algorithms presented are invariant under translations and Algorithms 44.3, 44.7, and 44.8 are invariant under rotations of the coordinate system, provided that the initial  $\mathbf{x}$  is translated and rotated accordingly.

Parameter control can introduce yet further invariances. All algorithms presented are scale invariant due to step-size adaptation. Furthermore, ellipsoidal functions that are in the reach of the mutation operator of the ES presented in Sects. 44.3.2–44.3.7 are eventually transformed, effectively, into spherical functions. These

ES are invariant under the respective affine transformations of the search space, given the initial conditions are chosen respectively.

### Variants

Evolution strategies have been extended and combined with other approaches in various ways. We mention here constraint handling [44.49, 50], fitness surrogates [44.51], multiobjective variants [44.52, 53], and exploitation of fitness values [44.54].

## 44.4 Theory

There is ample *empirical* evidence, that on many unimodal functions ES with step-size control, as those outlined in the previous section, converge fast and with probability one to the global optimum. Convergence proofs supporting this evidence are discussed in Sect. 44.4.3. On multimodal functions on the other hand, the probability to converge to the global optimum (in a single run of the same strategy) is generally smaller than one (but larger than zero), as suggested by observations and theoretical results [44.55]. Without parameter control on the other hand, elitist strategies always converge to the essential global optimum, however at a much slower rate (compare random search in Fig. 44.2). On a bounded domain and with mutation variances bounded away from zero, *nonelitist* strategies generate a *subsequence* of  $\mathbf{x}$ -values converging to the essential global optimum.

In this section, we use a time index  $t$  to denote iteration and assume, for notational convenience and without loss of generality (due to translation invariance), that the optimum of  $f$  is in  $\mathbf{x}^* = \mathbf{0}$ . This simplifies writing  $\mathbf{x}^{(t)} - \mathbf{x}^*$  to simply  $\mathbf{x}^{(t)}$  and then  $\|\mathbf{x}^{(t)}\|$  measures the distance to the optimum of the parental centroid in time step  $t$ .

Linear convergence plays a central role for ES. For a *deterministic* sequence  $\mathbf{x}^{(t)}$  linear convergence (toward zero) takes place if there exists a  $c > 0$  such that

$$\lim_{t \rightarrow \infty} \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} = \exp(-c), \quad (44.6)$$

which means, loosely speaking, that for  $t$  large enough, the distance to the optimum decreases in every step by the constant factor  $\exp(-c)$ . Taking the logarithm of (44.6), then exchanging the logarithm and the limit

and taking the Cesàro mean yields

$$\begin{aligned} \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^{T-1} \log \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} &= -c. \\ &= \frac{1}{T} \log \|\mathbf{x}^{(T)}\| / \|\mathbf{x}^{(0)}\| \end{aligned} \quad (44.7)$$

For a *sequence of random vectors*, we define linear convergence based on (44.7) as follows.

### Definition 44.1 Linear Convergence

The sequence of random vectors  $\mathbf{x}^{(t)}$  converges almost surely linearly to  $\mathbf{0}$  if there exists a  $c > 0$  such that

$$\begin{aligned} -c &= \lim_{T \rightarrow \infty} \frac{1}{T} \log \frac{\|\mathbf{x}^{(T)}\|}{\|\mathbf{x}^{(0)}\|} \text{ a.s.} \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^{T-1} \log \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} \text{ a.s.} \end{aligned} \quad (44.8)$$

The sequence converges *in expectation* linearly to  $\mathbf{0}$  if there exists a  $c > 0$  such that

$$-c = \lim_{t \rightarrow \infty} \mathbb{E} \log \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|}. \quad (44.9)$$

The constant  $c$  is the convergence rate of the algorithm.

Linear convergence, hence, means that asymptotically in  $t$ , the logarithm of the distance to the optimum decreases linearly in  $t$  like  $-ct$ . This behavior has been observed in Fig. 44.2 for the (1+1)-ES with 1/5th success rule on a unimodal spherical function.

Note that  $\lambda$  function evaluations are performed per iteration and it is then often useful to consider a conver-

gence rate *per function evaluation*, i. e., to normalize the convergence rate by  $\lambda$ .

The *progress rate* measures the reduction of the distance to optimum within a single generation [44.1].

### Definition 44.2 Progress Rate

The normalized progress rate is defined as the expected relative reduction of  $\|\mathbf{x}^{(t)}\|$

$$\begin{aligned}\varphi^* &= n \mathbb{E} \left( \frac{\|\mathbf{x}^{(t)}\| - \|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} \mid \mathbf{x}^{(t)}, s^{(t)} \right) \\ &= n \left( 1 - \mathbb{E} \left( \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} \mid \mathbf{x}^{(t)}, s^{(t)} \right) \right),\end{aligned}\quad (44.10)$$

where the expectation is taken over  $\mathbf{x}^{(t+1)}$ , given  $(\mathbf{x}^{(t)}, s^{(t)})$ . In situations commonly considered in theoretical analyses,  $\varphi^*$  does not depend on  $\mathbf{x}^{(t)}$  and is expressed as a function of strategy parameters  $s^{(t)}$ .

Definitions 44.1 and 44.2 are related, in that for a given  $\mathbf{x}^{(t)}$

$$\varphi^* \leq -n \log \mathbb{E} \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} \quad (44.11)$$

$$\leq -n \mathbb{E} \log \frac{\|\mathbf{x}^{(t+1)}\|}{\|\mathbf{x}^{(t)}\|} = nc. \quad (44.12)$$

Therefore, progress rate  $\varphi^*$  and convergence rate  $nc$  do not agree and we might observe convergence ( $c > 0$ ) while  $\varphi^* < 0$ . However for  $n \rightarrow \infty$ , we typically have  $\varphi^* = nc$  [44.56].

The normalized progress rate  $\varphi^*$  for ES has been extensively studied in various situations, see Sect. 44.4.2. Scale-invariance and (sometimes artificial) assumptions on the step-size typically ensure that the progress rates do not depend on  $t$ .

Another way to describe how fast an algorithm approaches the optimum is to count the number of function evaluations needed to reduce the distance to the optimum by a given factor  $1/\epsilon$  or, similarly, the runtime to hit a ball of radius  $\epsilon$  around the optimum, starting, e.g., from the distance one.

### Definition 44.3 Runtime

The runtime is the first hitting time of a ball around the optimum. Specifically, the runtime in number of func-

tion evaluations as a function of  $\epsilon$  reads

$$\begin{aligned}&\lambda \times \min \left\{ t : \|\mathbf{x}^{(t)}\| \leq \epsilon \times \|\mathbf{x}^{(0)}\| \right\} \\ &= \lambda \times \min \left\{ t : \frac{\|\mathbf{x}^{(t)}\|}{\|\mathbf{x}^{(0)}\|} \leq \epsilon \right\}.\end{aligned}\quad (44.13)$$

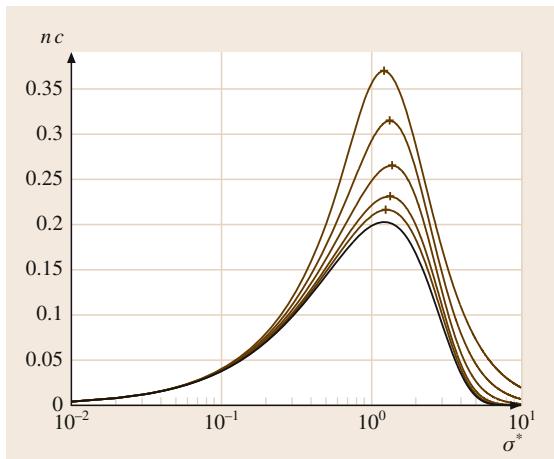

Linear convergence with rate  $c$  as given in (44.9) implies that, for  $\epsilon \rightarrow 0$ , the expected runtime divided by  $\log(1/\epsilon)$  goes to the constant  $\lambda/c$ .

### 44.4.1 Lower Runtime Bounds

Evolution strategies with a fixed number of parent and offspring individuals cannot converge faster than linearly and with a convergence rate of  $\mathcal{O}(1/n)$ . This means that their runtime is lower bounded by a constant times  $\log(1/\epsilon^n) = n \log(1/\epsilon)$  [44.57–61]. This result can be obtained by analyzing the branching factor of the tree of possible paths the algorithm can take. It therefore holds for any optimization algorithm taking decisions based solely on a bounded number of comparisons between fitness values [44.57–59].

More specifically, the runtime of any  $(1 + \lambda)$ -ES with isotropic mutations cannot be asymptotically faster than  $\propto n \log(1/\epsilon) / \lambda / \log(\lambda)$  [44.62]. Considering more restrictive classes of algorithms can provide more precise nonasymptotic bounds [44.60, 61]. Different approaches address in particular the  $(1+1)$ - and  $(1, \lambda)$ -ES and precisely characterize the fastest convergence rate that can be obtained with isotropic normal distributions on any objective function with any step-size adaptation mechanism [44.56, 63–65].

Considering the sphere function, the optimal convergence rate is attained with *distance proportional step-size*, that is, a step-size proportional to the distance of the parental centroid to the optimum,  $\sigma = \text{const} \times \|\mathbf{x}\| = \sigma^* \|\mathbf{x}\|/n$ . Optimal step-size and optimal convergence rate according to (44.8) and (44.9) can be expressed in terms of expectation of some random variables that are easily simulated numerically. The convergence rate of the  $(1+1)$ -ES with distance proportional step-size is shown in Fig. 44.4 as a function of the normalized step-size  $\sigma^* = n\sigma/\|\mathbf{x}\|$ . The peak of each curve is the upper bound for the convergence rate that can be achieved on any function with any form of step-size adaptation. As for the general bound, the evolution strategy converges linearly and the convergence rate  $c$  decreases to zero like  $1/n$  for  $n \rightarrow \infty$  [44.56, 65, 66], which is equivalent to linear scaling of the runtime in the dimension. The asymptotic limit for the conver-

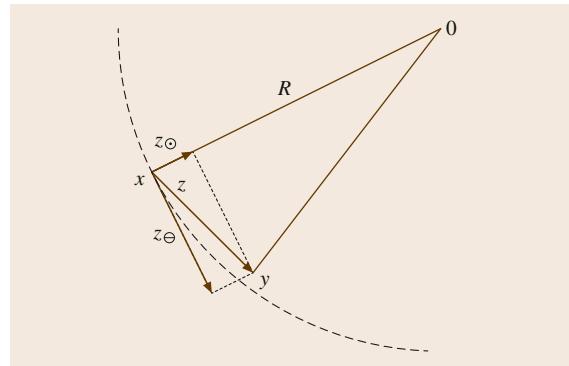

**Fig. 44.4** Normalized convergence rate  $nc$  versus normalized step-size  $n\sigma/\|\mathbf{x}\|$  of the (1+1)-ES with distance proportional step-size for  $n = 2, 3, 5, 10, 20, \infty$  (top to bottom). The peaks of the graphs represent the upper bound for the convergence rate of the (1+1)-ES with isotropic mutation (corresponding to the lower runtime bound). The limit curve for  $n$  to infinity (lowest curve) reveals the optimal normalized progress rate of  $\varphi^* \approx 0.202$  of the (1+1)-ES on sphere functions for  $n \rightarrow \infty$

gence rate of the (1+1)-ES, as shown in the lowest curve in Fig. 44.4, coincides with the progress rate expression given in the next section.

#### 44.4.2 Progress Rates

This section presents analytical approximations to progress rates of ES for sphere, ridge, and cigar functions in the limit  $n \rightarrow \infty$ . Both one-generation results and those that consider multiple time steps and cumulative step-size adaptation are considered.

The first analytical progress rate results date back to the early work of Rechenberg [44.1] and Schwefel [44.3], who considered the sphere and corridor models and very simple strategy variants. Further results have since been derived for various ridge functions, several classes of convex quadratic functions, and more general constrained linear problems. The strategies that results are available for have increased in complexity as well and today include multiparent strategies employing recombination as well as several step-size adaptation mechanisms. Only strategy variants with isotropic mutation distributions have been considered up to this point. However, parameter control strategies that successfully adapt the shape of the mutation

**Fig. 44.5** Decomposition of mutation vector  $z$  into a component  $z_\Theta$  in the direction of the negative of the gradient vector of the objective function and a perpendicular component  $z_\perp$

distribution (such as CMA-ES) effectively transform ellipsoidal functions into (almost) spherical ones; thus lending extra relevance to the analysis of sphere and sphere-like functions.

The simplest convex quadratic functions to be optimized are variants of the sphere function (see also the discussion of invariance in Sect. 44.3.8)

$$f(\mathbf{x}) = \|\mathbf{x}\|^2 = \sum_{i=1}^n x_i^2 = R^2,$$

where  $R$  denotes the distance from the optimal solution. Expressions for the progress rate of ES on sphere functions can be computed by decomposing mutation vectors into two components  $z_\Theta$  and  $z_\perp$  as illustrated in Fig. 44.5. Component  $z_\Theta$  is the projection of  $z$  onto the negative of the gradient vector  $\nabla f$  of the objective function. It contributes positively to the fitness of offspring candidate solution

$$\mathbf{y} = \mathbf{x} + \mathbf{z}$$

if and only if

$$-\nabla f(\mathbf{x}) \cdot \mathbf{z} > 0.$$

Component  $z_\perp = \mathbf{z} - z_\Theta$  is perpendicular to the gradient direction and contributes negatively to the offspring fitness. Its expected squared length exceeds that of  $z_\Theta$  by a factor of  $n - 1$ . Considering normalized quantities  $\sigma^* = \sigma n/R$  and  $\varphi^* = \varphi n/R$  allows giving concise mathematical representations of the scaling properties of various ES on spherical functions as shown below. Constant  $\sigma^*$  corresponds to the distance proportional step-size from Sect. 44.4.1.

### (1+1)-ES on Sphere Functions

The normalized progress rate of the (1+1)-ES on sphere functions is

$$\varphi^* = \frac{\sigma^*}{\sqrt{2\pi}} e^{-\frac{1}{8}\sigma^{*2}} - \frac{\sigma^{*2}}{4} \left[ 1 - \text{erf} \left( \frac{\sigma^*}{\sqrt{8}} \right) \right] \quad (44.14)$$

in the limit of  $n \rightarrow \infty$  [44.1]. The expression in square brackets is the success probability (i.e., the probability that the offspring candidate solution is superior to its parent and thus replaces it). The first term in (44.14) is the contribution to the normalized progress rate from the component  $z_{\odot}$  of the mutation vector that is parallel to the gradient vector. The second term results from the component  $z_{\ominus}$  that is perpendicular to the gradient direction.

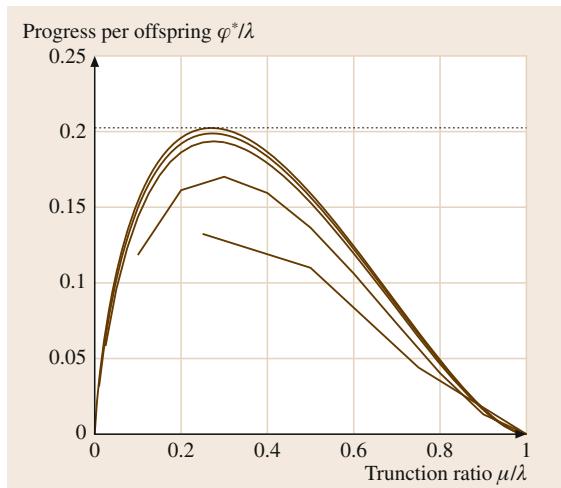

The black curve in Fig. 44.4 illustrates how the normalized progress rate of the (1+1)-ES on sphere functions in the limit  $n \rightarrow \infty$  depends on the normalized mutation strength. For small normalized mutation strengths, the normalized progress rate is small as the short steps that are made do not yield significant progress. The success probability is nearly one-half. For large normalized mutation strengths, progress is near zero as the overwhelming majority of steps result in poor offspring that are rejected. The normalized progress rate assumes a maximum value of  $\varphi^* = 0.202$  at normalized mutation strength  $\sigma^* = 1.224$ . The range of step-sizes for which close to optimal progress is achieved is referred to as the evolution window [44.1]. In the runs of the (1+1)-ES with constant step-size shown in Fig. 44.2, the normalized step-size initially is to the left of the evolution window (large relative distance to the optimal solution) and in the end to its right (small relative distance to the optimal solution), achieving maximal progress at a point in between.

### $(\mu/\mu, \lambda)$ -ES on Sphere Functions

The normalized progress rate of the  $(\mu/\mu, \lambda)$ -ES on sphere functions is described by

$$\varphi^* = \sigma^* c_{\mu/\mu, \lambda} - \frac{\sigma^{*2}}{2\mu} \quad (44.15)$$

in the limit  $n \rightarrow \infty$  [44.2]. The term  $c_{\mu/\mu, \lambda}$  is the expected value of the average of the  $\mu$  largest order statistics of  $\lambda$  independent standard normally distributed random numbers. For  $\lambda$  fixed,  $c_{\mu/\mu, \lambda}$  decreases with increasing  $\mu$ . For the fixed truncation ratio  $\mu/\lambda$ ,  $c_{\mu/\mu, \lambda}$  approaches a finite limit value as  $\lambda$  and  $\mu$  increase [44.8, 15].

**Fig. 44.6** Maximal normalized progress per offspring of the  $(\mu/\mu, \lambda)$ -ES on sphere functions for  $n \rightarrow \infty$  plotted against the truncation ratio. The curves correspond to, from bottom to top,  $\lambda = 4, 10, 40, 100, \infty$ . The dotted line represents the maximal progress rate of the (1+1)-ES

It is easily seen from (44.15) that the normalized progress rate of the  $(\mu/\mu, \lambda)$ -ES is maximized by normalized mutation strength

$$\sigma^* = \mu c_{\mu/\mu, \lambda} . \quad (44.16)$$

The normalized progress rate achieved with that setting is

$$\varphi^* = \frac{\mu c_{\mu/\mu, \lambda}^2}{2} . \quad (44.17)$$

The progress rate is negative if  $\sigma^* > 2\mu c_{\mu/\mu, \lambda}$ . Figure 44.6 illustrates how the optimal normalized progress rate per offspring depends on the population size parameters  $\mu$  and  $\lambda$ . Two interesting observations can be made from the figure:

- For all but the smallest values of  $\lambda$ , the  $(\mu/\mu, \lambda)$ -ES with  $\mu > 1$  is capable of significantly more rapid progress per offspring than the  $(1, \lambda)$ -ES. This contrasts with findings for the  $(\mu/1, \lambda)$ -ES, the performance of which on sphere functions for  $n \rightarrow \infty$  monotonically deteriorates with increasing  $\mu$  [44.8].
- For large  $\lambda$ , the optimal truncation ratio is  $\mu/\lambda = 0.27$ , and the corresponding progress per offspring is 0.202. Those values are identical to the optimal success probability and resulting normalized

progress rate of the (1+1)-ES. Beyer [44.8] shows that the correspondence is no coincidence and indeed exact. The step-sizes that the two strategies employ differ widely, however. The optimal step-size of the (1+1)-ES is 1.224; that of the  $(\mu/\mu, \lambda)$ -ES is  $\mu c_{\mu/\mu, \lambda}$  and for fixed truncation ratio  $\mu/\lambda$  increases (slightly superlinearly) with the population size. For example, optimal step-sizes of  $(\mu/\mu, 4\mu)$ -ES for  $\mu \in \{1, 2, 3\}$  are 1.029, 2.276, and 3.538, respectively. If offspring candidate solutions can be evaluated in parallel, the  $(\mu/\mu, \lambda)$ -ES is preferable to the (1+1)-ES, which does not benefit from the availability of parallel computational resources.

Equation (44.15) holds in the limit  $n \rightarrow \infty$  for any finite value of  $\lambda$ . In finite but high dimensional search spaces, it can serve as an approximation to the normalized progress rate of the  $(\mu/\mu, \lambda)$ -ES on sphere functions in the vicinity of the optimal step-size provided that  $\lambda$  is not too large. A better approximation for finite  $n$  is derived in [44.8, 15] (however compare also [44.56]).

The improved performance of the  $(\mu/\mu, \lambda)$ -ES for  $\mu > 1$  compared to the strategy that uses  $\mu = 1$  is a consequence of the factor  $\mu$  in the denominator of the term in (44.15) that contributes negatively to the normalized progress rate. The components  $z_{\odot}$  of mutation vectors selected for survival are correlated and likely to point in the direction opposite to the gradient vector. The perpendicular components  $z_{\ominus}$  in the limit  $n \rightarrow \infty$  have no influence on whether a candidate solution is selected for survival and are thus uncorrelated. The recombinative averaging of mutation vectors results in a length of the  $z_{\odot}$ -component similar to those of individual mutation vectors. However, the squared length of the components perpendicular to the gradient direction is reduced by a factor of  $\mu$ , resulting in the reduction of the negative term in (44.15) by a factor of  $\mu$ . Beyer [44.15] has coined the term *genetic repair* for this phenomenon.

Weighted recombination (compare Algorithms 44.7 and 44.8) can significantly increase the progress rate of  $(\mu/\mu, \lambda)$ -ES on sphere functions. If  $n$  is large, the  $k$ -th best candidate solution is optimally associated with a weight proportional to the expected value of the  $k$ -th largest order statistic of a sample of  $\lambda$  independent standard normally distributed random numbers. The resulting optimal normalized progress rate per offspring candidate solution for large values of  $\lambda$  then approaches a value of 0.5, exceeding that of optimal unweighted recombination by a factor of almost two and

a half [44.13]. The weights are symmetric about zero. If only positive weights are employed and  $\mu = |\lambda|/2$ , the optimal normalized progress rate per offspring with increasing  $\lambda$  approaches a value of 0.25. The weights in Algorithms 44.7 and 44.8 closely resemble those positive weights.

### $(\mu/\mu, \lambda)$ -ES on Noisy Sphere Functions

Noise in the objective function is most commonly modeled as being Gaussian. If evaluation of a candidate solution  $x$  yields a noisy objective function value  $f(x) + \sigma_{\epsilon} \mathcal{N}(0, 1)$ , then inferior candidate solutions will sometimes be selected for survival and superior ones discarded. As a result, progress rates decrease with increasing noise strength  $\sigma_{\epsilon}$ . Introducing normalized noise strength  $\sigma_{\epsilon}^* = \sigma_{\epsilon} n / (2R^2)$ , in the limit  $n \rightarrow \infty$ , the normalized progress rate of the  $(\mu/\mu, \lambda)$ -ES on noisy sphere functions is

$$\varphi^* = \frac{\sigma^* c_{\mu/\mu, \lambda}}{\sqrt{1 + \vartheta^2}} - \frac{\sigma^{*2}}{2\mu}, \quad (44.18)$$

where  $\vartheta = \sigma_{\epsilon}^* / \sigma^*$  is the noise-to-signal ratio that the strategy operates under [44.67]. Noise does not impact the term that contributes negatively to the strategy's progress. However, it acts to reduce the magnitude of the positive term stemming from the contributions of mutation vectors parallel to the gradient direction. Note that unless the noise scales such that  $\sigma_{\epsilon}^*$  is independent of the location in search space (i.e., the standard deviation of the noise term increases in direct proportion to  $f(x)$ , such as in a multiplicative noise model with constant noise strength), (44.18) describes progress in single time steps only rather than a rate of convergence.

Figure 44.7 illustrates for different offspring population sizes  $\lambda$  how the optimal progress rate per offspring depends on the noise strength. The curves have been obtained from (44.18) for optimal values of  $\sigma^*$  and  $\mu$ . As the averaging of mutation vectors results in a vector of reduced length, increasing  $\lambda$  (and  $\mu$  along with it) allows the strategy to operate using larger and larger step-sizes. Increasing the step-size reduces the noise-to-signal ratio  $\vartheta$  that the strategy operates under and thereby reduces the impact of noise on selection for survival. Through genetic repair, the  $(\mu/\mu, \lambda)$ -ES thus implicitly implements the rescaling of mutation vectors proposed in [44.2] for the  $(1, \lambda)$ -ES in the presence of noise. Compare  $c_m$  and  $\eta_x$  in Algorithms 44.7 and 44.8 that, for values smaller than one, implement the explicit rescaling. It needs to be emphasized though that in finite-dimensional search spaces, the ability to in-

crease  $\lambda$  without violating the assumptions made in the derivation of (44.18) is severely limited. Nonetheless, the benefits resulting from genetic repair are significant, and the performance of the  $(\mu/\mu, \lambda)$ -ES is much more robust in the presence of noise than that of the  $(1+1)$ -ES.

### Cumulative Step-Size Adaptation

All progress rate results discussed up to this point consider single time steps of the respective ES only. Analyses of the behavior of ES that include some form of step-size adaptation are considerably more difficult. Even for objective functions as simple as sphere functions, the state of the strategy is described by several variables with nonlinear, stochastic dynamics, and simplifying assumptions need to be made in order to arrive at quantitative results.

In the following, we consider the  $(\mu/\mu, \lambda)$ -ES with cumulative step-size adaptation (Algorithm 44.6 with (44.1) in place of Line 9 for mathematical convenience) and parameters set such that  $c_\sigma \rightarrow 0$  as  $n \rightarrow \infty$  and  $d = \Theta(1)$ . The state of the strategy on noisy sphere functions with  $\sigma_\epsilon^* = \text{const}$  (i.e., noise that decreases in strength as the optimal solution is approached) is described by the distance  $R$  of the parental centroid from the optimal solution, normalized step-size  $\sigma^*$ , the

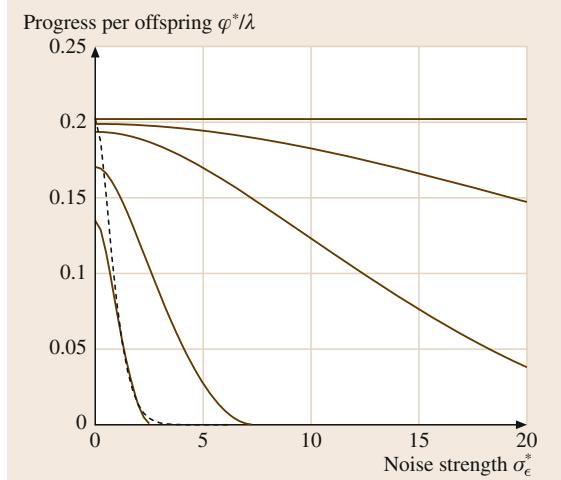

length of the search path  $s$  parallel to the direction of the gradient vector of the objective function, and that path's overall squared length. After initialization effects have faded, the distribution of the latter three quantities is time invariant. Mean values of the time invariant distribution can be approximated by computing expected values of the variables after a single iteration of the strategy in the limit  $n \rightarrow \infty$  and imposing the condition that those be equal to the respective values before that iteration. Solving the resulting system of equations for  $\sigma_\epsilon^* \leq \sqrt{2}\mu c_{\mu/\mu, \lambda}$  yields

$$\sigma^* = \mu c_{\mu/\mu, \lambda} \sqrt{2 - \left( \frac{\sigma_\epsilon^*}{\mu c_{\mu/\mu, \lambda}} \right)^2} \quad (44.19)$$

for the average normalized mutation strength assumed by the strategy [44.69, 70]. The corresponding normalized progress rate

$$\varphi^* = \frac{\sqrt{2}-1}{2} \mu c_{\mu/\mu, \lambda}^2 \left[ 2 - \left( \frac{\sigma_\epsilon^*}{\mu c_{\mu/\mu, \lambda}} \right)^2 \right] \quad (44.20)$$

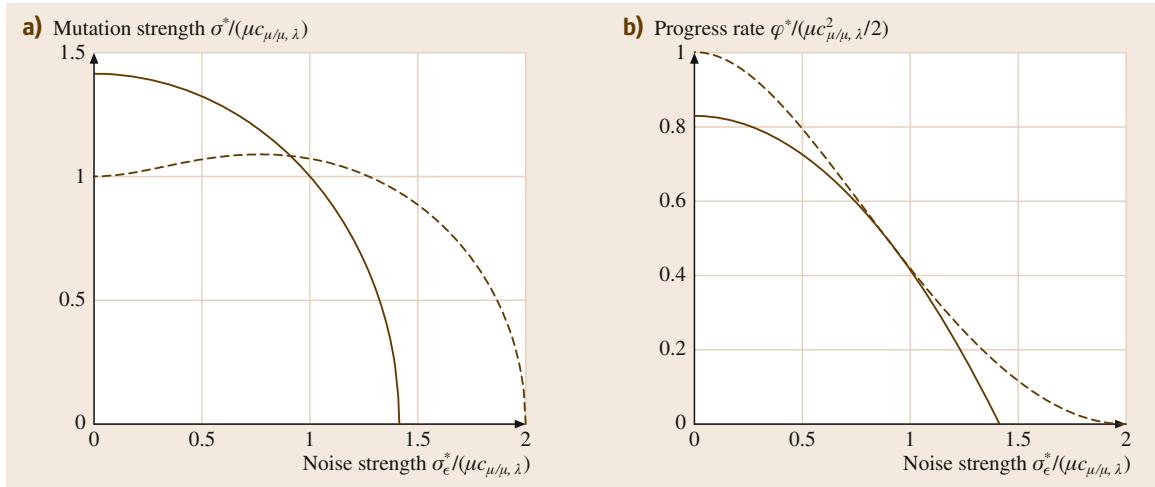

is obtained from (44.18). Both the average mutation strength and the resulting progress rate are plotted against the noise strength in Fig. 44.8. For small noise strengths, cumulative step-size adaptation generates mutation strengths that are larger than optimal. The evolution window continually shifts toward smaller values of the step-size, and adaptation remains behind its target. However, the resulting mutation strengths achieve progress rates within 20% of optimal ones. For large noise strengths, the situation is reversed and the mutation strengths generated by cumulative step-size adaptation are smaller than optimal. However, increasing the population size parameters  $\mu$  and  $\lambda$  allows shifting the operating regime of the strategy toward the left-hand side of the graphs in Fig. 44.8, where step-sizes are near optimal. As above, it is important to keep in mind the limitations of the results derived in the limit  $n \rightarrow \infty$ . In finite-dimensional search spaces the ability to compensate for large amounts of noise by increasing the population size is more limited than (44.19) and (44.20) suggest.

**Fig. 44.7** Optimal normalized progress rate per offspring of the  $(\mu/\mu, \lambda)$ -ES on noisy sphere functions for  $n \rightarrow \infty$  plotted against the normalized noise strength. The solid lines depict results for, from bottom to top,  $\lambda = 4, 10, 40, 100, \infty$  and optimally chosen  $\mu$ . The dashed line represents the optimal progress rate of the  $(1+1)$ -ES (after [44.68]).

### Parabolic Ridge Functions

A class of test functions that poses difficulties very different from those encountered in connection with

**Fig. 44.8a,b** Normalized mutation strength and normalized progress rate of the  $(\mu/\mu, \lambda)$ -ES with cumulative step size adaptation on noisy sphere functions for  $n \rightarrow \infty$  plotted against the normalized noise strength. The *dashed lines* depict optimal values

sphere functions are ridge functions,

$$f(\mathbf{x}) = x_1 + \xi \left( \sum_{i=2}^n x_i^2 \right)^{\alpha/2} = x_1 + \xi R^\alpha,$$

which include the parabolic ridge for  $\alpha = 2$ . The  $x_1$ -axis is referred to as the ridge axis, and  $R$  denotes the distance from that axis. Progress can be made by minimizing the distance from the ridge axis or by proceeding along it. The former requires decreasing step-sizes and is limited in its effect as  $R \geq 0$ . The latter allows indefinite progress and requires that the step-size does not decrease to zero. Short- and long-term goals may thus be conflicting, and inappropriate step-size adaptation may lead to stagnation.

As an optimal solution to the ridge problem does not exist, the progress rate  $\varphi$  of the  $(\mu/\mu, \lambda)$ -ES on ridge functions is defined as the expectation of the step made in the direction of the negative ridge axis. For constant step-size, the distance  $R$  of the parental centroid from the ridge axis assumes a time-invariant limit distribution. An approximation to the mean value of that distribution can be obtained by identifying that value of  $R$  for which the expected change is zero. Using this value yields

$$\varphi = \frac{2\mu c_{\mu/\mu, \lambda}^2}{n\xi(1 + \sqrt{1 + (2\mu c_{\mu/\mu, \lambda}/(n\xi\sigma))^2})} \quad (44.21)$$

for the progress rate of the  $(\mu/\mu, \lambda)$ -ES on parabolic ridge functions [44.71]. The strictly monotonic behav-

ior of the progress rate, increasing from a value of zero for  $\sigma = 0$  to  $\varphi = \mu c_{\mu/\mu, \lambda}^2/(n\xi)$  for  $\sigma \rightarrow \infty$ , is fundamentally different from that observed on sphere functions. However, the derivative of the progress rate with regard to the step-size for large values of  $\sigma$  tends to zero. The limited time horizon of any search as well as the intent of using ridge functions as local rather than global models of practically relevant objective functions both suggest that it may be unwise to increase the step-size without bounds.

The performance of cumulative step-size adaptation on parabolic ridge functions can be studied using the same approach as described above for sphere functions, yielding

$$\sigma = \frac{\mu c_{\mu/\mu, \lambda}}{\sqrt{2n\xi}} \quad (44.22)$$

for the (finite) average mutation strength [44.72]. From (44.21), the corresponding progress rate

$$\varphi = \frac{\mu c_{\mu/\mu, \lambda}^2}{2n\xi} \quad (44.23)$$

is greater than half of the progress rate attained with any finite step size.

### Cigar Functions

While parabolic ridge functions provide an environment for evaluating whether step-size adaptation mechanisms are able to avoid stagnation, the ability to

make continual meaningful positive progress with some constant nonzero step-size is, of course, atypical for practical optimization problems. A class of ridge-like functions that requires continual adaptation of the mutation strength and is thus a more realistic model of problems requiring ridge following are cigar functions:

$$f(\mathbf{x}) = x_1^2 + \xi \sum_{i=2}^n x_i^2 = x_1^2 + \xi R^2 ,$$

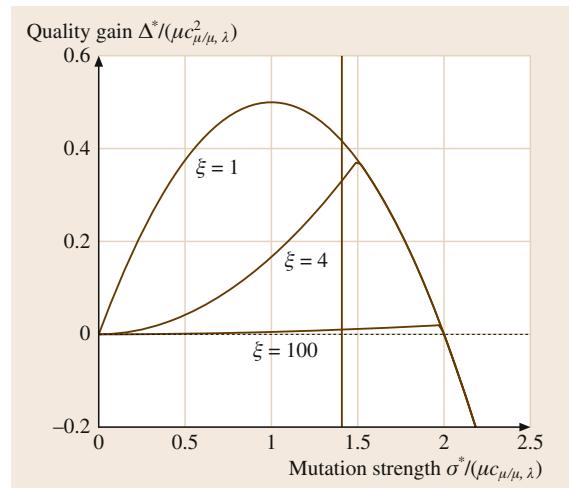

with parameter  $\xi \geq 1$  being the condition number of the Hessian matrix. Small values of  $\xi$  result in sphere-like characteristics, large values in ridge-like ones. As above,  $R$  measures the distance from the  $x_1$ -axis.

Assuming successful adaptation of the step-size, **ES** exhibit linear convergence on cigar functions. The expected relative per iteration change in the objective function value of the population centroid is referred to as the quality gain  $\Delta$  and determines the rate of convergence. In the limit  $n \rightarrow \infty$  it is described by

$$\Delta^* = \begin{cases} \frac{\sigma^{*2}}{2\mu(\xi-1)} & \text{if } \sigma^* < 2\mu c_{\mu/\mu,\lambda} \frac{\xi-1}{\xi} \\ c_{\mu/\mu,\lambda} \sigma^* - \frac{\sigma^{*2}}{2\mu} & \text{otherwise ,} \end{cases}$$

where  $\sigma^* = \sigma n / R$  and  $\Delta^* = \Delta n / 2$  [44.73]. That relationship is illustrated in Fig. 44.9 for several values of the conditioning parameter. The parabola for  $\xi = 1$  reflects the simple quadratic relationship for sphere functions seen in (44.15). (For the case of sphere functions, normalized progress rate and normalized quality gain are the same.) For cigar functions with large values of  $\xi$ , two separate regimes can be identified. For small step-sizes, the quality gain of the strategy is limited by the size of the steps that can be made in the direction of the  $x_1$ -axis. The  $x_1$ -component of the population centroid virtually never changes sign. The search process resembles one of ridge following, and we refer to the regime as the ridge regime. In the other regime, the step-size is such that the quality gain of the strategy is effectively limited by the ability to approach the optimal solution in the subspace spanned by the  $x_2, \dots, x_n$ -axes. The  $x_1$ -component of the population centroid changes sign much more frequently than in the ridge regime, as is the case on sphere functions. We thus refer to the regime as the sphere regime.

The approach to the analysis of the behavior of cumulative step-size adaptation explained above for

**Fig. 44.9** Normalized quality gain of  $(\mu/\mu, \lambda)$ -ES on cigar functions for  $n \rightarrow \infty$  plotted against the normalized mutation strength for  $\xi \in \{1, 4, 100\}$ . The vertical line represents the average normalized mutation strength generated by cumulative step-size adaptation

sphere and parabolic ridge functions can be applied to cigar functions as well, yielding

$$\sigma^* = \sqrt{2} \mu c_{\mu/\mu,\lambda}$$

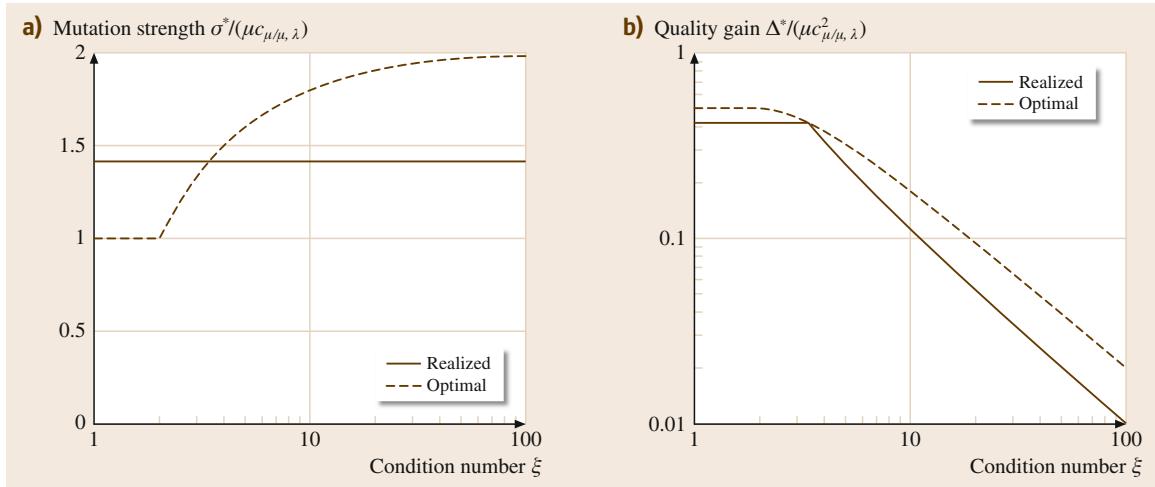

for the average normalized mutation strength generated by cumulative step-size adaptation [44.73]. The corresponding normalized quality gain is

$$\Delta^* = \begin{cases} (\sqrt{2}-1) \mu c_{\mu/\mu,\lambda}^2 & \text{if } \xi < \frac{\sqrt{2}}{\sqrt{2}-1} \\ \frac{\mu c_{\mu/\mu,\lambda}^2}{\xi-1} & \text{otherwise .} \end{cases}$$

Both are compared with optimal values in Fig. 44.10. For small condition numbers,  $(\mu/\mu, \lambda)$ -ES operate in the sphere regime and are within 20% of the optimal quality gain as seen earlier. For large condition numbers, the strategy operates in the ridge regime and achieves a quality gain within a factor of 2 of the optimal one, in accordance with the findings for the parabolic ridge above.

### Further Work

Further research regarding the progress rate of **ES** in different test environments includes work analyzing the behavior of mutative self-adaptation for linear [44.22],

**Fig. 44.10a,b** Normalized mutation strength and normalized quality gain of the  $(\mu/\mu, \lambda)$ -ES with cumulative step-size adaptation on cigar functions for  $n \rightarrow \infty$  plotted against the condition number of the cigar. The *dashed curves* represent optimal values

spherical [44.74], and ridge functions [44.75]. Hierarchically organized ES have been studied when applied to both parabolic ridge and sphere functions [44.76, 77]. Several step-size adaptation techniques have been compared for ridge functions, including, but not limited to, parabolic ones [44.78]. A further class of convex quadratic functions for which quality gain results have been derived is characterized by the occurrence of only two distinct eigenvalues of the Hessian, both of which occur with high multiplicity [44.79, 80].

An analytical investigation of the behavior of the (1+1)-ES on noisy sphere functions finds that failure to re-evaluate the parental candidate solution results in the systematic overvaluation of the parent and thus in potentially long periods of stagnation [44.68]. Contrary to what might be expected, the increased difficulty of replacing parental candidate solutions can have a positive effect on progress rates as it tends to prevent the selection for survival of offspring candidate solutions solely due to favorable noise values. The convergence behavior of the (1+1)-ES on finite-dimensional sphere functions is studied by *Jebalia et al.* [44.81] who show that the additive noise model is inappropriate in finite dimensions unless the parental candidate solution is re-evaluated, and who suggest a multiplicative noise model instead. An analysis of the behavior of  $(\mu, \lambda)$ -ES (without recombination) for noisy sphere functions finds that in contrast to the situation in the absence of noise, strategies with  $\mu > 1$  can outperform  $(1, \lambda)$ -ES if there is noise present [44.82]. The use of nonsingle-

ton populations increases the signal-to-noise ratio and thus allows for more effective selection of good candidate solutions. The effects of non-Gaussian forms of noise on the performance of  $(\mu/\mu, \lambda)$ -ES applied to the optimization of sphere functions have also been investigated [44.83].

Finally, there are some results regarding the optimization of time-varying objectives [44.84] as well as analyses of simple constraint handling techniques [44.85–87].

#### 44.4.3 Convergence Proofs

In the previous section, we have described theoretical results that involve approximations in their derivation and consider the limit for  $n \rightarrow \infty$ . In this section, exact results are discussed.

Convergence proofs with only mild assumptions on the objective function are easy to obtain for ES with a step-size that is effectively bounded from below and above (and, for nonelitist strategies, when additionally the search space is bounded) [44.12, 64]. In this case, the expected runtime to reach an  $\epsilon$ -ball around the global optimum (see also Definition 44.3) cannot be faster than  $\propto 1/\epsilon^n$ , as obtained with pure random search for  $\epsilon \rightarrow 0$  or  $n \rightarrow \infty$ . If the mutation distribution is not normal and exhibits a singularity in zero, convergence can be much faster than with random search even when the step-size is bounded away from zero [44.88]. Similarly, convergence proofs can be obtained for adap-

tive strategies that include provisions for using a fixed step-size and covariance matrix with some constant probability.

Convergence proofs for strategy variants that do not explicitly ensure that long steps are sampled for a sufficiently long time typically require much stronger restrictions on the set of objective functions that they hold for. Such proofs, however, have the potential to reveal much faster, namely linear convergence. Evolution strategies with the *artificial* distance proportional step-size,  $\sigma = \text{const} \times \|\mathbf{x}\|$ , exhibit, as shown above, linear convergence on the sphere function with an associated runtime proportional to  $\log(1/\epsilon)$  [44.63, 65, 81, 89]. This result can be easily proved by using a law of large numbers, because  $\|\mathbf{x}^{(t+1)}\|/\|\mathbf{x}^{(t)}\|$  are independent and identically distributed for all  $t$ .

Without the artificial choice of step-size,  $\sigma/\|\mathbf{x}\|$  becomes a random variable. If this random variable is a homogeneous Markov chain and stable enough to satisfy the law of large numbers, linear convergence is maintained [44.64, 89]. The stability of the Markov chain associated with the self-adaptive  $(1, \lambda)$ -ES on the sphere function has been shown in dimension

$n = 1$  [44.90] providing thus a proof of linear convergence of this algorithm. The extension of this proof to higher dimensions is straightforward.

Proofs that are formalized by upper bounds on the time to reduce the distance to the optimum by a given factor can also associate the linear dependency of the convergence rate in the dimension  $n$ . The  $(1 + \lambda)$ - and the  $(1, \lambda)$ -ES with common variants of the 1/5th success rule converge linearly on the sphere function with a runtime of  $\mathcal{O}(n \log(1/\epsilon) \lambda / \sqrt{\log \lambda})$  [44.62, 91]. When  $\lambda$  is smaller than  $\mathcal{O}(n)$ , the  $(1 + \lambda)$ -ES with a modified success rule is even  $\sqrt{\log \lambda}$  times faster and therefore matches the general lower runtime bound  $\Omega(n \log(1/\epsilon) \lambda / \log(\lambda))$  [44.62, Theorem 5]. On convex-quadratic functions, the asymptotic runtime of the  $(1+1)$ -ES is the same as on the sphere function and, at least in some cases, proportional to the condition number of the problem [44.92].

Convergence proofs of modern ES with recombination, of CSA-ES, CMA-ES, or xNES are not yet available; however, we believe that some of them are likely to be achieved in the coming decade.

# 45. Estimation of Distribution Algorithms

# Estimation o-

Martin Pelikan, Mark W. Hauschild, Fernando G. Lobo

Estimation of distribution algorithms ([EDAs](#)) guide the search for the optimum by building and sampling explicit probabilistic models of promising candidate solutions. However, [EDAs](#) are not only optimization techniques; besides the optimum or its approximation, [EDAs](#) provide practitioners with a series of probabilistic models that reveal a lot of information about the problem being solved. This information can in turn be used to design problem-specific neighborhood operators for local search, to bias future runs of [EDAs](#) on similar problems, or to create an efficient computational model of the problem. This chapter provides an introduction to [EDAs](#) as well as a number of pointers for obtaining more information about this class of algorithms.

Estimation of distribution algorithms ([EDAs](#)) [45.1–8], also called probabilistic model-building genetic algorithms ([PMBGAs](#)) and iterated density estimation evolutionary algorithms ([IDEAs](#)), view optimization as a series of incremental updates of a probabilistic model, starting with the model encoding the uniform distribution over admissible solutions and ending with the model that generates only the global optima. In the past decade and a half, [EDAs](#) have been applied to many challenging optimization problems [45.9–21]. In many of these studies, [EDAs](#) were shown to solve

problems that were intractable with other techniques or no other technique could achieve comparable results. However, the motive for the use of [EDAs](#) in practice is not only that these algorithms can solve difficult optimization problems, but that in addition to the optimum or its approximation [EDAs](#) provide practitioners with a compact computational model of the problem represented by a series of probabilistic models [45.22–24]. These probabilistic models reveal a lot of information about the problem domain, which can in turn be used to bias optimization of similar prob-

lems, create problem-specific neighborhood operators, and many other tasks. While many metaheuristics exist that essentially sample implicit probability distributions by using a combination of stochastic search operators, the insight into the problem represented by a series of explicit probabilistic models of promising candidate solutions gives **EDAs** an edge over most of other metaheuristics.

This chapter provides an introduction to **EDAs**. Additionally, the chapter presents numerous pointers for obtaining additional information about this class of algorithms.

The chapter is organized as follows. Section 45.1 outlines the basic procedure of an **EDA**. Section 45.2 presents a taxonomy of **EDAs** based on the type of decomposition encoded by the model and the type of local distributions used in the model. Section 45.3 reviews some of the most popular **EDAs**. Section 45.4 discusses major research directions and the past results in theoretical modeling of **EDAs**. Section 45.5 focuses on efficiency enhancement techniques for **EDAs**. Section 45.6 gives pointers for obtaining additional information about **EDAs**. Section 45.7 summarizes and concludes the chapter.

## 45.1 Basic **EDA** Procedure

### 45.1.1 Problem Definition

An optimization problem may be defined by specifying (1) a set of potential solutions to the problem and (2) a procedure for evaluating the quality of these solutions. The set of potential solutions is often defined using a general representation of admissible solutions and a set of constraints. The procedure for evaluating the quality of candidate solutions can either be defined as a function that is to be minimized or maximized (often referred to as an objective function or fitness function) or as a partial ordering operator. The task is to find a solution from the set of potential solutions that maximizes quality as defined by the evaluation procedure.

As an example, let us consider the quadratic assignment problem (**QAP**), which is one of the fundamental NP-hard combinatorial problems [45.25]. In **QAP**, the input consists of distances between  $n$  locations and flows between  $n$  facilities. The task is to find a one-to-one assignment of facilities to locations so that the overall cost is minimized. The cost for a pair of locations is defined as the product of the distance between these locations and the flow between the facilities assigned to these locations; the overall cost is the sum of the individual costs for all pairs of locations. Therefore, in **QAP**, potential solutions are defined as permutations that define assignments of facilities to locations and the solution quality is evaluated using the cost function discussed above. The task is to minimize the cost. As another example, consider the maximum satisfiability problem for propositional logic formulas defined in the conjunctive normal form with 3 literals per clause (**MAX3SAT**). In **MAX3SAT**, each potential solution

defines one interpretation of propositions (making each proposition either true or false), and the quality of a solution is measured by the number of clauses that are satisfied by the specific interpretation. The task is to find an interpretation that maximizes the number of satisfied clauses.

Without additional assumptions about the problem, one way to find the optimum is to repeat three main steps:

- *Generate* candidate solutions.
- *Evaluate* the generated solutions.
- *Update* the procedure for generating new candidate solutions according to the results of the evaluation.

Ideally, the quality of generated solutions would improve over time and after a reasonable number of iterations, the execution of these three steps would generate the global optimum or its accurate approximation. Different algorithms implement the above three steps in different ways, but the key idea remains the same – iteratively update the procedure for generating candidate solutions so that generated candidate solutions continually improve in quality.

### 45.1.2 **EDA** Procedure

In **EDAs**, the central idea is to maintain an *explicit probabilistic model* that represents a probability distribution over candidate solutions. In each iteration, the model is adjusted based on the results of the evaluation of candidate solutions so that it will generate better candidate solutions in the subsequent iterations. Note that using an explicit probabilistic model makes **EDAs** quite dif-

ferent from many other metaheuristics, such as genetic algorithms [45.26, 27] or simulated annealing [45.28, 29], in which the probability distribution used to generate new candidate solutions is often defined *implicitly* by a search operator or a combination of several search operators. Researchers often distinguish two main types of EDAs:

- *Population-based EDAs*. Population-based EDAs maintain a population (multiset) of candidate solutions, starting with a population generated at random according to the uniform distribution over all admissible solutions. Each iteration starts by creating a population of promising candidate solutions using the selection operator, which gives preference to solutions of higher quality. Any popular selection method for evolutionary algorithms can be used, such as truncation or tournament selection [45.30, 31]. For example, truncation selection selects the top  $\tau\%$  members of the population. A probabilistic model is then built for the selected solutions. New solutions are created by sampling the distribution encoded by the built model. The new solutions are then incorporated into the original population using a replacement operator. In full replacement, for example, the entire original population of candidate solutions is replaced by the new ones. A pseudocode of a population-based EDA is shown in Algorithm 45.1.
- *Incremental EDAs*. In incremental EDAs, the population of candidate solutions is fully replaced by a probabilistic model. The model is initialized so that it encodes the uniform distribution over all admissible solutions. The model is then updated incrementally by repeating the process of (1) sampling several candidate solutions from the current model and (2) adjusting the model based on the evaluation of these candidate solutions and their comparison so that the model becomes more likely to generate high-quality solutions in subsequent iterations. A pseudocode of an incremental EDA is shown in Algorithm 45.2.

#### Algorithm 45.1 Population-based estimation of distribution algorithm

```

1:  $t \leftarrow 0$ 
2: generate population  $P(0)$  of random solutions
3: while termination criteria not satisfied, repeat do
4:   evaluate all candidate solutions in  $P(t)$ 
5:   select promising solutions  $S(t)$  from  $P(t)$ 
6:   build a probabilistic model  $M(t)$  for  $S(t)$ 
```

```

7:   generate new solutions  $O(t)$  by sampling  $M(t)$ 
8:   create  $P(t+1)$  by combining  $O(t)$  and  $P(t)$ 
9:    $t \leftarrow t + 1$ 
10: end while
```

---

#### Algorithm 45.2 Incremental estimation of distribution algorithm

```

1:  $t \leftarrow 0$ 
2: initialize model  $M(0)$  to represent the uniform distribution over admissible solutions
3: while termination criteria not satisfied, repeat do
4:   generate population  $P(t)$  of candidate solutions by sampling  $M(t)$ 
5:   evaluate all candidate solutions in  $P(t)$ 
6:   create new model  $M(t+1)$  by adjusting  $M(t)$  according to evaluated  $P(t)$ 
7:    $t \leftarrow t + 1$ 
8: end while
```

---

Incremental EDAs often generate only a few candidate solutions at a time, whereas population-based EDAs often work with a large population of candidate solutions, building each model from scratch. Nonetheless, it is easy to see that the two approaches are essentially the same because even the population-based EDAs can be reformulated in an incremental-based manner.

The main components of a population-based EDA thus include:

- (1) A selection operator for selecting promising solutions.
- (2) An assumed class of probabilistic models to use for modeling and sampling.
- (3) A procedure for learning a probabilistic model for the selected solutions.
- (4) A procedure for sampling the built probabilistic model.
- (5) A replacement operator for combining the populations of old and new candidate solutions.

The main components of an incremental EDA include:

- (1) An assumed class of probabilistic models.
- (2) A procedure for adjusting the probabilistic model based on new candidate solutions and their evaluations.
- (3) A procedure for sampling the probabilistic model.

The procedure for learning a probabilistic model usually requires two subcomponents: a metric for evaluating the probabilistic models from the assumed class, and a search procedure for choosing a particular model based on the metric used. **EDAs** differ mainly in the class of probabilistic models and the procedures used for evaluating candidate models and searching for a good model.

The general outline of a population-based **EDA** is quite similar to that of a traditional evolutionary algorithm (**EA**) [45.32]; both guide the search toward promising solutions by iteratively performing selection and variation, the two key ingredients of any **EA**. In particular, components (1) and (5) are precisely the same as those used in other **EAs**. Components (2), (3), and (4), however, are unique to **EDAs**, and constitute their way of producing variation, as opposed to using recombination and mutation operators as is often done with other **EAs**.

As we shall see, this alternative perspective opens a way for designing search procedures from principled grounds by bringing to the evolutionary computation domain a vast body of knowledge from the machine learning literature, and in particular from probabilistic graphical models. The key idea of **EDAs** is to look at a population of previously visited good solutions as data, learn a model (or theory) of that data, and use the resulting model to infer where other good solutions might be. This approach is powerful, allowing a search algorithm to learn and adapt itself with respect to the optimization problem being solved, while it is being solved.

### 45.1.3 Simulation of an **EDA** by Hand

To better understand the **EDA** procedure, this section presents a simple **EDA** simulation by hand. The purpose of presenting the simulation is to clarify the components of the basic **EDA** procedure and to build intuition about the dynamics of an **EDA** run.

The simulation assumes that candidate solutions are represented by binary strings of fixed length  $n > 0$ . The objective function to maximize is onemax, which is defined as the sum of the bits in the input binary string  $(X_1, X_2, \dots, X_n)$

$$f_{\text{onemax}}(X_1, X_2, \dots, X_n) = \sum_{i=1}^n X_i . \quad (45.1)$$

The quality of a candidate solution improves with the number of 1s in the input string, and the optimum is the string of all 1s.

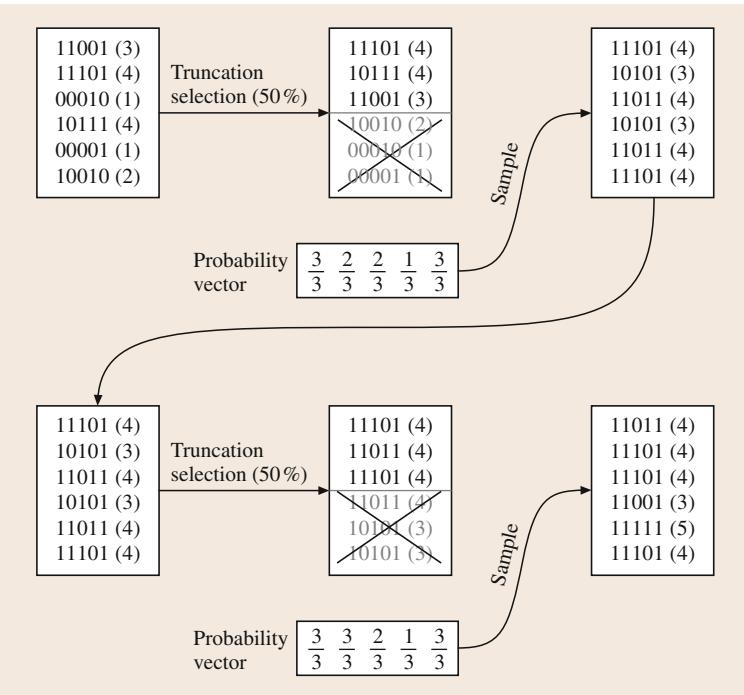

To model and sample candidate solutions, the simulation uses a *probability vector* [45.1, 6, 33]. A probability vector  $p$  for  $n$ -bit binary strings has  $n$  components,  $p = (p_1, p_2, \dots, p_n)$ . The component  $p_i$  represents the probability of observing a 1 in position  $i$  of a solution string. To learn the probability vector,  $p_i$  is set to the proportion of 1s in position  $i$  observed in the selected set of solutions. To sample a new candidate solution  $(X_1, X_2, \dots, X_n)$ , the components of the probability vector are polled and each  $X_i$  is set to 1 with probability  $p_i$ , and to 0 with probability  $1 - p_i$ .

The expected outcome of the learning and sampling of the probability vector is that the population of selected solutions and the population of new candidate solutions have the same proportion of 1s in each position. However, since the sampling considers each new candidate solution independently of others, the actual proportions may vary a little from their expected values. The probability-vector **EDA** described above is typically referred to as the *univariate marginal distribution algorithm* (**UMDA**) [45.6]; other **EDAs** based on the probability vector model [45.1, 33, 34] will be discussed in Sect. 45.3.1.

To keep the simulation simple, we consider a 5-bit onemax, a population of size  $N = 6$ , and truncation selection with threshold  $\tau = 50\%$ . Recall that the truncation selection with  $\tau = 50\%$  selects the top half of the current population.

Figure 45.1 shows the first two iterations of the **EDA** simulation. The initial population of candidate solutions is generated at random. Truncation selection then selects the best 50% of candidate solutions based on their evaluation using onemax to form the set of promising solutions. Next, the probability vector is created based on the selected solutions and the distribution encoded by the probability vector is sampled to generate new candidate solutions. The resulting population replaces the original population and the procedure repeats.

In both iterations of the simulation, the average objective-function value in the new population is greater than the average value in the population before selection. The increase in the average quality of the population is good news for us because we want to maximize the objective function, but why does this happen? Since for onemax the solutions with more 1s are better than those with fewer 1s, selection should increase the number of 1s in the population. The learning and sampling of the probability vector is not expected to create or destroy any bits and that is why the new population of candidate solutions should contain more 1s than the

**Fig. 45.1** Simple simulation of an **EDA** based on the probability-vector model for onemax. The fitness values of candidate solutions are shown inside parentheses

original population (both in the proportion and in the actual number). Since onemax value increases with the number of 1s, we can expect the overall quality of the population to increase over time. Ideally, every iteration should increase the objective-function values in the population unless no improvement is possible.

Nonetheless, the increase of the average objective-function value tells only half the story. A similar increase in the quality of the population in the first iteration would be achieved by just repeating selection alone without the use of the probabilistic model. However, by applying selection alone, no new solutions are ever created and the resulting algorithm produces no variation at all (i.e., there is no exploration of new candidate solutions). Since the initial population is generated at random, the **EDA** with selection alone would be just a poor algorithm for obtaining the best solution from the initial population. The learning and sampling of the probabilistic model provides a mechanism for

both (1) improving quality of new candidate solutions (under certain assumptions), and (2) facilitating exploration of the set of admissible solutions.

What we have seen in this simulation was an example of the simplest kind of **EDAs**. The assumed class of probabilistic models, the probability vector, has a fixed structure. Under these circumstances, the procedure for learning it becomes trivial because there are really no alternative models to choose from. This class of **EDAs** is quite limited in what it can do. As we shall see in a moment, there are other classes of **EDAs** that allow richer probabilistic models capable of capturing interactions among the variables of a given problem. More importantly, these interactions can be learned automatically on a problem by problem basis. This results of course in a more complex model building procedure, but the extra effort has been shown to be well worth it, especially when solving more difficult optimization problems [45.4, 5, 8, 22, 35–37].

## 45.2 Taxonomy of EDA Models

This section provides a high-level overview of the distinguishing characteristics of probabilistic models. The characteristics are discussed with respect to (1) the

types of interactions covered by the model and (2) the types of local distributions. This section only focuses on the key characteristics of the probabilistic models;

a more detailed overview of **EDAs** for various representations of candidate solutions will be covered by the following sections.

### 45.2.1 Classification Based on Problem Decomposition

To make the estimation and sampling tractable with reasonable sample sizes, most **EDAs** use probabilistic models that *decompose* the problem using unconditional or conditional independence. The way in which a model decomposes the problem provides one important characteristic that distinguishes different classes of probabilistic models. Classification of probabilistic models based on the way they decompose a problem is relevant regardless of the types of the underlying distributions or the representation of problem variables.

Most **EDAs** assume that candidate solutions are represented by fixed-length vectors of variables and they use graphical models to represent the underlying problem structure. Graphical models allow practitioners to represent both direct dependencies between problem variables as well as independence assumptions. One way to classify graphical models is to consider a hierarchy of model types based on the complexity of a model (see Fig. 45.2 for illustrative examples) [45.3, 4, 7]:

- *No dependencies.* In models that assume full independence, every variable is assumed to be independent of any other variable. That is, the probability distribution  $P(X_1, X_2, \dots, X_n)$  of the vector  $(X_1, X_2, \dots, X_n)$  of  $n$  variables is assumed to consist of a product of the distributions of individual

variables

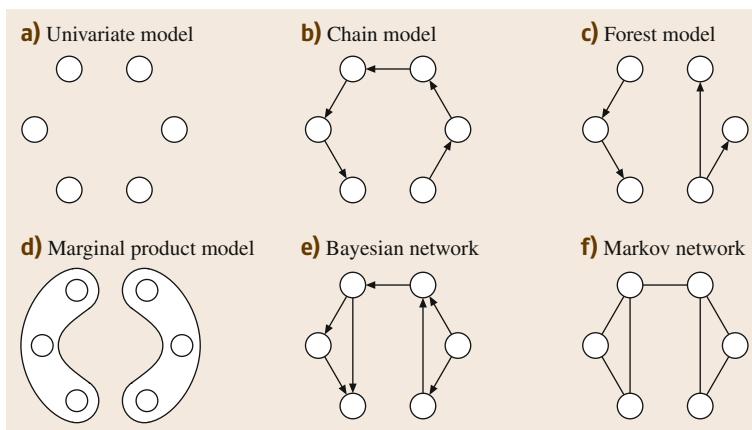

$$P(X_1, X_2, \dots, X_n) = \prod_{i=1}^n P(X_i). \quad (45.2)$$

The simulation presented in Sect. 45.1.3 was based on a model that assumed full independence of binary problem variables. **EDAs** based on univariate models that assume full independence of problem variables include the equilibrium genetic algorithm (**EGA**) [45.33], the population-based incremental learning (**PBIL**) [45.1], the **UMDA** [45.6], the compact genetic algorithm (**cGA**) [45.34], the stochastic hill climbing with learning by vectors of normal distributions [45.38], and the continuous **PBIL** [45.39].

- *Pairwise dependencies.* In this class of models, dependencies between variables form a tree or forest graph. In a tree graph, each variable except for the root of the tree is conditioned on its parent in a tree that contains all variables. A forest graph, on the other hand, is a collection of disconnected trees. Again, the forest contains all problem variables. Denoting by  $R$  the set of roots of the trees in a forest, and by  $X = (X_1, X_2, \dots, X_n)$  the entire vector of variables, the distribution from this class can be expressed as

$$\begin{aligned} & P(X_1, X_2, \dots, X_n) \\ &= \prod_{X_i \in R} P(X_i) \\ &\quad \times \prod_{X_i \in X \setminus R} P(X_i | \text{parent}(X_i)). \end{aligned} \quad (45.3)$$

A special type of a tree model is sometimes distinguished, in which the variables form a sequence

**Fig. 45.2a–f** Illustrative examples of graphical models. Problem variables are displayed as circles and dependencies are shown as edges between variables or clusters of variables. (a) Univariate model. (b) Chain model. (c) Forest model. (d) Marginal product model. (e) Bayesian network. (f) Markov network

(or a chain), and each variable except for the first one depends directly on its predecessor. Denoting by  $\pi(i)$  the index of the  $i$ th variable in the sequence, the distribution is given by

$$P(X_1, X_2, \dots, X_n) = P(X_{\pi(1)}) \prod_{i=2}^n \times P(X_{\pi(i)} | X_{\pi(i-1)}). \quad (45.4)$$

EDAs based on models with pairwise dependencies include the mutual information maximizing input clustering (**MIMIC**) [45.36], EDA based on dependency trees [45.35], and the bivariate marginal distribution algorithm (**BMDA**) [45.40].

- *Multivariate dependencies.* Multivariate models represent dependencies using either directed acyclic graphs or undirected graphs. Two representative models are popular in EDAs: (1) Bayesian networks and (2) Markov networks. A Bayesian network is represented by a directed acyclic graph where each node corresponds to a variable and each edge defines a direct conditional dependence. The probability distribution encoded by a Bayesian network can be written as

$$P(X_1, X_2, \dots, X_n) = \prod_{i=1}^n P(X_i | \text{parents}(X_i)). \quad (45.5)$$

A Bayesian network represents problem decomposition by conditional independence assumptions; each variable is assumed to be independent of any of its antecedents in the ancestral ordering of the variables, given the values of the variable's parents. Note that all models discussed thus far were special cases of Bayesian networks. In fact, a Bayesian network can represent an arbitrary multivariate distribution; however, for such a model to be practical, it is often desirable to consider Bayesian networks of limited complexity.

In Markov networks (Markov random field models), two variables are assumed to be independent of each other given a subset of variables defining the condition if every path between these variables is separated by one or more variables in the condition. A special subclass of multivariate models is sometimes considered in which the variables are divided into disjoint clusters, which are independent of each

other. These models are called marginal product models (**MPM**). Polytrees also represent a subclass of multivariate models in which a directed acyclic graph is used as the basic dependency structure but the graph is restricted so that at most one undirected path exists between any two vertices.

EDAs based on models with multivariate dependencies include the factorized distribution algorithm (**FDA**) [45.37], the learning **FDA** (**LFDA**) [45.37], the estimation of Bayesian network algorithm (**EBNA**) [45.41], the Bayesian optimization algorithm (**BOA**) [45.42, 43] and its hierarchical version (**hBOA**) [45.44], the extended compact genetic algorithm (**ECPGA**) [45.45], the polytree **EDA** [45.46], the continuous iterated density estimation algorithm [45.47], the estimation of multivariate normal algorithm (**EMNA**) [45.48], and the real-coded **BOA** (**rBOA**) [45.49].

- *Full dependence.* Models may be used that do not make *any* independence assumptions. However, such models must typically impose a number of other restrictions on the distribution to ensure that the models remain tractable for a moderate-to-large number of variables.

There are two additional types of probabilistic models that have been used in EDAs and that provide a somewhat different mechanism for decomposing the problem:

- *Grammar models.* Some EDAs use stochastic or deterministic grammars to represent the probability distribution over candidate solutions. The advantage of grammars is that they allow modeling of variable-length structures. Because of this, grammar distributions are mostly used as the basis for implementing genetic programming using EDAs [45.50], which represents candidate solutions using labeled trees of variable size. Grammar models are used, for example, in the probabilistic-grammar based **EDA** for genetic programming [45.51], the program distribution estimation with grammar model (**PRODIGY**) [45.52], or the **EDA** based on probabilistic grammars with latent annotations [45.53].
- *Feature-based models.* Feature-based models encode the distribution of the neighborhood of a candidate solution using position-independent substructures, which can be found in a variety of positions in fixed-length or variable-length solutions. This approach is used in the feature-based

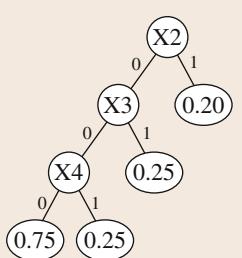

**BOA** [45.54]. Other features may be discovered, encoded, and used for guiding the exploration of the space of candidate solutions. Model-directed neighborhood structures are also used in other **EDA** variants, as will be discussed in Sect. 45.5.2.

### 45.2.2 Classification Based on Local Distributions in Graphical Models

Regardless of how a graphical model decomposes the problem, each model must also assume one or more classes of distributions to encode local conditional and marginal distributions. Some of the most common classes of local distributions are discussed below:

- *Probability tables.* For discrete representations, conditional and marginal probabilities can be encoded using *probability tables*, which define a probability for each relevant combination of values in each conditional or marginal probability term. This was the case, for example, in the simulation in Sect. 45.1.3, in which the probability distribution for each string position  $i$  was represented by the probability  $p_i$  of a 1; the probability of a 0 in the same position was simply  $1 - p_i$ . As another example, in Bayesian networks, for each variable a probability table can be used to define conditional probabilities of any value of the variable given any combination of values of the variable's parents. While probability tables cannot directly represent continuous probability distributions, they can be used even for real-valued representations in combination with a discretization method that maps real-valued variables into discrete categories; each of the discrete categories can then be represented using a single probability entry. Probability tables are

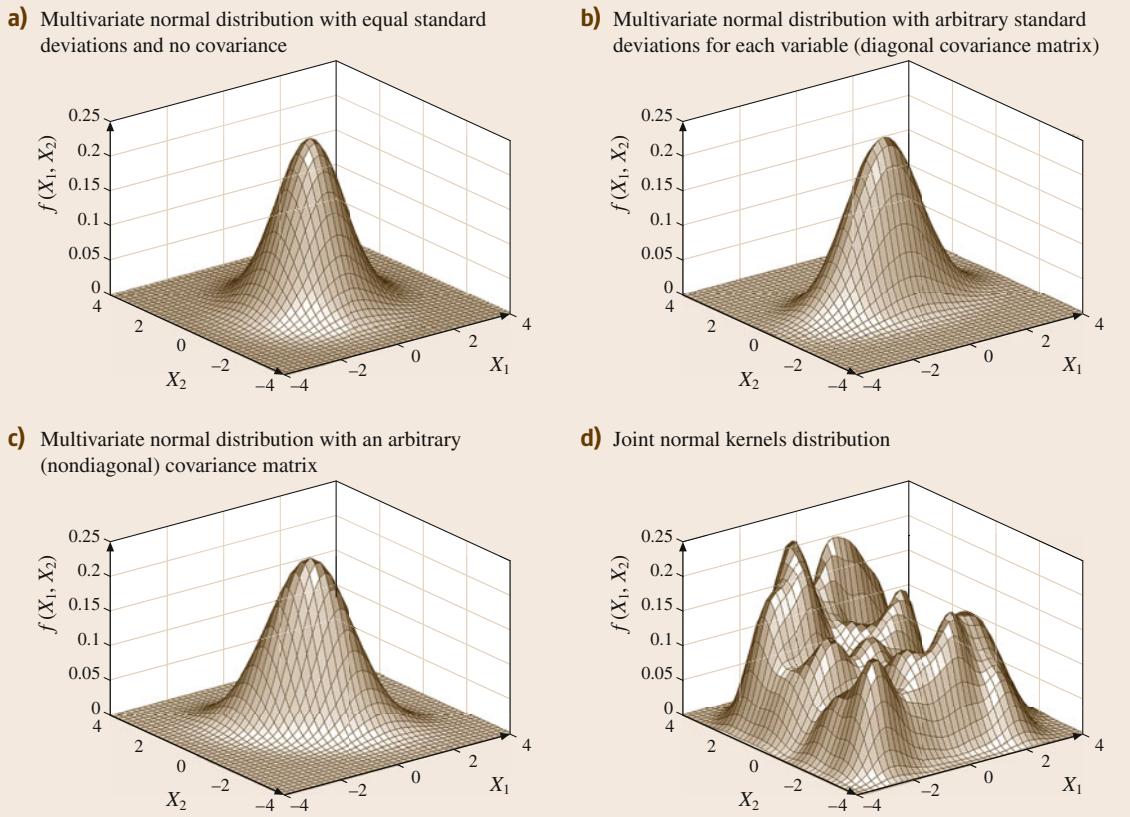

| X2 | X3 | X4 | $p(X_1   X_2, X_3, X_4)$ |
|----|----|----|--------------------------|
| 0  | 0  | 0  | 0.75                     |
| 0  | 0  | 0  | 0.25                     |
| 0  | 0  | 0  | 0.25                     |
| 0  | 0  | 0  | 0.25                     |
| 1  | 1  | 1  | 0.20                     |
| 1  | 1  | 1  | 0.20                     |
| 1  | 1  | 1  | 0.20                     |
| 1  | 1  | 1  | 0.20                     |

**Fig. 45.3** A conditional probability table for  $p(X_1 | X_2, X_3, X_4)$  and a corresponding decision tree that reduces the number of parameters (probabilities) from 8 to 4

used, for example, in **UMDA** [45.6], **BOA** [45.43] and **ECGA** [45.45]. An example conditional probability table is shown in Fig. 45.3.

- *Decision trees or graphs, default tables.* To avoid excessively large probability tables when many probabilities are either similar or negligible, more advanced local structures such as decision trees, decision graphs, or default tables may be used. In decision trees, for example, probabilities are stored in leaves of a decision tree in which each internal node represents a test on a variable and the children of the node correspond to the different outcomes of the test. Decision trees and decision graphs can also be used in combination with real-valued variables, in which the leaves store a continuous distribution in some way. More advanced structures such as decision trees and decision graphs are used, for example, in the decision-graph **BOA (dBOA)** [45.55], the hierarchical **BOA (hBOA)** [45.44], and the mixed **BOA (mBOA)** [45.56]. An example decision tree for representing conditional probabilities is shown in Fig. 45.3.
- *Multivariate, continuous distributions.* The normal distribution is by far the most popular distribution used in **EDAs** to represent univariate or multivariate distributions of real-valued variables. A multivariate normal distribution can encode a linear correlation between the variables using the covariance matrix, but it is often inefficient in representing many other types of interactions [45.56, 57]. Normal distributions were used in many **EDAs** for real-valued vectors [45.38, 39, 47, 48], although in many real-valued **EDAs** more advanced distributions were used as well. Examples of multivariate normal distributions are shown in Fig. 45.4a–c.
- *Mixtures of distributions.* A mixture distribution consists of multiple components. Each component is represented by a specific local probabilistic model, such as a normal distribution, and each component is assigned a probability. Mixture distributions were used in **EDAs** especially to enable **EDAs** for real-valued representations to deal with real-valued distributions with multiple basins of attraction, in which a single-peak distribution does not suffice. Mixture distributions were used, for example, in the real-valued iterated density estimation algorithms [45.47] or the real-coded **BOA** [45.49]. The use of mixture distributions is more popular in **EDAs** for real-valued representations, although mixture distributions were also

**Fig. 45.4a–d** Local models for continuous distributions over real-valued variables. **(a)** Multivariate normal distribution with equal standard deviations and no covariance, **(b)** Multivariate normal distribution with arbitrary standard deviations for each variable (diagonal covariance matrix), **(c)** Multivariate normal distribution with an arbitrary (nondiagonal) covariance matrix, **(d)** Joint normal kernels distribution

used to represent distributions over discrete representations in which the population consists of multiple dissimilar clusters [45.58] and in multi-objective EDAs [45.59, 60]. An example of a mixture of normal kernel distributions is shown in Fig. 45.4d.

- **Histograms.** In a number of EDAs for real-valued representations, to encode local distributions, real-valued variables or sets of such variables are divided into rectangular regions using a histogram-like model, and a separate probabilistic model is

used to represent the distribution in each region. Histogram models can be seen as a special subclass of the decision-tree models for real-valued variables. In real-valued EDAs, histograms were used, for example, in the histogram-based continuous EDA [45.61]. Histogram models can also be used for other representations; for example, when optimizing permutations, histograms can be used to represent different relative ordering constraints and their importance with respect to solution quality [45.62, 63].

## 45.3 Overview of EDAs

This section gives an overview of EDAs based on the representation of candidate solutions; although some of the EDAs can be used across several representations. Due to the large volume of work in EDAs in the past two decades, we do not aim to list every single variant of an EDA discussed in the past; instead, we focus on some of the most important representatives.

### 45.3.1 EDAs for Fixed-Length Strings over Finite Alphabets

EDAs for candidate solutions represented by fixed-length strings over a finite alphabet can use a variety of model types, from simple univariate models to complex Bayesian networks with local structures. This section reviews some of the work in this area. Candidate solutions are assumed to be represented by binary strings of fixed length  $n$ , although most methods presented here can be extended to optimization of strings over an arbitrary finite alphabet. The section classifies EDAs based on the order of interactions in the underlying dependency model along the lines discussed in Sect. 45.2.1 [45.3, 4, 7].

#### No Interactions

The EGA [45.33] and the population-based incremental learning (PBIL) [45.1] replace the population of candidate solutions represented as fixed-length binary strings by a probability vector  $(p_1, p_2, \dots, p_n)$ , where  $n$  is the number of bits in a string and  $p_i$  denotes the probability of a 1 in the  $i$ th position of solution strings. Each  $p_i$  is initially set to 0.5, which corresponds to a uniform distribution over the set of all solutions. In each iteration, PBIL generates  $s$  candidate solutions according to the current probability vector where  $s \geq 2$  denotes the selection pressure. Each value is generated independently of its context (remaining bits) and thus no interactions are considered (Fig. 45.2a). The best solution from the generated set of  $s$  solutions is then used to update the probability-vector entries using

$$p_i = p_i + \lambda(x_i - p_i),$$

where  $\lambda \in (0, 1)$  is the learning rate (say, 0.02), and  $x_i$  is the  $i$ th bit of the best solution. Using the above update rule, the probability  $p_i$  of a 1 in the  $i$ th position increases if the best solution contains a 1 in that position and decreases otherwise. In other words, probability-vector entries move toward the best solution and, consequently, the probability of generating this solution

increases. The process of generating new solutions and updating the probability vector is repeated until some termination criteria are met; for instance, the run can be terminated if all probability-vector entries are sufficiently close to either 0 or 1.

Prior work refers to PBIL also as the hill climbing with learning (HCwL) [45.64] and the incremental univariate marginal distribution algorithm (IUMDA) [45.65].

PBIL is an incremental EDA, because it proceeds by executing incremental updates of the model using a small sample of candidate solutions. However, there is a strong correlation between the learning rate in PBIL and the population size in population-based EDAs or other evolutionary algorithms; essentially, decreasing the learning rate  $\lambda$  corresponds to increasing the population size.

The cGA [45.34, 66] reduces the gap between PBIL and traditional steady-state genetic algorithms. Like PBIL, cGA replaces the population by a probability vector and all entries in the probability vector are initialized to 0.5. Each iteration updates the probability vector by mimicking the effect of a single competition between two sampled solutions, where the best replaces the worst, in a hypothetical population of size  $N$ . Denoting the bit in the  $i$ th position of the best and worst of the two sampled solutions by  $x_i$  and  $y_i$ , respectively, the probability-vector entries are updated as follows:

$$p_i = \begin{cases} p_i + \frac{1}{N} & \text{if } x_i = 1 \text{ and } y_i = 0 \\ p_i - \frac{1}{N} & \text{if } x_i = 0 \text{ and } y_i = 1 \\ p_i & \text{otherwise.} \end{cases}$$

Although cGA uses the probability vector instead of a population, updates of the probability vector correspond to replacing one candidate solution by another one using a population of size  $N$  and shuffling the resulting population using a univariate model that assumes full independence of problem variables.

The UMDA [45.6] maintains a population of solutions. Each iteration of UMDA starts by selecting a population of promising solutions using an arbitrary selection method of evolutionary algorithms. A probability vector is then computed using the selected population of promising solutions and new solutions are generated by sampling the probability vector. The

new solutions replace the old ones and the process is repeated until termination criteria are met. Although **UMDA** uses a probabilistic model as an intermediate step between the original and new populations unlike

**PBIL** and **cGA**, the performance, dynamics and limitations of **PBIL**, **cGA**, and **UMDA** are similar.

**PBIL**, **cGA**, and **UMDA** can solve problems decomposable into subproblems of order 1 in a linear or quadratic number of fitness evaluations. However, if decomposition into single-bit subproblems misleads the decision making away from the optimum, these algorithms scale up poorly with problem size [45.60, 67, 68].

### Pairwise Interactions

**EDAs** based on pairwise probabilistic models, such as a chain, a tree or a forest, represent the first step toward **EDAs** being capable of learning variable interactions and therefore solving decomposable problems of bounded order (difficulty) in a scalable manner.

The **MIMIC** algorithm [45.36] uses a chain distribution (Fig. 45.2b) specified by

- (1) an ordering of string positions (variables),
- (2) a probability of a 1 in the first position of the chain, and
- (3) conditional probabilities of every other position given the value in the previous position in the chain.

A chain probabilistic model encodes the probability distribution where all positions except the first are conditionally dependent on the previous position in the chain. After selecting promising solutions and computing marginal and conditional probabilities, **MIMIC** uses a greedy algorithm to maximize mutual information between the adjacent positions in the chain. In this fashion, the Kullback–Leibler divergence [45.69] between the chain and actual distributions is minimized. Nonetheless, the greedy algorithm does not guarantee global optimality of the constructed model (with respect to Kullback–Leibler divergence). The greedy algorithm starts in the position with the minimum unconditional entropy. The chain is expanded by adding a new position that minimizes the conditional entropy of the new variable given the last variable in the chain. Once the full chain is constructed for the selected population of promising solutions, new solutions are generated by sampling the distribution encoded by the chain. The use of pairwise interactions was one of the most important steps in the development of **EDAs** capable of solving decomposable problems of bounded difficulty scalably.

**MIMIC** was the first discrete **EDA** to not only learn and use a fixed set of statistics, but it was also capable of identifying the statistics that should be considered to solve the problem efficiently.

*Baluja* and *Davies* [45.35] use dependency trees (Fig. 45.2c) to model promising solutions. Like in **PBIL**, the population is replaced by a probability vector but in this case the probability vector contains all *pairwise* probabilities. The probabilities are initialized to 0.25. Each iteration adjusts the probability vector according to new promising solutions acquired on the fly. A dependency tree encodes the probability distribution where every variable except for the root is conditioned on the variable's parent in the tree. A variant of *Prim*'s algorithm for finding the minimum spanning tree [45.70] can be used to construct an optimal tree distribution. Here the task is to find a tree that maximizes mutual information between parents (nodes with successors) and their children (successors). This can be done by first randomly choosing a variable to form the root of the tree, and *hanging* new variables to the existing tree so that the mutual information between the parent of the new variable and the variable itself is maximized. In this way, the Kullback–Leibler divergence between the tree and actual distributions is minimized as shown in [45.71]. Once a full tree is constructed, new solutions are generated according to the distribution encoded by the constructed dependency tree and the conditional probabilities computed from the probability vector.

The **BMDA** [45.40] uses a forest distribution (a set of mutually independent dependency trees, see Fig. 45.2c). This class of models is even more general than the class of dependency trees, because any forest that contains two or more disjoint trees cannot be generally represented by a tree. As a measure to determine whether to connect two variables, **BMDA** uses a Pearson's chi-square test [45.72]. This measure is also used to discriminate the remaining dependencies in order to construct the final model. To learn a model, **BMDA** uses a variant of *Prim*'s algorithm [45.70].

Pairwise models capture some interactions in a problem with reasonable computational overhead. **EDAs** with pairwise probabilistic models can identify, propagate, and juxtapose partial solutions of order 2, and therefore they work well on problems decomposable into subproblems of order at most two [45.35, 36, 40, 65, 73]. Nonetheless, capturing only some pairwise interactions has still been shown to be insufficient for solving all decomposable problems of bounded difficulty scalably [45.40, 73].

### Multivariate Interactions

Using general multivariate models allows powerful **EDAs** capable of solving problems of bounded difficulty quickly, accurately, and reliably [45.4, 5, 8, 22, 37]. On the other hand, learning distributions with multivariate interactions necessitates more complex model-learning algorithms that require significant computational time and still do not guarantee global optimality of the resulting model. Nonetheless, many difficult problems are intractable using simple models and the use of complex models and algorithms is necessary.

The **FDA** [45.74] uses a fixed factorized distribution throughout the whole run. The model is allowed to contain multivariate marginal and conditional probabilities, but **FDA** learns only the probabilities, not the structure (dependencies and independencies). To solve a problem using **FDA**, we must first decompose the problem and then factorize the decomposition. While it is useful to incorporate prior information about the regularities in the search space, **FDA** necessitates that the practitioner is able to decompose the problem using a probabilistic model ahead of time. **FDA** does not learn *what statistics* are important to process within the **EDA** framework, it must be given that information in advance. A variant of **FDA** where probabilistic models are restricted to poly-trees was also proposed [45.46].

The **ECGA** [45.45] uses an **MPM** that partitions the variables into disjoint subsets (Fig. 45.2d). Each partition (subset) is treated as a single variable and different partitions are considered to be mutually independent. To decide between alternative **MPMs**, **ECGA** uses a variant of the minimum description length (**MDL**) metric [45.75–77], which favors models that allow higher compression of data (in this case, the selected set of promising solutions). More specifically, the Bayesian information criterion (**BIC**) [45.78] is used. To find a good model, **ECGA** uses a greedy algorithm that starts with each variable forming one partition (like in **UMDA**). Each iteration of the greedy algorithm merges two partitions that maximize the improvement of the model with respect to **BIC**. If no more improvement is possible, the current model is used. **ECGA** provides robust and scalable solution for problems that can be decomposed into independent subproblems of bounded order (separable problems) [45.79–81]. However, many real-world problems contain overlapping dependencies, which cannot be accurately modeled by dividing the variables into disjoint partitions; this can result in poor performance of **ECGA**.

The dependency-structure matrix genetic algorithm (**DSMGA**) [45.82–84] uses a similar class of models as

**ECGA** that splits the variables into independent clusters or linkage groups. However, **DSMGA** builds models via dependency structure matrix clustering techniques.

The **BOA** [45.42] builds a Bayesian network for the population of promising solutions (Fig. 45.2e) and samples the built network to generate new candidate solutions. **BOA** uses the Bayesian–Dirichlet metric subject to a maximum model-complexity constraint [45.85–87] to discriminate competing models, but other metrics (such as **BIC**) have been analyzed in **BOA** as well [45.88]. In all variants of **BOA**, the model is constructed by a greedy algorithm that iteratively adds a new dependency in the model that maximizes the model quality. Other elementary graph operators – such as edge removals and reversals – can be incorporated, but edge additions are most important. The construction is terminated when no more improvement is possible. The greedy algorithm used to learn a model in **BOA** is similar to the one used in **ECGA**. However, Bayesian networks can encode more complex dependencies and independencies than models used in **ECGA**. Therefore, **BOA** is also applicable to problems with overlapping dependencies. **BOA** uses an equivalent class of models as **FDA**; however, **BOA** learns both the structure and the probabilities of the model. Although **BOA** does not require problem-specific knowledge in advance, prior information about the problem can be incorporated using Bayesian statistics, and the relative influence of prior information and the population of promising solutions can be tuned by the user [45.89, 90].

A discussion of the use of Bayesian networks as an extension to tree models can also be found in *Baluja's* and *Davies'* work [45.91]. An **EDA** that uses Bayesian networks to model promising solutions was independently developed by *Etxeberria* and *Larrañaga* [45.41], who called it the **EBNA**. *Mühlenbein* and *Mahnig* [45.37] improved the original **FDA** by using Bayesian networks together with the greedy algorithm for learning the networks described above; the modification of **FDA** was named the (**LFDA**). An incremental version of **BOA**, the incremental **BOA** (**iBOA**) was proposed by *Pelikan et al.* [45.92].

The hierarchical **BOA** (**hBOA**) [45.44] extends **BOA** by employing local structures to represent local distributions instead of using standard conditional probability tables. This enables **hBOA** to more efficiently represent distributions with high-order interactions. Furthermore, **hBOA** incorporates a niching technique called restricted tournament selection [45.93] to ensure effective diversity preservation. The two exten-

sions enable **hBOA** to solve problems decomposable into subproblems of bounded order over a number of levels of difficulty of a hierarchy [45.44, 94].

Markov networks are yet another class of models that can be used to identify and use multivariate interactions in **EDAs**. Markov networks are undirected graphical models (Fig. 45.2f). Compared to Bayesian networks, Markov networks may sometimes cover the same distribution using fewer edges in the dependency model, but the sampling of these models becomes more complicated than the sampling of Bayesian networks. Markov networks are used, for example, in the Markov network **EDA (MN-EDA)** [45.95] and the density estimation using Markov random fields algorithm (**DEUM**) [45.96, 97].

Helmholtz machines used in the Bayesian evolutionary algorithm proposed by *Zhang and Shin* [45.98] can also encode multivariate interactions. Helmholtz machines encode interactions by introducing new, hidden variables, which are connected to every variable.

**EDAs** that use models capable of covering multivariate interactions can solve a wide range of problems in a scalable manner; promising results were reported on a broad range of problems, including several classes of spin-glass systems [45.22, 99–101], graph partitioning [45.90, 102, 103], telecommunication network optimization [45.104], silicon cluster optimization [45.80], scheduling [45.105], forest management [45.13], ground water remediation system design [45.106, 107], multiobjective knapsack [45.20], and others.

### 45.3.2 EDAs for Real-Valued Vectors

There are two basic approaches to extending **EDAs** for discrete, fixed-length strings to other domains such as real-valued vectors:

- Map the other representation to the domain of fixed-length discrete strings, solve the discrete problem, and map the solution back to the problem's original representation.
- Extend or modify the class of probabilistic models to other domains.

A number of studies have been published about the mapping of real-valued representations into a discrete one in evolutionary computation [45.26, 108–111]; this section focuses on **EDAs** from the second category. The approaches are classified along the lines presented in Sect. 45.2 [45.7, 22].

### Single-Peak Normal Distributions

The stochastic hill climbing with learning by vectors of normal distributions (**SHCLVND**) [45.38] is a straightforward extension of **PBIL** to vectors of real-valued variables using a normal distribution to model each variable. **SHCLVND** replaces the population of real-valued solutions by a vector of means  $\mu = (\mu_1, \dots, \mu_n)$ , where  $\mu_i$  denotes a mean of the distribution for the  $i$ th variable. The same standard deviation  $\sigma$  is used for all variables. See Fig. 45.4a for an example model. In each generation (iteration), a random set of solutions is first generated according to  $\mu$  and  $\sigma$ . The best solution out of this subset is then used to update the entries in  $\mu$  by shifting each  $\mu_i$  toward the value of the  $i$ th variable in the best solution using an update rule similar to the one used in **PBIL**. Additionally, each generation reduces the standard deviation to make the future exploration of the search space narrower. A similar algorithm was independently developed by *Sebag and Ducoulombier* [45.39], who also discussed several approaches to evolving a standard deviation for each variable.

### Mixtures of Normal Distributions

The probability density function of a normal distribution is centered around its mean and decreases exponentially with square distance from the mean. If there are multiple *clouds* of values, a normal distribution must either focus on only one of these clouds, or it can embrace multiple clouds at the expense of including the low-density area between them. In both cases, the resulting distribution cannot model the data accurately. One way of extending standard single-peak normal-distribution models to enable coverage of multiple groups of similar points is to use a *mixture* of normal distributions. Each component of the mixture of normal distributions is a normal distribution by itself. A coefficient is specified for each component of the mixture to denote the probability that a random point belongs to this component. The probability density function of a mixture is thus computed by multiplying the density function of each mixture component by the probability that a random point belongs to the component, and adding these weighted densities together.

*Gallagher et al.* [45.112, 113] extended **EDAs** based on single-peak normal distributions by using an adaptive mixture of normal distributions to model each variable. The parameters of the mixture (including the number of components) evolve based on the discovered promising solutions. Using mixture distributions is a significant improvement compared to single-peak

normal distributions, because mixtures allow simultaneous exploration of multiple basins of attraction for each variable.

Within the **IDEA** framework, *Bosman* and *Thierens* [45.47] proposed **IDEAs** using the joint normal kernels distribution, where a single normal distribution is placed around each selected solution (Fig. 45.4d). A joint normal kernels distribution can be therefore seen as an extreme use of mixture distributions with one mixture component per point in the training sample. The variance of each normal distribution can be fixed to a relatively small value, but it should be preferable to adapt variances according to the current state of search. Using kernel distributions corresponds to using a fixed zero-mean normally distributed mutation for each promising solution as is often done in evolution strategies [45.114]. That is why it is possible to directly take up strategies for adapting the variance of each kernel from evolution strategies [45.114–117].

### Joint Normal Distributions and Their Mixtures

What changes when instead of fitting each variable with a separate normal distribution or a mixture of normal distributions, groups of variables are considered together? Let us first consider using a single-peak normal distribution. In multivariate domains, a joint normal distribution can be defined by a vector of  $n$  means (one mean per variable) and a covariance matrix of size  $n \times n$ . Diagonal elements of the covariance matrix specify the variances for all variables, whereas nondiagonal elements specify linear dependencies between pairs of variables. Considering each variable separately corresponds to setting all nondiagonal elements in a covariance matrix to 0. Using different deviations for different variables allows for *squeezing* or *stretching* the distribution along the axes. On the other hand, using nondiagonal entries in the covariance matrix allows rotating the distribution around its mean. Figure 45.4b and c illustrates the difference between a joint normal distribution using only diagonal elements of the covariance matrix and a distribution using the full covariance matrix. Therefore, using a covariance matrix introduces another degree of freedom and improves the expressiveness of a distribution. Again, one can use a number of joint normal distributions in a mixture, where each component consists of its mean, covariance matrix, and weight.

A joint normal distribution including a full or partial covariance matrix was used within the **IDEA** framework [45.47] and in the estimation of Gaussian

networks algorithm (**EGNA**) [45.48]. Both these algorithms can be seen as extensions of **EDAs** that model each variable by a single normal distribution, which allow also the use of nondiagonal elements of the covariance matrix.

*Bosman* and *Thierens* [45.118] proposed *mixed IDEAs* as an extension of **EDAs** that use a mixture of normal distributions to model each variable. Mixed **IDEAs** allow multiple variables to be modeled by a separate mixture of joint normal distributions. At one extreme, each variable can have a separate mixture; at another extreme, one mixture of joint distributions covering all the variables is used. Despite that learning such a general class of distributions is quite difficult and a large number of samples is necessary for reasonable accuracy, good results were reported on single-objective [45.118] as well as multiobjective problems [45.59, 119, 120]. Using mixture models for all variables was also proposed as a technique for reducing model complexity in discrete **EDAs** [45.58].

Real-valued **EDAs** presented so far are applicable to real-valued optimization problems without requiring differentiability or continuity of the underlying problem. However, if it is possible to at least partially differentiate the problem, gradient information can be used to incorporate some form of gradient-based local search and the performance of real-valued **EDAs** can be significantly improved. A study on combining real-valued **EDAs** within the **IDEA** framework with gradient-based local search can be found, for example, in [45.121].

One of the crucial limitations of using estimation of real-valued distributions is that real-valued **EDAs** have a tendency to lose diversity too fast even when the problem is relatively easy to solve [45.122]; for example, maximum likelihood estimation and sampling of a normal distribution will lead to diversity loss even while climbing a simple linear slope. That is why several **EDAs** were proposed that aim to control variance of the probabilistic model so that the loss of variance is avoided and yet the effective exploration is not hampered by an overly large variance of the model. For example, the adapted maximum-likelihood Gaussian model iterated density-estimation evolutionary algorithm (AMaLGaM) scales up the covariance matrix to prevent premature convergence on slopes [45.123, 124].

### Other Real-Valued **EDAs**

Using normal distributions is not the only approach to modeling real-valued distributions. Other density func-

tions are frequently used to model real-valued probability distributions, including histogram distributions, interval distributions, and others. A brief review of real-valued **EDAs** that use other than normal distributions or their mixtures follows.

In the algorithm proposed by *Servet* et al. [45.125], an interval  $(a_i, b_i)$  and a number  $z_i \in (0, 1)$  are stored for each variable. By  $z_i$ , the probability that the  $i$ th variable is in the lower half of  $(a_i, b_i)$  is denoted. Each  $z_i$  is initialized to 0.5. To generate a new candidate solution, the value of each variable is selected randomly from the corresponding interval. The best solution is then used to update the value of each  $z_i$ . If the value of the  $i$ th variable of the best solution is in a lower half of  $(a_i, b_i)$ ,  $z_i$  is shifted toward 0; otherwise,  $z_i$  is shifted toward 1. When  $z_i$  gets close to 0, interval  $(a_i, b_i)$  is reduced to its lower half; if  $z_i$  gets close to 1, interval  $(a_i, b_i)$  is reduced to its upper half.

**EDAs** proposed in [45.47, 126] use empirical histograms to model each variable as opposed to using a single normal distribution or a mixture of normal distributions. In these approaches, a histogram for each single variable is constructed. New points are then generated according to the distribution encoded by the histograms for all variables. The sampling of a histogram proceeds by first selecting a particular bin based on its relative frequency, and then generating a random point from the interval corresponding to the bin. It is straightforward to replace the histograms in the above methods by various classification and discretization methods of statistics and machine learning (such as  $k$ -means clustering) [45.108].

*Pelikan* et al. [45.111, 127] use an adaptive mapping from the continuous domain to the discrete one in combination with discrete **EDAs**. The population of promising solutions is first discretized using equal-width histograms, equal-height histograms,  $k$ -means clustering, or other classification techniques. A population of promising discrete solutions is then selected. New points are created by applying a discrete recombination operator to the selected population of promising discrete solutions. For example, new solutions can be generated by building and sampling a Bayesian network like in **BOA**. The resulting discrete solutions are then mapped back into the continuous domain by sampling each class (a bin or a cluster) using the original values of the variables in the selected population of continuous solutions (before discretization). The resulting solutions are perturbed using one of the adaptive mutation operators of evolution strategies [45.114–117]. In this way, competent discrete **EDAs** can be com-

bined with advanced methods based on adaptive local search in the continuous domain. A related approach was proposed by *Chen* and *Chen* [45.109], who propose a split-on-demand adaptive discretization method to use in combination with **ECGA** and report promising results on several benchmarks and one real-world problem.

The mixed Bayesian optimization algorithm (**mBOA**) developed by *Ocenasek* and *Schwarz* [45.56] models vectors of real-valued variables using an extension of Bayesian networks with local structures. A model used in **mBOA** consists of a decision tree for each variable. Each internal node in the decision tree for a variable is a test on the value of another variable. Each test on a variable is specified by a particular value, which is also included in the node. The test considers two cases: the value of the variable is greater or equal than the value in the node or it is smaller. Each internal node has two children, each child corresponding to one of the two results of the test specified in this node. Leaves in a decision tree thus correspond to rectangular regions in the search space. For each leaf, the decision tree for the variable specifies a single-variable mixture of normal distributions centered around the values of this variable in the solutions consistent with the path to the leaf. Thus, for each variable, the model in **mBOA** divides the space reduced to other variables into rectangular regions, and it uses a single-variable normal kernels distribution to model the variable in each region. The adaptive variant of **mBOA** (**am-BOA**) [45.128] extends **mBOA** by employing variance adaptation with the goal of maximizing effectiveness of the search for the optimum on real-valued problems.

### 45.3.3 EDAs for Genetic Programming

In genetic programming [45.129], the task is to solve optimization problems with candidate solutions represented by labeled trees that encode computer programs or symbolic expressions. Internal nodes of a tree represent functions or commands; leaves represent functions with no arguments, variables, and constants. There are two key challenges that one must deal with when applying **EDAs** to genetic programming. Firstly, the length of programs is expected to vary and it is difficult to estimate how large the solution will be without solving the problem first. Secondly, small changes in parent-child relationships often lead to large changes in the performance of a candidate solution, and often the relationship between nodes in the program trees is more

important than their actual position. Despite these challenges, even in this problem domain, **EDAs** have been quite successful. In this section, we briefly outline some **EDAs** for genetic programming.

The probabilistic incremental program evolution (**PIPE**) algorithm [45.130, 131] uses a probabilistic model in the form of a tree of a specified maximum allowable size. Nodes in the model specify probabilities of functions and terminals. **PIPE** does not capture any interactions between the nodes in the model. The model is updated by adjusting the probabilities based on the population of selected solutions using an update rule similar to the one in **PBIL** [45.1]. New program trees are generated in a top-down fashion starting in the root and continuing to lower levels of the tree. More specifically, if the model generates a function in a node and that function requires additional arguments, the successors (children) of the node are generated to form the arguments of the function. If a terminal is generated, the generation along this path terminates. An extension of **PIPE** named hierarchical probabilistic incremental program evolution (**H-PIPE**) was later proposed [45.132]. In **H-PIPE**, nodes of a model are allowed to contain subroutines, and both the subroutines as well as the overall program are evolved.

**Handley** [45.133] used tree probabilistic models to represent populations of programs (trees) in genetic programming. Although the goal of this work was to compress the population of computer programs in genetic programming, Handley's approach can be used within the **EDA** framework to model and sample candidate solutions represented by computer programs or symbolic expressions. A similar model was used in estimation of distribution programming (**EDP**) [45.134], which extended **PIPE** by employing parent-child dependencies in candidate labeled trees. Specifically, in **EDP** the content of each node is conditioned on the node's parent.

The extended compact genetic programming (**ECGP**) [45.135] assumes a maximum tree of maximum branching like **PIPE**. Nonetheless, **ECGP** uses an **MPM** which partitions nodes into clusters of strongly correlated nodes. This allows **ECGP** to capture and exploit interactions between nodes in program trees, and solve problems that are difficult for conventional genetic programming and **PIPE**. There are four main characteristics that distinguish **ECGP** and **EDP**. **ECGP** is able to capture dependencies between more than two nodes, it learns the dependency structure based on the promising candidate trees, and it is not restricted to the dependencies between parents and

their children. On the other hand, **ECGP** is somewhat limited in its ability to efficiently encode long-range interactions compared to probabilistic models that do not assume that groups of variables must be fully independent of each other.
