*Looks* et al. [45.136] proposed to use Bayesian networks to model and sample program trees. Combinatory logic is used to represent program trees in a unified manner. Program trees translated with combinatory logic are then modeled with Bayesian networks of **BOA**, **EBNA**, and **LFDA**. Contrary to most other **EDAs** for genetic programming presented in this section, in the approach of *Looks* et al. the size of computer programs is not limited, but solutions are allowed to grow over time. *Looks* later developed a more powerful framework for competent program evolution using **EDAs**, which was named meta-optimizing semantic evolutionary search (**MOSES**) [45.54, 137, 138]. The key facets of **MOSES** include the division of the population into demes, the reduction of the problem of evolving computer programs to the one of building a representation with tunable features (knobs), and the use of hierarchical **BOA** [45.44] or another competent evolutionary algorithm to model demes and sample new candidate program solutions.

Several **EDAs** for genetic programming used probabilistic models based on grammar rules [45.51, 52, 139, 140]. Most grammar-based **EDAs** for genetic programming use a context-free grammar. The stochastic grammar-based genetic programming (**SG-GP**) [45.140, 140] started with a fixed context-free grammar with a default probability for each rule; the probabilities attached to the different rules were gradually adjusted based on the best candidate programs. The program evolution with explicit learning (**PEEL**) [45.139] used a probabilistic L-system with rules applicable at specific depths and locations; the probabilities of the rules were adapted using a variant of ant colony optimization (**ACO**) [45.141]. Another grammar-based **EDA** for genetic programming was proposed by *Bosman* and *de Jong* [45.51], who used a context-free grammar that was initialized to a minimum stochastic context-free grammar and adjusted to better fit promising candidate solutions by expanding rules and incorporating depth information into the rules. Grammar model-based program evolution (**GMPE**) [45.52, 142] also uses a probabilistic context-free grammar. In **GMPE**, new rules are allowed to be created and old rules may be eliminated from the model. A variant of the minimum-message-length metric is used in **GMPE** to compare grammars according to their quality. *Tanev* [45.143] incorporated

stochastic context-sensitive grammars into the grammar-guided genetic programming [45.144–146].

#### 45.3.4 EDAs for Permutation Problems

In many problems, candidate solutions are most naturally represented by permutations. This is the case, for example, in many scheduling or facility location problems. These types of problems often contain two specific types of features or constraints that EDAs need to capture. The first is the *absolute* position of a symbol in a string and the second is the *relative* ordering of specific symbols. In some problems, such as the traveling salesman problem, relative ordering constraints matter the most. In others, such as the QAP, both the relative ordering and the absolute positions matter.

One approach to permutation problems is to apply an EDA for problems not involving permutations in combination with a mapping function between the EDA representation and the admissible permutations. For example, one may use the random key encoding [45.147] to transfer the problem of finding a good permutation into the problem of finding a high-quality real-valued vector, allowing the use of EDAs for optimization of real-valued vectors in solving permutation-based problems [45.148, 149]. Random key encoding represents a permutation as a vector of real numbers. The permutation is defined by the reordering of the values in the vector that sorts the values in ascending order. The main advantage of using random keys is that any real-valued vector defines a valid permutation and any EDA capable of solving problems defined on vectors of real numbers can thus be used to solve permutation problems. However, since EDAs do not process the aforementioned types of regularities in permutation problems directly their performance can often be poor [45.148, 150]. That is why several EDAs were developed that aim to encode either type of constraints for permutation problems explicitly.

To solve problems where candidate solutions are permutations of a string, Bengoetxea et al. [45.151] start with a Bayesian network model built using the same approach as in EBNA [45.41]. However, the sampling method is changed to ensure that only valid permutations are generated. This approach was shown to have promise in solving the inexact graph matching problem. In much the same way, the dependency-tree EDA (dtEDA) of Pelikan et al. [45.152] starts with a dependency-tree model [45.35, 71] and modifies the sampling to ensure that only valid permutations are

generated. dtEDA for permutation problems was used to solve structured QAPs with great success [45.152]. Bayesian networks and tree models are capable of encoding both the absolute position and the relative ordering constraints, although for some problem types, such models may turn out to be rather inefficient.

Bosman and Thierens [45.148] extended the real-valued EDA to the permutation domain by storing the dependencies between different positions in a permutation in the induced chromosome element exchanger (ICE). ICE works by first using a real-valued EDA, which encodes permutations as real-valued vectors using the random keys encoding. ICE extends the real-valued EDA by using a specialized crossover operator. By applying the crossover directly to permutations instead of simply sampling the model, relative ordering is taken into account. The resulting algorithm was shown to outperform many real-valued EDAs that use the random key encoding alone [45.148].

The edge-histogram-based sampling algorithm (EHBSA) [45.63, 153] works by creating an edge histogram matrix (EHM). For each pair of symbols, EHM stores the probabilities that one of these symbols will follow the other one in a permutation. To generate new solutions, EHBSA starts with a randomly chosen symbol. EHM is then sampled repeatedly to generate new symbols in the solution, normalizing the probabilities based on what values have already been generated. EHM does not take into account absolute positions at all; in order to address problems in which absolute positions are important, EHBSA was extended to use templates [45.153]. To generate new solutions, first a random string from the population was picked as a template. New solutions were then generated by removing random parts of the template string and generating the missing parts by sampling from EHM. The resulting algorithm was shown to be better than most other EDAs on the traveling salesman problem. In another study, the node-histogram based sampling algorithm (NHBSA) was proposed by Tsutsui et al. [45.63], which used a model capable of storing node frequencies in each position (thereby encoding absolute position constraints) and also used a template.

Zhang et al. [45.154–156] proposed to use guided mutation to optimize both permutation problems [45.154] as well as graph problems [45.156]. In guided mutation, the parts of the solution that are to be modified using a stochastic neighborhood operator are identified by analyzing a probabilistic model of the population of promising candidate solutions.

## 45.4 EDA Theory

Along with the design and application of EDAs, the theoretical understanding of these algorithms has improved significantly since the first EDAs were proposed. One way to classify key areas of theoretical study of EDAs follows [45.3]:

- *Convergence proofs.* Some of the most important results in EDA theory focus on the number of iterations of an EDA on a particular class of problems or the conditions that allow EDAs to provably converge to a global optimum. The convergence time (number of iterations until convergence) of UMDA on onemax for selection methods with fixed selection intensity was derived by Mühlenbein and Schlierkamp-Voosen [45.157]. The convergence of FDA on separable additively decomposable functions (ADFs) was explored by Mühlenbein and Mahnig [45.158], who developed an exact formula for convergence time when using fitness-proportionate selection. Since, in practice, fitness-proportionate selection is rarely used because of its sensitivity to some linear and many other transformations of the objective function, truncation selection was also examined and an equation was derived giving the approximate time to convergence from the analysis of the onemax function. Later, Mühlenbein and Mahnig [45.37] adapted the theoretical model to the class of general ADFs where subproblems were allowed to interact. Under the assumption of Boltzmann selection, theory of graphical models was used to derive sufficient conditions for an FDA model so that FDA with a large enough population is guaranteed to converge to a model that generates only the global optima. Zhang [45.159] analyzed stability of fixed points of limit models of UMDA and FDA, and showed that at least for some problems the chance of converging to the global optimum is indeed increased when using higher order models of FDA rather than only the probability vector of UMDA. Convergence properties of PBIL were studied, for example, in [45.64, 160, 161].
- *Population sizing.* The convergence proofs mentioned above assumed infinite populations in order to simplify calculations. However, in practice using an infinite population is not possible and the choice of an adequate population size is crucial, similarly as for other population-based evolutionary algorithms [45.162–165]. Using a population that is too small can lead to convergence to solutions of low quality and inability to reliably find the global optimum. On the other hand, using a population that is too large can lead to an increased complexity of building and sampling probabilistic models, evaluating populations, and executing other EDA components. Similar to genetic algorithms, EDAs must have a population size sufficiently large to provide an adequate initial supply of partial solutions in an adequate problem decomposition [45.163, 166] and to ensure that good decisions are made between competing partial solutions [45.165]. However, the population must also be large enough for EDAs to make good decisions about the presence or the absence of statistically significant variable interactions. To examine this topic, Pelikan et al. [45.166] analyzed the population size required for BOA to solve decomposable problems of bounded difficulty with uniformly and nonuniformly scaled subproblems. The results showed that the population sizes required grew nearly linearly with the number of subproblems (or problem size). The results also showed that the approximate number of evaluations grew subquadratically for uniformly scaled subproblems but was quadratic on some nonuniformly scaled subproblems. Yu et al. [45.167] refined the model of Pelikan et al. [45.166] to provide a more accurate bound for the adequate population size in multivariate entropy-based EDAs such as ECGA and BOA, and also examined the effects of the selection pressure on the population size. Population sizing was also empirically analyzed in FDA by Mühlenbein [45.168].
- *Diversity loss.* Stochastic errors in sampling can lead to a loss of diversity that may sometimes hamper EDA performance. Shapiro [45.169] examined the susceptibility of UMDA to diversity loss and discussed how it is necessary to set the learning parameters in such a way that this does not happen. Bosman et al. [45.170] examined diversity loss in EDAs for solving real-valued problems and the approaches to alleviating this difficulty. The results showed that due to diversity loss some of the state-of-the-art EDAs for real-valued problems could still fail on slope-like regions in the search space. The authors proposed using anticipated mean shift (AMS) to shift the mean of new solutions each generation in order to effectively maintain diversity.
- *Memory complexity.* Another factor of importance in EDA problem solving is the memory required to

solve the problem. *Gao and Culberson* [45.171] examined the space complexity of the **FDA** and **BOA** on additively decomposable functions where overlap was allowed between subfunctions. *Gao and Culberson* [45.171] proved that the space complexity of **FDA** and **BOA** is exponential in the problem size even with very sparse interaction between variables. While these results are somewhat negative, the authors point out that this only shows that **EDAs** have limitations and work best when the interaction structure is of bounded size. Note that one way to reduce the memory complexity of **EDAs** is to use incremental **EDAs**, such as **PBIL** [45.1], **cGA** [45.34] or the incremental Bayesian optimization algorithm (**iBOA**) [45.92].

- *Model accuracy.* A number of studies examined the accuracy of models in **EDAs**. *Hauschild* et al. [45.172] analyzed the models generated by **hBOA** when solving concatenated traps, random additively decomposable problems, hierarchical traps and two-dimensional Ising spin glasses. The models generated were then compared to the underlying problem structure by analyzing the number of spurious and correct dependencies. The results showed that the models corresponded closely to the structure of the underlying problems and that the models did not change significantly between consequent iterations of **hBOA**. The relationship between the probabilistic models learned by **BOA** and the underlying problem structure was also explored by *Lima* et al. [45.173]. One of the most important contribu-

tions of this study was to demonstrate the dramatic effect that selection has on spurious dependencies. The results showed that model accuracy was significantly improved when using truncation selection compared to tournament selection. Motivated by these results, the authors modified the complexity penalty of **BOA** model building to take into account tournament sizes when using binary tournament selection. *Echegoyen* et al. [45.174] also analyzed the structural accuracy of the models using **EBNA** on concatenated traps, two variants of Ising spin glass and MAXSAT. In this work, two variations of **EBNA** were compared, one that was given the complete model structure based on the underlying problem and another that learned the approximate structure. The authors then examined the probability at any generation that the models would generate the optimal solution. The results showed that it was not strictly necessary to have all the interactions that were in the complete model in order to solve the problems. Finally, the effects of spurious linkages on **EDA** performance were examined by *Radetic* and *Pelikan* [45.175]. The authors started by proposing a theoretical model to describe the effects of spurious (unnecessary) dependencies on the population sizing of **EDAs**. This model was then tested empirically on onemax and the results showed that while it would be expected that spurious dependencies would have little effect on population size, when niching was included the effects were substantial.

## 45.5 Efficiency Enhancement Techniques for **EDAs**

**EDAs** can solve many classes of important problems in a robust and scalable manner, oftentimes requiring only a low-order polynomial growth of the number of function evaluations with respect to the number of decision variables [45.4, 5, 8, 22, 74, 166, 176]. However, even a low-order polynomial complexity is sometimes insufficient for practical application of **EDAs** especially when the number of decision variables is extremely large, when evaluation of candidate solutions is computationally expensive, or when there are many conflicting objectives to optimize. The good news is that a number of approaches exist that can be used to further enhance efficiency of **EDAs**. Some of these techniques can be adopted from genetic and evolutionary algorithms with little or no change. However, some techniques are directly targeted at **EDAs** because these techniques

exploit some of the unique advantages of **EDAs** over most other metaheuristics. Specifically, some efficiency enhancements capitalize on the facts that the use of probabilistic models in **EDAs** provides a rigorous and flexible framework for incorporating prior knowledge about the problem into optimization, and that **EDAs** provide practitioners with a series of probabilistic models that reveal a lot of information about the problem. This section reviews some of the most important efficiency enhancement techniques for **EDAs** with main focus on techniques developed specifically for **EDAs**.

### 45.5.1 Parallelization

One of the most straightforward approaches to speeding up any algorithm is to distribute the computation

over a number of computational nodes so that several computational tasks can be executed in parallel. There are two main bottlenecks of **EDAs** that are typically addressed by parallelization: (1) fitness evaluation, and (2) model building and sampling. If fitness evaluation is computationally expensive, a master–slave architecture can be used for distributing fitness evaluations and collecting the results [45.177]. If most computational time is spent in model building and sampling, model building and sampling should be parallelized [45.4, 178, 179].

Many parallelization techniques and much of the theory can be adopted from research on parallelization in genetic and evolutionary algorithms [45.177]. In the context of **EDAs**, parallelization of model building was discussed, for example, by Ocenasek et al. [45.178–181] who proposed the parallel **BOA**, **mBOA** and **hBOA**, and by Larrañaga and Lozano [45.4] who parallelized model building in **EBNA**. One of the most impressive results in parallelization of **EDAs** was published by Sastry et al. [45.14, 182] who proposed a highly efficient, fully parallelized implementation of **cGA** to solve large-scale problems with millions to billions of variables even with a substantial amount of external noise in the objective function.

### 45.5.2 Hybridization

An optimization hybrid combines two or more optimizers in a single procedure [45.183–185]. Typically, a *global* procedure and a *local* procedure are combined; the global procedure is expected to find promising regions and the local procedure is expected to find local optima quickly within reasonable basins of attraction. Global and local search are used in concert to find good solutions faster and more reliably than would be possible using either procedure alone.

Numerous studies have proposed to combine **EDAs** with variants of local search both in the discrete domain [45.22, 99, 186] and in the real-valued domain [45.187]. The main reason for combining **EDAs** with local search is that by reducing the search space to the local optima, the structure of the problem can be identified more easily and the population-sizing requirements can be significantly decreased [45.22, 99]. Furthermore, the search reduces to the space of basins of attraction around each local optimum as opposed to the space of all admissible solutions.

However, hybridization of **EDAs** is not restricted to the combination of an **EDA** with simple local search. As was already pointed out, probabilistic models often contain a lot of information about the problem. By min-

ing these models for information about the structure and other properties of the problem landscape, decisions can be made about the nature and likely effectiveness of particular local search procedures and appropriate neighborhood structures for those procedures [45.188–192]. In turn, subsequent local search as well as the coordination of the global and local search in a hybrid can be managed so that excellent solutions are found quickly, reliably and accurately.

There are two main approaches to the design of **EDA**-based (model-directed) hybrids with advanced neighborhoods: (1) Belief propagation, which uses the probabilistic model to generate the maximum likely instance [45.189–191] and (2) local search with an advanced neighborhood structure derived from an **EDA** model [45.188, 192]. However, it is important to note that the use of **EDA** models is not limited to advanced neighborhood structures or belief propagation, and one may envision the use of probabilistic models to control the division of time resources between the global and local searcher and in a number of other tasks.

Local search based on advanced neighborhood structures in a hill-climbing like procedure [45.193, 194] is strongly related to model-directed hybridization using **EDAs**, although in this approach no estimation of distributions takes place. The basic idea is to use a linkage learning approach to detect important interactions between problem variables, and then run a local search based on a neighborhood defined by the underlying problem decomposition.

### 45.5.3 Time Continuation

To achieve the same solution quality, one may run an **EDA** or another population-based metaheuristic with a large population for one convergence epoch, or run the algorithm with a small population for a large number of convergence epochs with controlled restarts between these epochs [45.195]. Similar tradeoffs are involved in the design of efficient and reliable hybrid procedures where an appropriate division of computational resources between the component algorithms is critical. The term *time continuation* is used to refer to the tradeoffs involved [45.196].

Two important studies related to time continuation in **EDAs** were published by Sastry and Goldberg [45.197, 198]. Based on a theoretical model of an **ECGA**-based hybrid, Sastry showed that under certain assumptions, the neighborhoods created from **EDA**-built models provide sufficient information for local search to succeed on its own even on classes of prob-

lems for which local search with standard neighborhoods performs poorly. However, in many other cases, **EDA**-driven search in a hybrid with local search based on the adaptive neighborhood should perform better, especially if the structure of the problem is complex and the problem is affected by external noise.

One of the promising research directions related to time continuation in **EDAs** is to mine probabilistic models discovered by **EDAs** to find an optimal way to exploit time continuation tradeoffs, be it in an **EDA** alone or in an **EDA**-based hybrid.

#### 45.5.4 Using Prior Knowledge and Learning from Experience

The use of prior knowledge has had longstanding study and use in optimization. For example, promising partial solutions may be used to bias the initial population of candidate solutions, specialized search operators can be designed to solve a particular class of problems, or representations can be biased in order to make the search for the optimum an easier task. However, one of the limitations of most of these approaches is that the prior knowledge must be incorporated by hand and the approaches are limited to one specific problem domain.

The use of probabilistic models provides **EDAs** with a unique framework for incorporating prior knowledge into optimization because of the possibility of using Bayesian statistics to combine prior knowledge with data in the learning of probabilistic models [45.23, 90, 199–201]. Furthermore, the use of probabilistic models in **EDAs** provides a basis for learning from previous runs in order to solve new problem instances of similar type with increased speed, accuracy, and reliability [45.22–24]. Practitioners can thus incorporate two sources of bias into **EDAs**: (1) prior knowledge and (2) information obtained from models from prior **EDA** runs on similar problems (or runs of some other algorithm); these two sources can of course be combined using Bayesian statistics or in another way [45.23, 24, 90, 200]. Then, the bias can be incorporated into **EDAs** either by restricting the class of allowable models [45.199] or by increasing scores of models that appear to be more likely than others [45.23, 24, 90, 200].

For example, *Hauschild et al.* [45.24, 89] proposed to use a probability coincidence matrix to store probabilities of Bayesian-network dependencies between pairs of problem variables in prior **hBOA** runs and to bias the model building in **hBOA** on future problem instances of similar type using the matrix. Other related

approaches were proposed [45.24, 200] that were based on combining a distance metric on problem variables and the pool of models obtained in previous runs on problems of similar type. The use of a distance metric in combination with prior **EDA** runs is somewhat more broadly applicable and promises to be more useful for practitioners. One of the main reasons for this is that this approach allows the use of bias derived from prior runs on problems of smaller size to bias optimization of larger problems. Furthermore, the approach is applicable even in cases where the meaning of a variable and its context change significantly from one problem instance to another.

#### 45.5.5 Fitness Evaluation Relaxation

To reduce the number of the objective function evaluations, a model of the objective function can be built [45.202–204]. While models of the objective function can be created for any optimization method, **EDAs** enable the use of probabilistic models for creating relatively complex computational models of the problem in a fully automated manner. Specifically, if an advanced **EDA** is used that contains a complex probabilistic model, the model can be mined to provide a set of statistics that can be estimated for an accurate, efficient computational model of the objective function. The model can then be used to replace some of the evaluations, possibly most of them. It was shown that the use of adequate models of the objective function can yield multiplicative speedups of several tens [45.202–204].

#### 45.5.6 Incremental and Sporadic Model Building

With sporadic model-building, the probabilities (parameters) of the model are updated in every iteration, but the structure of the probabilistic model is rebuilt only once in every few iterations (generations) [45.205]. Sporadic model building was shown to yield significant speedups that increased with problem size, mainly because building model structure is the most computationally expensive part of model building but model structure often changes only little between consequent iterations of an **EDA**. With incremental model building, the model is built incrementally starting from the structure discovered in the previous iteration [45.41]. This can often reduce computational resources required to learn an accurate model.

## 45.6 Starting Points for Obtaining Additional Information

This section provides pointers for obtaining additional information about **EDAs**.

### 45.6.1 Introductory Books and Tutorials

Numerous books and other publications exist that provide introduction to **EDAs** and additional starting points. The following list of references includes some of them: [45.2–5, 7, 8, 22, 206].

### 45.6.2 Software

The following list includes some of the popular **EDA** implementations available online. These implementations should provide a good starting point for the interested reader. Entries in the list are ordered alphabetically. Note that the list is *not* exhaustive:

- Adapted maximum-likelihood Gaussian model iterated density estimation evolutionary algorithm (AMaLGaM) [45.124]: [http://homepages.cwi.nl/~bosman/source\\_code.php](http://homepages.cwi.nl/~bosman/source_code.php)
- Bayesian optimization algorithm (**BOA**) [45.43]; **BOA** with decision graphs [45.55]; dependency-tree **EDA** [45.35]: <http://medal-lab.org/>
- Demos of aggregation pheromone system (**APS**) [45.207] and histogram-based **EDAs** for permutation-based problems (**EHBSA**) [45.63]: <http://www.hannan-u.ac.jp/~tsutsui/research-e.html>
- Distribution estimation using Markov random fields (**DEUM**) [45.96, 97]: <http://sidshakya.com/Downloads/Main.html>
- Extended compact genetic algorithm [45.45],  $\xi$ -ary **ECGA**, **BOA** [45.43], **BOA** with decision trees/graphs [45.55], and others: <http://illigal.org/>
- Mixed **BOA** (**mBOA**) [45.56], adaptive **mBOA** (**am-BOA**) [45.128]: <http://jiri.ocenasek.com/>
- Probabilistic incremental program evolution (**PIPE**) [45.131]: <ftp://ftp.idsia.ch/pub/rafal/>
- Real-coded **BOA** (**rBOA**) [45.49], multiobjective **rBOA** [45.208]: <http://www.evolution.re.kr/>
- Regularity model based multiobjective **EDA** (**RM-MEDA**) [45.209]; hybrid of differential evolution and **EDA** [45.210]; model-based multiobjective evolutionary algorithm (**MMEA**) [45.155],

and others: <http://cswww.essex.ac.uk/staff/qzhang/mypublication.htm>

### 45.6.3 Journals

The following journals are key venues for papers on **EDAs** and evolutionary computation, although papers on **EDAs** can be found in many other journals focusing on optimization, artificial intelligence, machine learning, and applications:

- *Evolutionary Computation* (MIT Press): <http://www.mitpressjournals.org/loi/evco>
- *Evolutionary Intelligence* (Springer): <http://www.springer.com/engineering/journal/12065>
- *Genetic Programming and Evolvable Machines* (Springer): <http://www.springer.com/computer/ai/journal/10710>
- *IEEE Transactions on Evolutionary Computation* (IEEE Press): <http://ieeexplore.ieee.org/servlet/opac?punumber=4235>
- *Natural Computing* (Springer): <http://www.springer.com/computer/theoretical+computer+science/journal/11047>
- *Swarm and Evolutionary Computation* (Elsevier): <http://www.journals.elsevier.com/swarm-and-evolutionary-computation/>

### 45.6.4 Conferences

The following conferences provide the most important venues for publishing papers on **EDAs** and evolutionary computation, although similarly as for journals, papers on **EDAs** are often published in other venues:

- *ACM SIGEVO Genetic and Evolutionary Computation Conference (GECCO)*
- *European Workshops on Applications of Evolutionary Computation (EvoWorkshops)*
- *IEEE Congress on Evolutionary Computation (CEC)*
- *Main European Events on Evolutionary Computation (EvoStar)*
- *Parallel Problem Solving in Nature (PPSN)*
- *Simulated Evolution and Learning (SEAL)*

## 45.7 Summary and Conclusions

**EDAs** are a class of stochastic optimization algorithms that have been gaining popularity due to their ability to solve a broad array of complex problems with excellent performance and scalability. Moreover, while many of these algorithms have been shown to perform well with little or no problem-specific information, such information can be used advantageously if available.

**EDAs** have their roots in the fields of evolutionary computation and machine learning. From evolutionary computation, **EDAs** borrow the idea of using a population of solutions that evolves through iterations of selection and variation. From machine learning, **EDAs** borrow the idea of learning models from data, and they use the resulting models to guide the search for better solutions. This approach is powerful especially because it allows the search algorithm to adapt to the problem being solved, giving **EDAs** the possibility of being an effective *black-box* search algorithm. Since most real-world problems have some sort of inherent structure (as opposed to being completely random), there is a hope that **EDAs** can learn such a structure, or at least parts of it, and put that knowledge to good use in searching for optima.

Another key characteristic of **EDAs**, and one that sets them apart from other metaheuristics, lies in the

fact that the sequence of probabilistic models learned along a particular run (or a sequence of runs) yields important information that can be exploited for other means. For example, such information can be used for building surrogate models of the objective function leading to significant performance speedups, for designing effective neighborhoods for local search when conventional neighborhoods fail, and even for learning about characteristics of an entire class of problems that can in turn be used to solve other instances of the same problem class.

This chapter gave an introduction and reviewed both the history and the state-of-the-art in **EDA** research. The basic concepts of these algorithms were presented and a taxonomy was outlined from the views based on the model decomposition and the type of local distributions. The most popular **EDAs** proposed in the literature were then surveyed according to the most common representations for candidate solutions. Finally, the major theoretical research areas and efficiency enhancement techniques for **EDAs** were highlighted. This chapter should be valuable both for those who want to grasp the basic ideas of **EDAs** as well as for those who want to have a coherent view of **EDA** research.

# Parallel Evolutionary Algorithms

Dirk Sudholt

Evolutionary algorithms (EAs) have given rise to many parallel variants, fuelled by the rapidly increasing number of CPU cores and the ready availability of computation power through GPUs and cloud computing. A very popular approach is to parallelize evolution in island models, or coarse-grained EAs, by evolving different populations on different processors. These populations run independently most of the time, but they periodically communicate genetic information to coordinate search. Many applications have shown that island models can speed up computation significantly, and that parallel populations can further increase solution diversity.

The aim of this book chapter is to give a gentle introduction into the design and analysis of parallel evolutionary algorithms, in order to understand how parallel EAs work, and to explain when and how speedups over sequential EAs can be obtained.

Understanding how parallel EAs work is a challenging goal as they represent interacting stochastic processes, whose dynamics are determined by several parameters and design choices. This chapter uses a theory-guided perspective to explain how key parameters affect performance, based on recent advances on the theory of parallel EAs. The presented results give insight into the fundamental working principles of parallel EAs, assess the impact of parameters and design choices on performance, and contribute to an informed design of effective parallel EAs.

Recent years have witnessed the emergence of a huge number of parallel computer architectures. Almost ev-

ery desktop or notebook PC, and even mobile phones, come with several CPU cores built in. Also GPUs

have been discovered as a source of massive computation power at no extra cost. Commercial IT solutions often use clusters with hundreds and thousands of CPU cores and cloud computing has become an affordable and convenient way of gaining CPU power.

With these resources readily available, it has become more important than ever to design algorithms that can be implemented effectively in a parallel architecture. Evolutionary algorithms ([EA](#)) are popular general-purpose metaheuristics inspired by the natural evolution of species. By using operators like mutation, recombination, and selection, a multi-set of solutions – the *population* – is evolved over time. The hope is that this artificial evolution will explore vast regions of the search space and yet use the principle of *survival of the fittest* to generate good solutions for the problem at hand. Countless applications as well as theoretical results have demonstrated that these algorithms are effective on many hard optimization problems.

One of many advantages of [EAs](#) is that they are easy to parallelize. The process of artificial evolution can be implemented on parallel hardware in various ways. It is possible to parallelize specific operations, or to parallelize the evolutionary process itself. The latter approach has led to a variety of search algorithms called island models or cellular evolutionary algorithms. They differ from a sequential implementation in that evolution happens in a spatially structured network. Subpopulations evolve on different processors and good solutions are communicated between processors. The spread of information can be tuned easily via key parameters of the algorithm. A slow spread of information can lead to a larger diversity in the system, hence increasing exploration.

Many applications have shown that parallel [EAs](#) can speed up computation and find better solutions, compared to a sequential [EA](#). This book chapter reviews the most common forms of parallel [EAs](#). We highlight what distinguishes parallel [EAs](#) from sequential [EAs](#). We also make an effort to understand the search dynamics of parallel [EA](#). This addresses a very hot topic since, as of today, even the impact of the most basic parameters of a parallel evolutionary algorithms are not well understood.

The chapter has a particular emphasis on theoretical results. This includes runtime analysis, or computa-

tional complexity analysis. The goal is to estimate the expected time until an [EA](#) finds a satisfactory solution for a particular problem, or problem class, by rigorous mathematical studies. This area has led to very fruitful results for general [EAs](#) in the last decade [46.1, 2]. Only recently have researchers turned to investigating parallel evolutionary algorithms from this perspective [46.3–7]. The results help to get insight into the search behavior of parallel [EAs](#) and how parameters and design choices affect performance. The presentation of these results is kept informal in order to make it accessible to a broad audience. Instead of presenting theorems and complete formal proofs, we focus on key ideas and insights that can be drawn from these analyses.

The outline of this chapter is as follows. In Sect. 46.1 we first introduce parallel models of evolutionary algorithms, along with a discussion of key design choices and parameters. Section 46.2 considers performance measures for parallel [EAs](#), particularly notions for *speedup* of a parallel [EA](#) when compared to sequential [EAs](#).

Section 46.3 deals with the spread of information in parallel [EAs](#). We review various models used to describe how the number of *good* solutions increases in a parallel [EA](#). This also gives insight into the time until the whole system is taken over by good solutions, the so-called *takeover time*.

In Sect. 46.4 we present selected examples where parallel [EAs](#) were shown to outperform sequential evolutionary algorithms. Drastic speedups were shown on illustrative example functions. This holds for various forms of parallelization, from independent runs to offspring populations and island models.

Section 46.5 finally reviews a general method for estimating the expected running time of parallel [EAs](#). This method can be used to transfer bounds for a sequential [EA](#) to a corresponding parallel [EA](#), in an automated fashion. We go into a bit more detail here, in order to enable the reader to apply this method by her/himself. Illustrative example applications are given that also include problems from combinatorial optimization.

The chapter finishes with conclusions in Sect. 46.6 and pointers to further literature on parallel evolutionary algorithms.

## 46.1 Parallel Models

### 46.1.1 Master-Slave Models

There are many ways how to use parallel machines. A simple way of using parallelization is to execute operations on separate processors. This can concern variation operators like mutation and recombination as well as function evaluations. In fact, it makes most sense for function evaluations as these operations can be performed independently and they are often among the most expensive operations. This kind of architecture is known as *master-slave model*. One machine represents the master and it distributes the workload for executing operations to several other machines called slaves. It is well suited for the creation of offspring populations as offspring can be created and evaluated independently, after suitable parents have been selected.

The system is typically synchronized: the master waits until all slaves have completed their operations before moving on. However, it is possible to use asynchronous systems where the master does not wait for slaves that take too long.

The behavior of synchronized master-slave models is not different from their sequential counterparts. The implementation is different, but the algorithm – and therefore search behavior – is the same.

### 46.1.2 Independent Runs

Parallel machines can also be used to simulate different, independent runs of the same algorithm in parallel. Such a system is very easy to set up as no communication during the runtime is required. Only after all runs have been stopped, do the results need to be collected and the best solution (or a selection of different high-quality solutions) is output.

Alternatively, all machines can periodically communicate their current best solutions so that the system can be stopped as soon as a satisfactory solution has been found. As for master-slave models, this prevents us from having to wait until the longest run has finished.

Despite its simplicity, independent runs can be quite effective. Consider a setting where a single run of an algorithm has a particular *success probability*, i. e., a probability of finding a satisfactory solution within a given time frame. Let this probability be denoted  $p$ . By using several independent runs, this success probability can be increased significantly. This approach is commonly known as *probability amplification*.

The probability that in  $\lambda$  independent runs no run is successful is  $(1-p)^\lambda$ . The probability that there is at least one successful run among these is, therefore,

$$1 - (1-p)^\lambda. \quad (46.1)$$

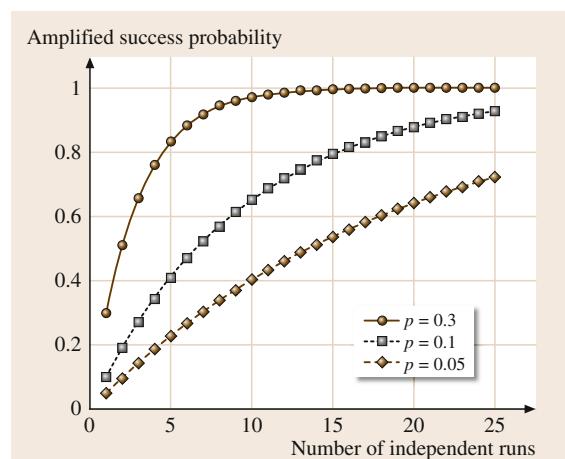

Figure 46.1 illustrates this amplified success probability for various choices of  $\lambda$  and  $p$ .

We can see that for a small number of processors the success probability increases almost linearly. If the number of processors is large, a saturation effect occurs. The benefit of using ever more processors decreases with the number of processors used. The point where saturation happens depends crucially on  $p$ ; for smaller success probabilities saturation happens only with a fairly large number of processors.

Furthermore, independent runs can be set up with different initial conditions or different parameters. This is useful to effectively explore the parameter space and to find good parameter settings in a short time.

### 46.1.3 Island Models

Independent runs suffer from obvious drawbacks: once a run reaches a situation where its population has become stuck in a difficult local optimum, it will most likely remain stuck forever. This is unfortunate since other runs might reach more promising regions of the search space at the same time. It makes more sense to

**Fig. 46.1** Plots of the amplified success probability  $1 - (1-p)^\lambda$  of a parallel system with  $\lambda$  independent runs, each having success probability  $p$

establish some form of communication between the different runs to coordinate search, so that runs that have reached low-quality solutions can join in on the search in more promising regions.

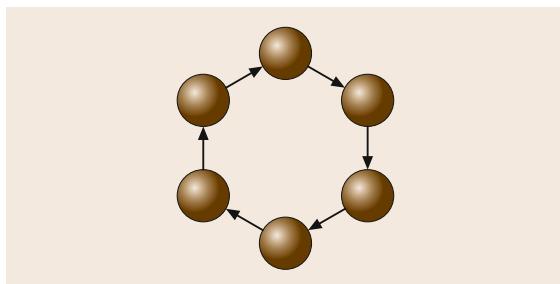

In *island models*, also called *distributed EAs*, the *coarse-grained model*, or the *multi-deme model*, the population of each run is regarded an island. One often speaks of islands as *subpopulations* that together form the population of the whole island model. Islands evolve independently as in the independent run model, for most of the time. However, periodically solutions are exchanged between islands in a process called *migration*.

The idea is to have a *migration topology*, a directed graph with islands as its nodes and directed edges connecting two islands. At certain points of time selected individuals from each island are sent off to neighbored islands, i.e., islands that can be reached by a directed edge in the topology. These individuals are called migrants and they are included in the target island after a further selection process. This way, islands can communicate and compete with one another. Islands that get stuck in low-fitness regions of the search space can be taken over by individuals from more successful islands. This helps to coordinate search, focus on the most promising regions of the search space, and use the available resources effectively. An example of an island model is given in Fig. 46.2. Algorithm 46.1 shows the general scheme of a basic island model.

#### Algorithm 46.1 Scheme of an island model with migration interval $\tau$

```

1: Initialize a population made up of subpopulations
   or islands,  $P^{(0)} = \{P_1^{(0)}, \dots, P_m^{(0)}\}$ .
2: Let  $t := 1$ .
3: loop
4:   for each island  $i$  do in parallel
5:     if  $t \bmod \tau = 0$  then
```

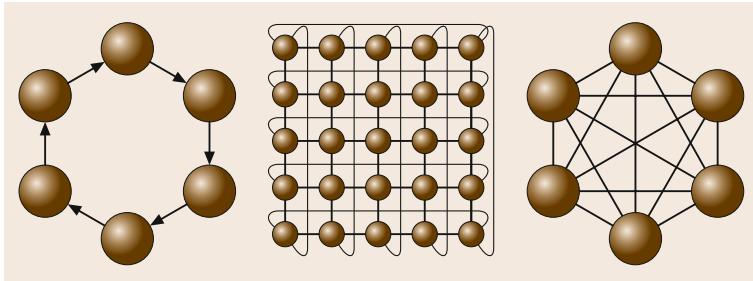

**Fig. 46.2** Sketch of an island model with six islands and an example topology

```

6:       Send selected individuals from island  $P_i^{(t)}$ 
   to selected neighbored islands.
7:       Receive immigrants  $I_i^{(t)}$  from islands for
   which island  $P_i^{(t)}$  is a neighbor.
8:       Replace  $P_i^{(t)}$  by a subpopulation resulting
   from a selection among  $P_i^{(t)}$  and  $I_i^{(t)}$ .
9:   end if
10:  Produce  $P_i^{(t+1)}$  by applying reproduction op-
    erators and selection to  $P_i^{(t)}$ .
11: end for
12: Let  $t := t + 1$ .
13: end loop
```

There are many design choices that affect the behavior of such an island model:

- *Emigration policy.* When migrants are sent, they can be removed from the sending island. Alternatively, copies of selected individuals can be emigrated. The latter is often called *pollination*. Also the selection of migrants is important. One might select the best, worst, or random individuals.
- *Immigration policy.* Immigrants can replace the worst individuals in the target population, random individuals, or be subjected to the same kind of selection used within the islands for parent selection or selection for replacement. Crowding mechanisms can be used, such as replacing the most similar individuals. In addition, immigrants can be recombined with individuals present on the island before selection.
- *Migration interval.* The time interval between migrations determines the speed at which information is spread throughout an island model. Its reciprocal is often called *migration frequency*. Frequent migrations imply a rapid spread of information, while rare migrations allow for more exploration. Note that a migration interval of  $\infty$  yields independent runs as a special case.
- *Number of migrants.* The number of migrants, also called *migration size*, is another parameter that determines how quickly an island can be taken over by immigrants.
- *Migration topology.* Also the choice of the migration topology impacts search behavior. The topology can be a directed or undirected graph – after all, undirected graphs can be seen as special cases of directed graphs. Common topologies include unidirectional rings (a ring with directed edges

**Fig. 46.3** Sketches of common topologies: a unidirectional ring, a torus, and a complete graph. Other common topologies include bidirectional rings where all edges are undirected and grid graphs where the edges wrapping around the torus are removed

only in one direction), bidirectional rings, torus or grid graphs, hypercubes, scale-free graphs [46.8], random graphs [46.9], and complete graphs. Figure 46.3 sketches some of these topologies. An important characteristic of a topology  $T = (V, E)$  is its *diameter*: the maximum number of edges on any shortest path between two vertices. Formally,  $\text{diam}(T) = \max_{u, v \in V} \text{dist}(u, v)$ , where  $\text{dist}(u, v)$  is the graph distance, the number of edges on a shortest path from  $u$  to  $v$ . The diameter gives a good indication of the time needed to propagate information throughout the topology. Rings and torus graphs have large diameters, while hypercubes, complete graphs, and many scale-free graphs have small diameters.

Island models with non-complete topologies are also called *stepping stone models*. The impact of these design choices will be discussed in more detail in Sect. 46.3.

If all islands run the same algorithm under identical conditions, we speak of a *homogeneous island model*. *Heterogeneous island models* contain islands with different characteristics. Different algorithms might be used, different representations, objective functions, or parameters. Using heterogeneous islands might be useful if one is not sure what the best algorithm is for a particular problem. It also makes sense in the context of multiobjective optimization or when a diverse set of solutions is sought, as the islands can reflect different objective functions, or variations of the same objective functions, with an emphasis on different criteria.

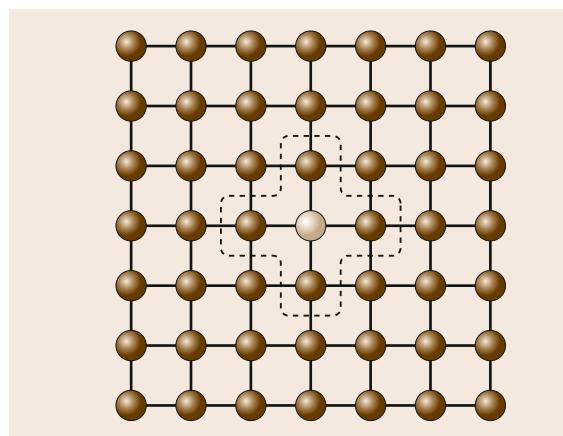

Skolicki [46.10] proposed a two-level view of search dynamics in island models. The term *intra-island evolution* describes the evolutionary process that takes place within each island. On a higher level, *inter-island evolution* describes the interaction between different islands. He argues that islands can be regarded as individuals in a higher-level evolution. Islands compete with one another and islands can take over other islands, just like

individuals can replace other individuals in a regular population. One conclusion is that with this perspective an island models looks more like a compact entity.

The two levels of evolution obviously interact with one another. Which level is more important is determined by the migration interval and the other parameters of the system that affect the spread of information.

#### 46.1.4 Cellular EAs

Cellular EAs represent a special case of island models with a more fine-grained form of parallelization. Like in the island model we have islands connected by a fixed topology. Rings and two-dimensional torus graphs are the most common choice. The most striking characteristic is that each island only contains a single individual. Islands are often called *cells* in this context, which explains the term *cellular EA*. Each individual is only allowed to mate with its neighbors in the topology. This kind of interaction happens in every generation. This corresponds to a migration interval of 1 in the con-

**Fig. 46.4** Sketch of a cellular EA on a  $7 \times 7$  grid graph. The dashed line indicates the neighborhood of the highlighted cell

text of island models. Figure 46.4 shows a sketch of a cellular EA. A scheme of a cellular EA is given in Algorithm 46.2.

#### Algorithm 46.2 Scheme of a cellular EA

```

1: Initialize all cells to form a population  $P^{(0)} = \{P_1^{(0)}, \dots, P_m^{(0)}\}$ . Let  $t := 0$ .
2: loop
3:   for each cell  $i$  do in parallel
4:     Select a set  $S_i$  of individuals from  $P_i^{(t)}$  out of all cells neighbored to cell  $i$ .
5:     Create a set  $R_i$  by applying reproduction operators to  $S_i$ .
6:     Create  $P_i^{(t+1)}$  by selecting an individual from  $\{P_i^{(t)}\} \cup R_i$ .
7:   end for
8:   Let  $t := t + 1$ .
9: end loop
```

Cellular EAs yield a much more fine-grained system; they have therefore been called *fine-grained models*, *neighborhood models*, or *diffusion models*. The difference to island models is that no evolution takes place on the cell itself, i. e., there is no intra-island evolution. Improvements can only be obtained by cells interacting with one another. It is, however, possible that an island can interact with itself.

In terms of the two-level view on island models, in cellular EAs the intra-island dynamics have effectively been removed. After all, each island only contains a single individual. Fine-grained models are well suited for investigations of inter-island dynamics. In fact, the first runtime analyses considered fine-grained island models, where each island contains a single individual [46.4, 5]. Other studies dealt with fine-grained systems that use a migration interval larger than 1 [46.3, 6, 7].

For replacing individuals the same strategies as listed for island models can be used. All cells can be updated synchronously, in which case we speak of a *synchronous cellular EA*. A common way of implementing this is to create a new, temporary population. All parents are taken from the current population and new individuals are written into the temporary population. At the end of the process, the current population is replaced by the temporary population.

Alternatively, cells can be updated sequentially, resulting in an *asynchronous cellular EA*. This is likely to result in a different search behavior as individu-

als can mate with offspring of their neighbors. Alba et al. [46.11] define the following update strategies. The terms are tailored towards two-dimensional grids or torus graphs as they are inspired by cellular automata. It is, however, easy to adapt these strategies to arbitrary topologies:

- *Uniform choice*: the next cell to be updated is chosen uniformly at random.
- *Fixed line sweep*: the cells are updated sequentially, line by line in a grid/torus topology.
- *Fixed random sweep*: the cells are updated sequentially, according to some fixed order. This order is determined by a permutation of all cells. This permutation is created uniformly at random during initialization and kept throughout the whole run.
- *New random sweep*: this strategy is like fixed random sweep, but after each sweep is completed a new permutation is created uniformly at random.

A time step or generation is defined as the time needed to update  $m$  cells,  $m$  being the number of cells in the grid. The last three strategies ensure that within each time step each cell is updated exactly once. This yields a much more balanced treatment for all cells. With the uniform choice model is it likely that some cells must wait for a long time before being updated. In the limit, the waiting time for updates follows a Poisson distribution. Consider the random number of updates until the last cell has been updated at least once. This random process is known as the *coupon collector problem* [46.12, page 32], as it resembles the process of collecting coupons, which are drawn uniformly at random. A simple analysis shows that the expected number of updates until the last cell has been updated in the uniform choice model (or all coupons have been collected) equals

$$m \cdot \sum_{i=1}^m \frac{1}{i} \approx m \cdot \ln(m).$$

This is equivalent to

$$\sum_{i=1}^m \frac{1}{i} \approx \ln m$$

time steps, which can be significantly larger than 1, the time for completing a sweep in any given order.

Cellular **EAs** are often compared to cellular automata. In the context of the latter, it is common practice to consider a two-dimensional grid and different neighborhoods. The neighborhood in Fig. 46.2 is called the *von Neumann neighborhood* or *Linear 5*. It includes the cell itself and its four neighbors along the directions north, south, west, and east. The *Moore neighborhood* or *Compact 9* in addition also contains the four cells to the north west, north east, south west, and south east. Also larger neighborhoods are common, containing cells that are further away from the center cell.

Note that using a large neighborhood on a two-dimensional grid is equivalent to considering a graph where, starting with a torus graph, for each vertex edges to nearby vertices have been added. We will, therefore, in the remainder of this chapter stick to the common notion of neighbors in a graph (i.e., vertices connected by an edge), unless there is a good reason not to.

### 46.1.5 A Unified Hypergraph Model for Population Structures

Sprave [46.13] proposed a unified model for population structures. It is based on hypergraphs; an extension of graphs where edges can connect more than two vertices. We present an informal definition to focus on the ideas; for formal definitions we refer to [46.13]. A hypergraph contains a set of vertices and a collection of hyperedges. Each hyperedge is a non-empty set of vertices. Two vertices are neighbored in the hypergraph if there is a hyperedge that contains both vertices. Note that the special case where each hyperedge contains two different vertices results in an undirected graph.

In Sprave's model each vertex represents an individual. Hyperedges represent the set of possible parents for each individual. The model unifies various common population models:

- *Panmictic populations*: for panmictic populations we have a set of vertices  $V$  and there is a single hyperedge that equals the whole vertex set. This reflects the fact that in a panmictic population each individual has all individuals as potential parents.
- *Island models with migration*: if migration is understood in the sense that individuals are removed, the set of potential parents for an individual contains all potential immigrants as well as all individuals from its own island, except for those that are being emigrated.
- *Island models with pollination*: if pollination is used, the set of potential parents contains all immigrants and all individuals on its own island.
- *Cellular EAs*: For each individual, the potential parents are its neighbors in the topology.

In the case of coarse-grained models, the hypergraph may depend on time. More precisely, we have different sets of potential parents when migration is used, compared to generations without migration. Sprave considers this by defining a dynamic population structure: instead of considering a single, fixed hypergraph, we consider a sequence of hypergraphs over time.

### 46.1.6 Hybrid Models

It is also possible to combine several of the above approaches. For instance, one can imagine an island model where each island runs a cellular **EA** to further promote diversity. Or one can think of hierarchical island models where islands are island models themselves. In such a system it makes sense that the inner-layer island models use more frequent migrations than the outer-layer island model. Island models and cellular **EAs** can also be implemented as master–slave models to achieve a better speedup.

## 46.2 Effects of Parallelization

An obvious effect of parallelization is that the computation time can be reduced by using multiple processors. This section describes performance measured that can be used to define this speedup. We also consider beneficial effects of using parallel **EAs** that can lead to superlinear speedups.

### 46.2.1 Performance Measures for Parallel EAs

The computation time of a parallel **EA** can be defined in various ways. It makes sense to use wall-clock time as the performance measure as this accounts for the

overhead by parallelization. Under certain conditions, it is also possible to use the number of generations or function evaluations. This is feasible if these measures reflect the real running time in an adequate way, for instance if the execution of a generation (or a function evaluation) dominates the computational effort, including the effort for coordinating different machines. It is also feasible if one can estimate the overhead or the communication costs separately.

We consider settings where an EA is run until a certain goal is fulfilled. Goals can be reaching a global or local optimum or reaching a certain minimum fitness. In such a setting the goal is fixed and the running time of the EA can vary. This is in contrast to setups where the running time is fixed to a predetermined number of generations and then the quality or accuracy of the obtained solutions is compared. As Alba pointed out [46.14], performance comparisons of parallel and sequential EAs only make sense if they reach the same accuracy. In the following, we focus on the former setting where the same goal is used.

Still, defining speedup formally is far from trivial. It is not at all clear against what algorithm a parallel algorithm should be compared. However, this decision is essential to clarify the meaning of speedup. Not clarifying it, or using the wrong comparison, can easily yield misleading results and false claims. We present a taxonomy inspired by Alba [46.14], restricted to cases where a fixed goal is given:

- *Strong speedup*: the parallel run time of a parallel algorithm is compared against the sequential run time of the *best known sequential algorithm*. It was called *absolute speedup* by Barr and Hickman [46.15]. This measure captures in how far parallelization can improve upon the best known algorithms. However, it is often difficult to determine the best sequential algorithm. Most researchers, therefore, do not use strong speedup [46.14].
- *Weak speedup*: the parallel run time of an algorithm is compared against *its own sequential run time*. This gives rise to two subcases where the notion of its own sequential run time is made precise:
  - *Single machine/panmixia*: the parallel EA is compared against a canonical, panmictic version of it, running on a single machine. For instance, we might compare an island model with  $m$  islands against an EA running a single island. Thereby, the EA run on all islands is the same in both cases.

- *Orthodox*: the parallel EA running on  $m$  machines is compared against the same parallel EA running on a single machine. This kind of speedup was called *relative speedup* by Barr and Hickman [46.15].

In the light of these essential differences, it is essential for researchers to clarify their notion of speedup.

Having clarified the comparison, we can now define the speedup and other measures. Let  $T_m$  denote the time for  $m$  machines to reach the goal. Let  $T_1$  denote the time for a single machine, where the algorithm is chosen according to one of the definitions of speedup defined above.

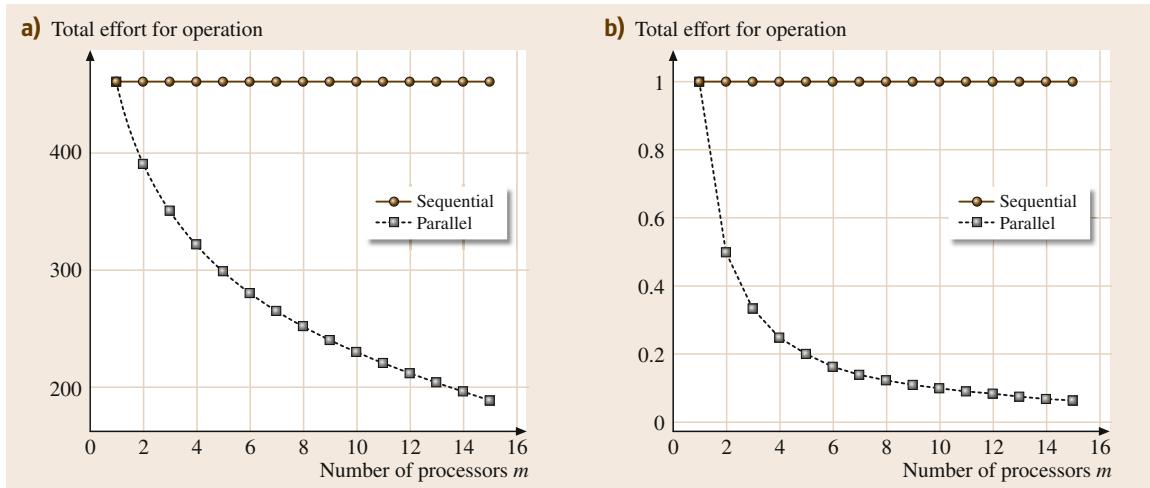

The idea is to consider the ratio of  $T_m$  and the time for a single machine,  $T_1$ , as speedup. However, as we are dealing with randomized algorithms,  $T_1$  and  $T_m$  are random variables and so the ratio of both is a random variable as well. It makes more sense to consider the ratio of expected times for both the parallel and the sequential algorithm as speedup

$$s_m = \frac{E(T_1)}{E(T_m)} .$$

Note that  $T_1$  and  $T_m$  might have very dissimilar probability distributions. Even when both are re-scaled appropriately to obtain the best possible match between the two, they might still have different shapes and different variances. In some cases it might make sense to consider the median or other statistics instead of the expectation.

According to the speedup  $s_m$  we distinguish the following cases:

- *Sublinear speedup*: if  $s_m < m$  we speak of a *sublinear speedup*. This implies that the total computation time across all machines is larger than the total computation time of the single machine (assuming no idle times in the parallel algorithm).
- *Linear speedup*: the case  $s_m = m$  is known as *linear speedup*. There, the parallel and the sequential algorithm have the same total time. This outcome is very desirable as it means that parallelization does not come at a cost. There is no noticeable overhead in the parallel algorithm.
- *Superlinear speedup*: if  $s_m > m$  we have a *superlinear speedup*. The total computation time of the parallel algorithm is even smaller than that of the single machine. This case is considered in more detail in the following section.

**Fig. 46.5a,b** Total effort for executing an operation on a single, panmictic population of size  $\mu = 100$  (sequential algorithm) and a parallel algorithm with  $m$  processors and  $m$  subpopulations of size  $\mu/m = 100/m$  each. The effort on a population of size  $n$  is assumed to be  $n \ln n$  (a) and  $n^2$  (b). Note that no overhead is considered for the parallel algorithm

Speedup is the best known measure, but not the only one used regularly. For the sake of completeness, we mention other measures. The *efficiency* is a normalization of the speedup

$$e_m = \frac{s_m}{m}.$$

Obviously,  $e_m = 1$  is equivalent to a linear speedup. Lower efficiencies correspond to sublinear speedups, higher ones to superlinear speedups.

Another measure is called *incremental efficiency* and it measures the speedup when moving from  $m - 1$  processors to  $m$  processors

$$\text{ie}_m = \frac{(m - 1) \cdot E(T_{m-1})}{m \cdot E(T_m)}.$$

There is also a generalized form where  $m - 1$  is replaced by  $m' < m$  in the above formula. This reflects the speedup when going from  $m'$  processors to  $m$  processors.

## 46.2.2 Superlinear Speedups

At first glance superlinear speedups seem astonishing. How can a parallel algorithm have a smaller total computation time than a sequential counterpart? After all, parallelization usually comes with significant overhead that slows down the algorithm. The existence of superlinear speedups has been discussed

controversially in the literature. However, there are convincing reasons why a superlinear speedup might occur.

Alba [46.14] mentions physical sources as one possible reason. A parallel machine might have more resources in terms of memory or caches. When moving from a single machine to a parallel one, the algorithm might – purposely or not – make use of these additional resources. Also, each machine might only have to deal with smaller data packages. It might be that the smaller data fits into the cache while this was not the case for the single machine. This can make a significant performance difference.

When comparing a single panmictic population against smaller subpopulations, it might be easier to deal with the subpopulations. This holds even when the total population sizes of both systems are the same. In particular, a parallel system has an advantage if operations need time which grows faster than linearly with the size of the (sub)population.

We give two illustrative examples. Compare a single panmictic population of size  $\mu$  with  $m$  subpopulations of size  $\mu/m$  each. Some selection mechanisms, like ranking selection, might have to sort the individuals in the population according to their fitness. In a straightforward implementation one might use well-known sorting algorithms such as (randomized) *QuickSort*, *MergeSort*, or *HeapSort*. All of these are known to take time  $\Theta(n \ln n)$  for sorting  $n$  elements, on average. Let us disregard the hidden constant and the randomness of

randomized *QuickSort* and assume that the time is precisely  $n \ln n$ .

Now the effort of sorting the panmictic population is  $\mu \ln \mu$ . The total effort for sorting  $m$  populations of size  $\mu/m$  each is

$$\begin{aligned} m \cdot \mu/m \cdot \ln(\mu/m) &= \mu \cdot \ln(\mu/m) \\ &= \mu \ln(\mu) - \mu \cdot \ln(m). \end{aligned}$$

So, the parallel system executes this operation faster, with a difference of  $\mu \cdot \ln(m)$  time steps in terms of the total computation time.

This effect becomes more pronounced the more expensive operations are used (with respect to the population size). Assume that some selection mechanism or diversity mechanism is used, which compares every individual against every other one. Then the effort for the panmictic population is roughly  $\mu^2$  time steps. However, for the parallel EA and its subpopulations the total

effort would only be

$$m \cdot (\mu/m)^2 = \mu^2/m.$$

This is faster than the panmictic EA by a factor of  $m$ .

The above two growth curves are actually very typical running times for operations that take more than linear time. A table with time bounds for common selection mechanisms can be found in Goldberg and Deb [46.16]. Figure 46.5 shows plots for the total effort in both scenarios for a population size of  $\mu = 100$ . One can see that even with a small number of processors the total effort decreases quite significantly. To put this into perspective, most operations require only linear time. Also the overhead by parallelization was not accounted for. However, the discussion gives some hints as to why the execution time for smaller subpopulations can decrease significantly in practice.

## 46.3 On the Spread of Information in Parallel EAs

In order to understand how parallel EAs work, it is vital to get an idea on how quickly information is propagated. The spread of information is the most distinguishing aspect of parallel EAs, particularly distributed EAs. This includes island models and cellular EAs. Many design choices can tune the speed at which information is transmitted: the topology, the migration interval, the number of migrants, and the policies for emigration and immigration.

### 46.3.1 Logistic Models for Growth Curves

Many researchers have turned to investigating the selection pressure in distributed EAs in a simplified model. Assume that in the whole system we only have two types of solutions: current best individuals and worse solutions. No variation is used, i.e., we consider EAs using neither mutation nor crossover. The question is the following. Using only selection and migration, how long does it take for the best solutions to take over the whole system? This time, starting from a single best solution, is referred to as *takeover time*.

It is strongly related to the study of *growth curves*: how the number of best solutions increases over time. The takeover time is the first point of time at which the number of best solutions has grown to the whole population.

Growth curves are determined by both inter-island dynamics and intra-island dynamics: how quickly current best solutions spread in one island's population, and how quickly they populate neighbored islands, until the whole topology is taken over. Both dynamics are linked: intra-island dynamics can have a direct impact on inter-island dynamics as the fraction of best individuals can decide how many (if any) best individuals emigrate.

For intra-island dynamics one can consider results on panmictic EAs. Logistic curves have been proposed and found to fit simulations of takeover times very well for common selection schemes [46.16]. These curves are defined by the following equation. If  $P(t)$  is the proportion of best individuals in the population at time  $t$ , then

$$P(t) = \frac{1}{1 + \left( \frac{1}{P(0)} - 1 \right) e^{-at}},$$

where  $a$  is called the growth coefficient. One can see that the proportion of best individuals increases exponentially, but then the curve saturates as the proportion approaches 1.

Sarma and De Jong [46.17] considered growth curves in cellular EAs. They presented a detailed empirical study of the effects of the neighborhood size and

the shape of the neighborhood for different selection schemes. They showed that logistic curves as defined above can model the growth curves in cellular EAs reasonably well.

*Alba and Luque* [46.18] proposed a logistic model called LOG tailored towards distributed EAs with periodic migration. If  $\tau$  denotes the migration interval and  $m$  is the number of islands, then

$$P_{\text{LOG}}(t) = \sum_{i=0}^{m-1} \frac{1/m}{1 + a \cdot e^{-b(t-\tau \cdot i)}}.$$

In this model  $a$  and  $b$  are adjustable parameters. The model counts subsequent increases of the proportion of best individuals during migrations. However, it does not include any information about the topology and the authors admit that it only works appropriately on the ring topology [46.19, Section 4.2]. They, therefore, present an even more detailed model called TOP, which includes the diameter  $\text{diam}(T)$  of the topology  $T$ .

$$\begin{aligned} P_{\text{TOP}}(t) = & \sum_{i=0}^{\text{diam}(T)-1} \frac{1/m}{1 + a \cdot e^{-b(t-\tau \cdot i)}} \\ & + \frac{m - \text{diam}(T)/m}{1 + a \cdot e^{-b(t-\tau \cdot \text{diam}(T))}}. \end{aligned}$$

Simulations show that this model yields very accurate fits for ring, star, and complete topologies [46.19, Section 4.3].

*Luque and Alba* [46.19, Section 4.3] proceed by analyzing the effect of the migration interval and the number of migrants. With a large migration interval, the growth curves tend to make jumps during migration and flatten out quickly to form plateaus during periods without migration. The resulting curves look like step functions, and the size of these steps varies with the migration interval.

Varying the number of migrants changes the slope of these steps. A large number of migrants has a better chance of transmitting best individuals than a small number of migrants. However, the influence of the number of migrants was found to be less drastic than the impact of the migration interval. When a medium or large migration frequency is used, the impact of the number of migrants is negligible [46.19, Section 4.5]. The same conclusion was made earlier by *Skolicki and De Jong* [46.20].

*Luque and Alba* also presented experiments with a model based on the *Sprave's* hypergraph formulation of distributed EAs [46.13]. This model gave a better fit

than the simple logistic model LOG, but it was less accurate than the model TOP that included the diameter.

For the sake of completeness, we also mention that *Giacobini et al.* [46.21] proposed an improved model for asynchronous cellular EAs, which is not based on logistic curves.

### 46.3.2 Rigorous Takeover Times

*Rudolph* [46.22, 23] rigorously analyzed takeover times in panmictic populations, for various selection schemes. In [46.22] he also dealt with the probability that the best solution takes over the whole population; this is not evident for non-elitistic algorithms. In [46.23] *Rudolph* considered selection schemes made elitistic by undoing the last selection in case the best solution would become extinct otherwise. Under this scheme the expected takeover time in a population of size  $\mu$  is  $O(\mu \log \mu)$ .

In [46.24] *Rudolph* considered spatially structured populations in a fine-grained model. Each population has size 1, therefore vertices in the migration topology can be identified with individuals. Migration happens in every generation. Assume that initially only one vertex  $i$  in the topology is a best individual. If in every generation each non-best vertex is taken over by the best individual in its neighborhood, then the takeover time from vertex  $i$  equals

$$\max_{j \in V} \text{dist}(i, j),$$

where  $V$  is the set of vertices and  $\text{dist}(i, j)$  denotes the graph distance, the number of edges on a shortest path from  $i$  to  $j$ .

*Rudolph* defines the takeover time in a setting where the initial best solution has the same chance of evolving at every vertex. Then

$$\frac{1}{|V|} \sum_{i \in V} \max_{j \in V} \text{dist}(i, j)$$

is the expected takeover time if, as above, best solutions are always propagated to their neighbors with probability 1. If this probability is lower, the expected takeover time might be higher. The above formula still represents a lower bound. Note that in non-elitist EAs it is possible that all best solutions might get lost, leading to a positive extinction probability [46.24].

Note that  $\max_{j \in V} \text{dist}(i, j)$  is bounded by the *diameter* of the topology. The diameter is hence a trivial lower bound on the takeover times. *Rudolph* [46.24]

conjectures that the diameter is more important than the selection mechanism used in the distributed EA.

In [46.25] the author generalizes the above arguments to coarse-grained models. Islands can contain larger populations and migration happens with a fixed frequency. In his model the author assumes that in each island new best individuals can only be generated by immigration. Migration always communicates best individuals. Hence, the takeover time boils down to a deterministic time until the last island has been reached, plus a random component for the time until all islands have been taken over completely.

Rudolph [46.25] gives tight bounds for unidirectional rings, based on the fact that each island with a best individual will send one such individual to each neighbored island. Hence, on the latter island the number of best individuals increases by 1, unless the island has been taken over completely. For more dense topologies he gives a general upper bound, which may not be tight for all graphs. If there is an island that receives best individuals from  $k > 1$  other islands, the number of best individuals increases by  $k$ . (The number  $k$  could even increase over time.) It was left as an open problem to derive more tight bounds for interesting topologies other than unidirectional rings.

Other researchers followed up on Rudolph's seminal work. Giacobini et al. [46.26] presented theoretical and empirical results for the selection pressure on ring topologies, or linear cellular EAs. Giacobini et al. [46.27] did the same for toroidal cellular EAs. In particular, they considered takeover times for asynchronous cellular EAs, under various common update schemes. Finally, Giacobini et al. investigated growth curves for small-world graphs [46.9].

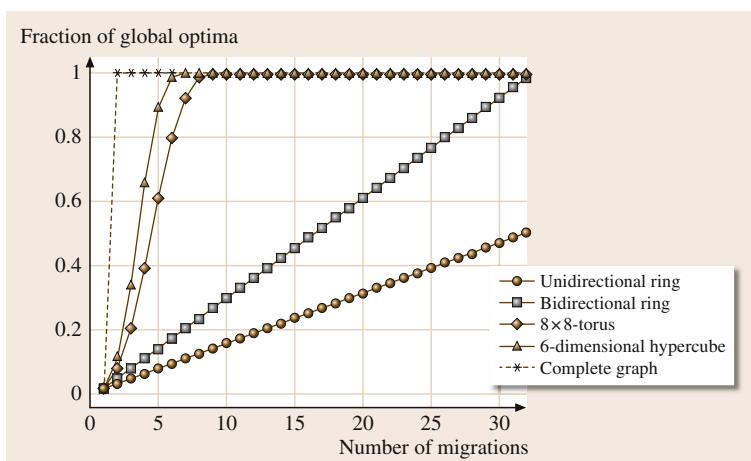

The assumption from Rudolph's model that only immigration can create new best individuals is not always realistic. If standard mutation operators are used, there is a constant probability of creating a clone of a selected parent simply by not flipping any bits. This can lead to a rapid increase in the number of high-fitness individuals.

This argument on the takeover of good solutions in panmictic populations has been studied as part of rigorous runtime analyses of population-based EAs. Witt [46.28] considered a simple  $(\mu + 1)$  EA with uniform parent selection, standard bit mutations, no crossover, and cut selection at the end of the generation. From his work it follows that good solutions take over the population in expected time  $O(\mu \log \mu)$ . More precisely, if currently there is at least one individual with current best fitness  $i$ , then after  $O(\mu \log \mu)$  generations all individuals in the population will have fitness  $i$  at least.

Sudholt [46.29, Lemma 2] extended these arguments to a  $(\mu + \lambda)$  EA and proved an upper bound of  $O(\mu/\lambda \cdot \log \mu + \log \mu)$ . Note that, in contrast to other studies of takeover times, both results apply *real* EAs that actually use mutation. Extending these arguments to distributed EAs is an interesting topic for future work.

### 46.3.3 Maximum Growth Curves

Now, we consider inter-island dynamics in more detail. Assume for simplicity that intra-island takeover happens quickly: after each migration transmitting at least one best solution, the target island is completely taken over by best solutions before the next migra-

**Fig. 46.6** Plots of growth curves in an island model with 64 islands. We assume that in between two migrations all islands containing a current best solution completely take over all neighbored islands in the topology. Initially, one island contains a current best solution and all other islands are worse. The curves show the fraction of current best solutions in the system for different topologies: a unidirectional ring, a bidirectional ring, a square torus, a hypercube, and a complete graph

tion. We start with only one island containing a best solution, assuming that all individuals on this island are best solutions. We call such an island an optimal island. If migrants are not subject to variation while emigrating or immigrating, we will always select best solutions for migration and, hence, successfully transmit best solutions.

These assumptions give rise to a deterministic spread of best solutions: after each migration, each optimal island will turn all neighbored islands into optimal islands. This is very similar to *Rudolph's* model [46.25], but it also accounts for a rapid intra-island takeover in between migrations.

We consider growth curves on various graph classes: unidirectional and bidirectional rings, square torus graphs, hypercubes, and complete graphs. Figure 46.6 shows these curves for all these graphs on 64 vertices. The torus graph has side lengths  $8 \times 8$ . The hypercube has dimension 6. Each vertex has a label made of 6 bits. All possible values for this bit string are present in the graph. Two vertices are neighbored if their labels differ in exactly one bit.

For the unidirectional ring, after  $i - 1$  migrations we have exactly  $i$  optimal islands, if  $i \leq m$ . The growth curve is, therefore, linear. For the bidirectional ring information spreads twice as fast as it can spread in two directions. After  $i - 1$  migrations we have  $2i - 1$  optimal islands if  $2i - 1 \leq m$ .

The torus allows communication in two dimensions. After one migration there are  $1 + 4 = 5$  optimal islands. After two migrations this number is  $1 + 4 + 8$ , and after three migrations it is  $1 + 4 + 8 + 12$ . In general, after  $i - 1$  migrations we have

$$1 + \sum_{j=1}^{i-1} 4j = 1 + 2i(i-1) = 1 + 2i^2 - 2i$$

optimal islands, as long as the optimal islands can freely spread out in all four directions, north, south, west, and east. At some point the ends of the region of optimal islands will meet, i. e., the northern tip meets the southern one and the same goes for west and east. Afterwards, we observe regions of non-optimal islands that constantly shrink, until all islands are optimal. The growth curve for the torus is hence quadratic at first and then it starts to saturate. The deterministic growth on torus graphs was also considered in [46.30].

For the hypercube, we can without loss of generality assume that the initial optimal island has a label

containing only zeros. After one migration all islands whose label contains a single one become optimal. After two migrations the same holds for all islands with two ones, and so on. The number of optimal islands after  $i$  migrations in a  $d$ -dimensional hypercube (i. e.,  $m = 2^d$ ) is hence  $\sum_{j=0}^i \binom{d}{j}$ . This number is close to  $2^d$  during the first migrations and then at some point starts to saturate. The complete graph is the simplest one to analyze here as it will be completely optimal after one migration.

These arguments and Fig. 46.6 show that the growth curves can depend tremendously on the migration topology. For sparse topologies like rings or torus graphs, in the beginning the growth is linear or quadratic, respectively. This is much slower than the exponential growth observed in logistic curves. Furthermore, for the ring there is no saturation; linear curves are quite dissimilar to logistic curves.

This suggests that logistic curves might not be the best models for growth curves across all topologies. The plots by *Luque* and *Alba* [46.19, Section 4.3] show a remarkably good overall fit for their TOP model. However, this might be due to the optimal choice of the parameters  $a$  and  $b$  and the fact that logistic curves are easily adaptable to various curves of roughly similar shape. We believe that it is possible to derive even more accurate models for common topologies, based on results by *Giacobini* et al. [46.9, 26, 27]. This is an interesting challenge for future work.

#### 46.3.4 Propagation

So far, we have only considered models where migration always successfully transmits best individuals. For non-trivial selection of emigrants, this is not always given. Also if crossover is used during migration, due to disruptive effects migration is not always successful. If we consider randomized migration processes, things become more interesting.

*Rowe* et al. [46.31] considered a model of *propagation* in networks. Consider a network where vertices are either informed or not. In each round, each informed vertex tries to inform each of its neighbors. Every such trial is successful with a given probability  $p$ , and then the target island becomes informed. These decisions are made independently. Note that an uninformed island might obtain a probability larger than  $p$  of becoming informed, in case several informed islands try to inform it. The model is inspired by models from epidemiology; it can be used to model the spread of a disease.

The model of propagation of information directly applies to our previous setting where the network is the migration topology and  $p$  describes the probability of successfully migrating a current best solution. Note that when looking for estimations of growth curves and upper bounds on the takeover time, we can assume that  $p$  is a lower bound on the actual probability of a successful transmission. Then the model becomes applicable to a broader range of settings, where islands can have different transmission probabilities.

On some graphs like unidirectional rings, we can just multiply our growth curves by  $p$  to reflect the expected number of optimal islands after a certain time. It then follows that the time for taking over all  $m$  islands is by a factor of  $1/p$  larger than in the previous, deterministic model.

However, this reasoning does not hold in general. Multiplying the takeover time in the deterministic setting by  $1/p$  does not always give the expected takeover time in the random model. Consider a star graph (or *hub*), where initially only the center vertex is informed. In the deterministic case  $p = 1$ , the takeover time is clearly 1. However, if  $0 < p < 1$ , the time until the last vertex is informed is given by the maximum of  $n - 1$  independent geometric distributions with parameter  $p$ . For constant  $p$ , this time is of order  $\Theta(\log n)$ , i.e., the time until the last vertex is informed is much larger than the expected time for any specific island to be informed.

*Rowe et al.* [46.31] presented a detailed analysis of hubs. They also show how to obtain a general upper bound that holds for all graphs. For every graph  $G$  with  $n$  vertices and diameter  $\text{diam}(G)$  the expected takeover time is bounded by

$$O\left(\frac{\text{diam}(G) + \log n}{p}\right).$$

Both terms  $\text{diam}(G)$  and  $\log n$  make sense. The diameter describes what distance needs to be overcome in order to inform all vertices in the network. The factor  $1/p$  gives the expected time until a next vertex is informed, assuming that it has only one informed neighbor. We also obtain  $\text{diam}(G)$  (without a factor  $1/p$ ) as a lower bound on the takeover time. The additive term  $+\log n$  is necessary to account for a potentially large variance, as seen in the example for star graphs.

If the diameter of the graph is at least  $\Omega(\log n)$ , we can drop the  $+\log n$ -term in the asymptotic bound, leading to an upper bound of  $O(\text{diam}(G)/p)$ .

Interestingly, the concept of propagation also appears in other contexts. When solving shortest paths problems in graphs, metaheuristics like evolutionary algorithms [46.32–34] and ant colony optimization (ACO) [46.35, 36] tend to propagate shortest paths through the graph. In the single-source shortest paths problem (SSSP) one is looking for shortest paths from a source vertex to all other vertices of the graph. The EAs and ACO algorithms tend to find shortest paths first for vertices that are *close* to the source, in a sense that their shortest paths only contain few edges. If these shortest paths are found, it enables the algorithm to find shortest paths for vertices that are further away.

When a shortest paths to vertex  $u$  is found and there is an edge  $\{u, v\}$  in the graph, it is easy to find a shortest path for  $v$ . In the case of evolutionary algorithms, an EA only needs to assign  $u$  as a predecessor of  $v$  on the shortest path in a lucky mutation in order to find a shortest path to  $v$ . In the case of ACO, pheromones enable an ant to follow pheromones between the source and  $u$ , and so it only has to decide to travel between  $u$  and  $v$  to find a shortest path to  $v$ , with good probability.

*Doerr et al.* [46.34, Lemma 3] used tail bounds to prove that the time for propagating shortest paths with an EA is highly concentrated. If the graph has diameter  $\text{diam}(G) \geq \log n$ , the EA with high probability finds all shortest paths in time  $O(\text{diam}(G)/p)$ , where  $p = \Theta(n^{-2})$  in this case. This result is similar to the one obtained by *Rowe et al.* [46.31]; asymptotically, both bounds are equal. However, the result by *Doerr et al.* [46.33] also allows for conclusions about growth curves.

*Lässig and Sudholt* [46.6, Theorem 3] introduced yet another argument for the analysis of propagation times. They considered *layers* of vertices. The  $i$ -th layer contains all vertices that have shortest paths of at most  $i$  edges, and that are not on any smaller layer. They bound the time until information is propagated throughout all vertices of a layer. This is feasible since all vertices in layer  $i$  are informed with probability at least  $p$  if all vertices in layers  $1, \dots, i-1$  are informed. If  $n_i$  is the number of vertices in layer  $i$ , the time until the last vertex in this layer is informed is  $O(n_i \cdot \log n_i)$ . This gives a bound for the total takeover time of  $O(\text{diam}(G) \cdot \ln(en/\text{diam}(G)))$ . For small ( $\text{diam}(G) = O(1)$ ) or large ( $\text{diam}(G) = \Omega(n)$ ) diameters, we get the same asymptotic bound as before. For other values it is slightly worse.

However, the layering of vertices allows for inclusion of intra-island effects. Assume that the transmis-

sion probability  $p$  only applies once islands have been taken over (to a significantly large degree) by best individuals. This is a realistic setting as with only a single best individual the probability of selecting it for emigration (or pollination, to be precise) might be very small. If all islands need time  $T_{\text{intra}}$  in order to reach this stage

after the first best individual has reached the island, we obtain an upper bound of

$$O(\text{diam}(G) \cdot \ln(en/\text{diam}(G))) + \text{diam}(G) \cdot T_{\text{intra}}$$

for the takeover time.

## 46.4 Examples Where Parallel EAs Excel

Parallel EAs have been applied to a very broad range of problems, including many NP-hard problems from combinatorial optimization. The present literature is immense; already early surveys like the one by Alba and Troya [46.37] present long lists of applications of parallel EAs. Further applications can be found in [46.38–40]. Research on and applications of parallel metaheuristics has increased in recent years, due to the emergence of parallel computer architectures.

Crainic and Hail [46.41] review applications of parallel metaheuristics, with a focus on graph coloring, partitioning problems, covering problems, Steiner tree problems, satisfiability problems, location and network design, as well as the quadratic assignment problems with its famous special cases: the traveling salesman problem and vehicle routing problems. Luque and Alba [46.19] present selected applications for natural language tagging, the design of combinatorial logic circuits, the workforce planning problem, and the bioinformatics problem of assembling DNA fragments.

The literature is too vast to be reviewed in this section. Also, for many hard practical problems it is often hard to determine the effect that parallelization has on search dynamics. The reasons behind the success of parallel models often remain elusive. We follow a different route and describe theoretical studies of evolutionary algorithms where parallelization was proven to be helpful. This concerns illustrative toy functions as well as problems from combinatorial optimization. All following settings are well understood and allow us to gain insights into the effect of parallelization. We consider parallel variants of the most simple evolutionary algorithm called  $(1+1)$  evolutionary algorithm, shortly  $(1+1)$  EA. It is described in Algorithm 46.3 and it only uses mutation and selection in a population containing just one current search point. We are interested in the *optimization time*, defined as the number of generations until the algorithm first finds a global optimum. Unless noted otherwise, we consider pseudo-

Boolean optimization: the search space contains all bit strings of length  $n$  and the task is to maximize a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$ . We use the common notation  $x = x_1 \dots x_n$  for bit strings.

---

**Algorithm 46.3**  $(1+1)$  EA for maximizing  $f: \{0, 1\}^n \rightarrow \mathbb{R}$

- 1: Initialize  $x \in \{0, 1\}^n$  uniformly at random.
  - 2: **loop**
  - 3: Create  $x'$  by copying  $x$  and flipping each bit independently with probability  $1/n$ .
  - 4: if  $f(x') \geq f(x)$  then  $x := x'$ .
  - 5: **end loop**
- 

The presentation in this section is kept informal. For theorems with precise results, including all preconditions, we refer to the respective papers.

### 46.4.1 Independent Runs

Independent runs prove useful if the running time has a large variance. The reason is that the optimization time equals the time until *the fastest* run has found a global optimum.

The variance can be particularly large in the case when the objective function yields local optima that are very hard to overcome. Bimodal functions contain two local optima, and typically only one is a global optimum. One such example was already analyzed theoretically in the seminal runtime analysis paper by Droste et al. [46.42].

We review the analysis of a similar function that leads to a simpler analysis. The function *TwoMax* was considered by Friedrich et al. [46.43] in the context of diversity mechanisms. It is a function of unitation: the fitness only depends on the number of bits set to 1. The function contains two symmetric slopes that increase linearly with the distance to  $n/2$ . Only one of these slopes leads to a global optimum. Formally, the function

is defined as the maximum of  $OneMax := \sum_{i=1}^n x_i$  and its symmetric cousin  $ZeroMax := \sum_{i=1}^n (1-x_i)$ , with an additional fitness bonus for the all-ones bit string

$$TwoMax(x) := \max \left\{ \sum_{i=1}^n x_i, \sum_{i=1}^n (1-x_i) \right\} + \prod_{i=1}^n x_i.$$

See Fig. 46.7 for a sketch.

The  $(1+1)$  EA reaches either a local optimum or a global optimum in expected time  $O(n \log n)$ . Due to the perfect symmetry of the function on the remainder of the search space, the probability that this is the global optimum is exactly  $1/2$ . If a local optimum is reached, the  $(1+1)$  EA has to flip all bits in one mutation in order to reach the global optimum. The probability for this event is exactly  $n^{-n}$ .

The authors consider deterministic crowding [46.43] in a population of size  $\mu$  as a diversity mechanism. It has the same search behavior as  $\mu$  independent runs of the  $(1+1)$  EA, except that the running time is counted in a different way. Their result directly transfers to this parallel model. The only assumption is that the number of independent runs is polynomially bounded in  $n$ .

The probability of finding a global optimum after  $O(n \log n)$  generations of the parallel system is amplified to  $1 - 2^{-\mu}$ . This means that only with probability  $2^{-\mu}$  we arrive at a situation where the parallel EA needs to escape from a local optimum. When all  $m$  islands are in this situation, the probability that at least

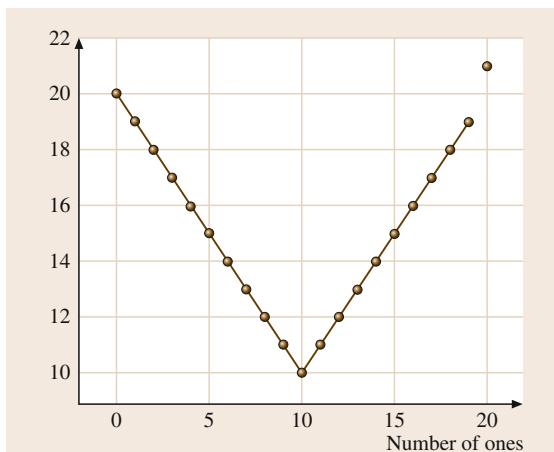

Fig. 46.7 Plots of the bimodal function  $TwoMax$  as defined in [46.43]

one island makes this jump in one generation is at most

$$1 - (1 - n^{-n})^m = \Theta(m \cdot n^{-n}),$$

where the last equality holds since  $m$  is asymptotically smaller than  $n^n$ .

This implies that the expected number of generations of a parallel system with  $m$  independent runs is

$$O(n \log n) + 2^{-m} \cdot \Theta\left(\frac{n^n}{m}\right).$$

We can see from this formula that the number of runs  $m$  has an immense impact on the expected running time. Increasing the number of runs by 1 decreases the second summand by more than a factor of 2. The speedup is, therefore, exponential, up to a point where the running time is dominated by the first term  $O(n \log n)$ . Note in particular that  $\log(n^t) = n \log n$  processors are sufficient to decrease the expected running time to  $O(n \log n)$ .

This is a very simple example of a superlinear speedup, with regard to the optimization time.

The observed effects also occur in combinatorial optimization. Witt [46.44] analyzed the  $(1+1)$  EA on the NP-hard PARTITION problem. The task can be regarded as scheduling on two machines: given a sequence of jobs, each with a specific effort, the goal is to distribute the jobs on two machines to that the largest execution time (the makespan) is minimized.

On worst-case instances the  $(1+1)$  EA has a constant probability of getting stuck in a bad local optimum. The expected time to find a solution with a makespan of less than  $(4/3 - \varepsilon) \cdot OPT$  is  $n^{\Omega(n)}$ , where  $\varepsilon > 0$  is an arbitrary constant and  $OPT$  is the value of the optimal solution.

However, if the  $(1+1)$  EA is lucky, it can, indeed, achieve a good approximation of the global optimum. Assume we are aiming at a solution with a makespan of at most  $(1 + \varepsilon) \cdot OPT$ , for some  $\varepsilon > 0$  we can choose. Witt's analysis shows that then  $2^{(e \log e + e) \cdot \lceil 2/\varepsilon \rceil \ln(4/\varepsilon) + O(1/\varepsilon)}$  parallel runs output a solution of this quality with probability at least  $3/4$ . (This probability can be further amplified quite easily by using more runs.) Each run takes time  $O(n \ln(1/\varepsilon))$ . The parallel model represents what is known as a *polynomial-time randomized approximation scheme (PRAS)*. The desired approximation quality  $(1 + \varepsilon)$  can be specified, and if  $\varepsilon$  is fixed, the total computation time is bounded by a polynomial in  $n$ . This was the first example that parallel runs of a randomized search heuristics constitute a PRAS for an NP-hard problem.

### 46.4.2 Offspring Populations

Using offspring populations in a master–slave architecture can decrease the parallel running time and lead to a speedup. We will discuss this issue further in Sect. 46.5 as offspring populations are very similar to island models on complete topologies. For now, we present one example where offspring populations decrease the optimization time very drastically.

Jansen et al. [46.45] compared the  $(1+1)$  EA against a variant  $(1+\lambda)$  EA that creates  $\lambda$  offspring in parallel and compares the current search point against the best offspring. They constructed a function SufSamp where offspring populations have a significant advantage. We refrain from giving a formal definition, but instead describe the main ideas. The vast majority of all search points tend to lead an EA towards the start of a path through the search space. The points on this path have increasing fitness, thus encouraging an EA to follow it. All points outside the path are worse, so the EA will stay on the path.

The path leads to a local optimum at the end. However, the function also includes a number of smaller paths that branch off the main path, see Fig. 46.8. All these paths lead to global optima, but they are difficult to discover. This makes a difference between the  $(1+1)$  EA and the  $(1+\lambda)$  EA for sufficiently large  $\lambda$ . The  $(1+1)$  EA typically follows the main path without discovering the smaller paths branching off. At the end of the main path it thus becomes stuck in a local optimum. The analysis in [46.45] shows that the  $(1+1)$  EA needs superpolynomial time, with high probability.

Contrarily, the  $(1+\lambda)$  EA performs a more thorough search as it progresses on the main path. The many offspring tend to discover at least one of the smaller branches. The fitness on the smaller branches is larger than the fitness of the main path, so the EA will move away from the main path and follow a smaller path. It then finds a global optimum in polynomial time, with high probability.

Interestingly, this construction can be easily adapted to show an opposite result. We replace the local optimum at the end of the main path by a global optimum

and replace all global optima at the end of the smaller branches by local optima. This yields another function SufSamp', also shown in Fig. 46.8. By the same reasoning as above, the  $(1+\lambda)$  EA will become stuck and the  $(1+1)$  EA will find a global optimum in polynomial time, with high probability.

While the example is clearly constructed and artificial, it can be seen as a cautionary tale. The reader might be tempted to think that using offspring populations instead of creating a single offspring can never increase the number of *generations* needed to find the optimum. After all, evolutionary search with offspring population is more intense and improvements can be found more easily. As we focus on the number of generations (and do not count the effort for creating  $\lambda$  offspring), it is tempting to claim that offspring populations are never disadvantageous.

The second example shows that this claim – however obvious it may seem – does not hold for general problem classes. Note that this statement is also implied by the well-known *no free lunch theorems* [46.46], but the above results are much stronger and more concrete.

### 46.4.3 Island Models

The examples so far have shown that a more thorough search – by independent runs or increased sampling of offspring – can lead to more efficient running times. Lässig and Sudholt [46.3] presented a first example where communication makes the difference between exponential and polynomial running times, in a typical run. They constructed a family of problems called  $LOLZ_{n,z,b,\ell}$  where a simple island model finds the optimum in polynomial time, with high probability. This holds for a proper choice of the migration interval and any migration topology that is not too sparse. The islands run  $(1+1)$  EAs, hence the island model resembles a fine-grained model.

Contrarily, both a panmictic population as well as independent islands need exponential time, with high probability. This shows that the weak speedup versus panmixia is superlinear, even exponential (when considering speedups with respect to the typical running

**Fig. 46.8** Sketches of the functions SufSamp (left) and SufSamp' (right). The fitness is indicated by the color

**Table 46.1** Examples of solutions for the function LOLZ with four blocks and  $z = 3$ , along with their fitness values. All blocks have to be optimized from left to right. The sketch shows in bold all bits that are counted in the fitness evaluation. Note how in  $x_3$  in the third block only the first  $z = 3$  zeros are counted. Further 0-bits are ignored. The only way to escape from this local optimum is to flip all  $z$  0-bits in this block simultaneously

|       |                  |                  |                  |          |                         |
|-------|------------------|------------------|------------------|----------|-------------------------|
| $x_1$ | <b>111</b> 10011 | 11010100         | 11010110         | 01011110 | $\text{LOLZ}(x_1) = 4$  |
| $x_2$ | <b>1111</b> 1111 | <b>110</b> 10100 | 11010110         | 01011110 | $\text{LOLZ}(x_2) = 10$ |
| $x_3$ | <b>1111</b> 1111 | <b>1111</b> 1111 | <b>0000</b> 0110 | 01011110 | $\text{LOLZ}(x_3) = 19$ |

time instead of the expected running time). Unlike previous examples, it also shows that more sophisticated means of parallelization can be better than independent runs.

The basic idea of this construction is as follows. An EA can increase the fitness of its current solutions by gathering a prefix of bits with the same value. Generally, a prefix of  $i$  leading ones yields the same fitness as a prefix of  $i$  leading zeros. The EA has to make a decision whether to collect leading ones (LOs) or leading zeros (LZs). This not only holds for the (1 + 1) EA but also for a (not too large) panmictic population as genetic drift will lead the whole population to either leading ones or leading zeros.

In the beginning, both decisions are symmetric. However, after a significant prefix has been gathered, symmetry is broken: after the prefix has reached a length of  $z$ ,  $z$  being a parameter of the function, only leading ones lead to a further fitness increase. If the EA has gone for leading zeros, it becomes stuck in a local optimum. The parameter  $z$  determines the difficulty of escaping from this local optimum.

This construction is repeated on several blocks of the bit string that need to be optimized one-by-one. Each block has length  $\ell$ . Only if the right decision towards the leading ones is made on the first block, can the block be filled with further leading ones. Once the first block contains only leading ones, the fitness depends on the prefix in the second block, and a further decision between leading ones and leading zeros needs to be made. Figure 46.1 illustrates the problem definition.

So, the problem requires an EA to make several decisions in succession. The number of blocks,  $b$ , is another parameter that determines how many decisions need to be made. Panmictic populations will sooner or later make a wrong decision and become stuck in some local optimum. If  $b$  is not too small, the same holds for independent runs.

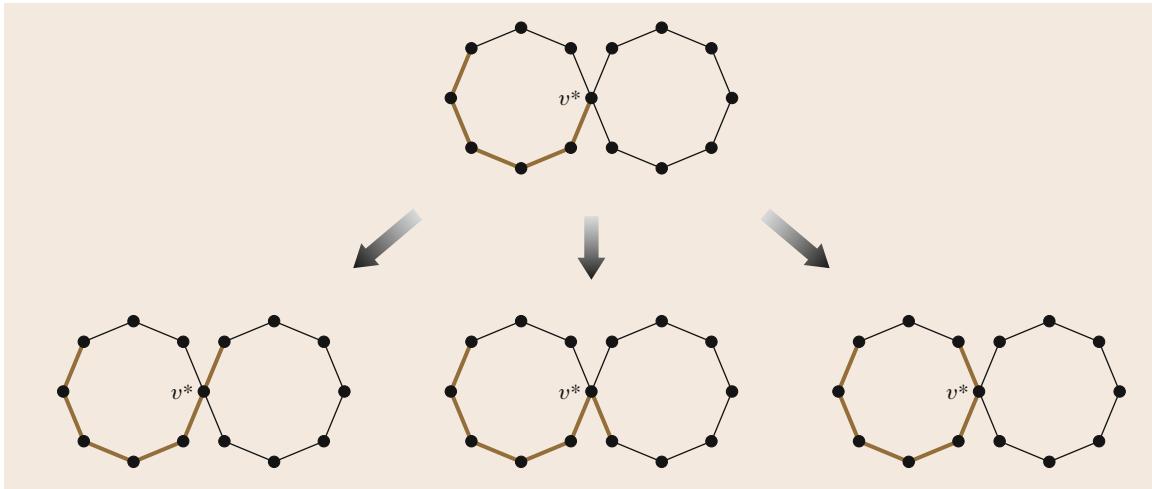

However, an island model can effectively communicate the right decisions on blocks to other islands. Islands that have become stuck in a local optimum can

be taken over by other islands that have made the correct decision. These dynamics make up the success of the island model as it can be shown to find global optima with high probability. A requirement is, though, that the migration interval is carefully tuned so that migration only transmits the right information. If migration happens before the symmetry between leading ones and leading zeros is broken, it might be that islands with leading zeros take over islands with leading ones. Lässig and Sudholt [46.3] give sufficient conditions under which this does not happen, with high probability.

An interesting finding is also how islands can regain independence. During migration, genetic information about future blocks is transmitted. Hence, after migration all islands contain the same genotype on future blocks. This is a real threat as this dependence might imply that all islands make the same decision after moving on to the next block. Then all diversity would be lost.

However, under the conditions given in [46.3] there is a period of independent evolution following migration, before any island moves on to a new block. During this period of independence, the genotypes of future blocks are subjected to random mutations, independently for each island. The reader might think of moving particles in some space. Initially, all bits are in the same position. However, then particles start moving around randomly. Naturally, they will spread out and separate from one another. After some time the distribution of particles will resemble a uniform distribution. In particular, an observer would not be able to distinguish whether the positions of particles were obtained by this random process or by simply drawing them from a uniform distribution.

The same effect occurs with bits of future blocks; after some time all bits of a future block will be indistinguishable from a random bit string. This shows that independence can not only be gained by independent runs, but also by periods of independent evolution. One could say that the island model combines the advantages of two worlds: independent evolution and selection pressure through migration. The island model

**Fig. 46.9** Sketch of the graph  $G'$ . The *top* shows a configuration where a decision at  $v^*$  has to be made. The three configurations *below* show the possible outcomes. All these transitions occur with equal probability, but only the one *on the bottom right* leads to a solution where rotations are necessary

is only successful because it can use both migration and periods of independent evolution.

The theoretical results [46.3] were complemented by experiments in [46.47]. The aim was to look at what impact the choice of the migration topology and the choice of the migration interval have on performance, regarding the function LOLZ. The theoretical results made a statement about a broad class of dense topologies, but required a very precise migration interval. The experiments showed that the island model is far more robust with respect to the migration interval than suggested by theory.

Depending on the migration interval, some topologies were better than others. The topologies involved were a bidirectional ring, a torus with edges wrapping around, a hypercube graph, and the complete graph. We considered the success rate of the island model, stopping it as soon as all islands had reached local or global optima. We then performed statistical tests comparing these success rates. For small migration intervals, i.e., frequent migrations, sparse topologies were better than dense ones. For large migration intervals, i.e., rare migrations, the effect was the opposite. This effect was expected; however, we also found that the torus was generally better than the hypercube. This is surprising, as both have a similar density. Table 46.2 shows the ranking obtained for commonly used topologies.

Superlinear speedups with island models also occur in simpler settings. Lässig and Sudholt [46.6] also considered island models for the Eulerian cycle prob-

lem. Given an undirected Eulerian graph, the task is to find a Eulerian cycle, i.e., a traversal of the graph on which each edge is traversed exactly once. This problem can be solved efficiently by tailored algorithms, but it served as an excellent test bed for studying the performance of evolutionary algorithms [46.48–51].

Instead of bit strings, the problem representation by Neumann [46.48] is based on permutations of the edges of the graph. Each such permutation gives rise to a *walk*: starting with the first edge, a walk is the longest sequence of edges such that two subsequent edges in the permutation share a common vertex. The walk encoded by the permutation ends when the next edge does not share a vertex with the current one. A walk that contains all edges represents a Eulerian cycle. The length of the walk gives the fitness of the current solution.

Neumann [46.48] considered a simple instance that consists of two cycles of equal size, connected by one common vertex  $v^*$  (Fig. 46.9). The instance is interesting as it represents a worst case for the time until an

**Table 46.2** Performance comparison according to success rates for commonly used migration topologies. The notion  $A \prec B$  means that topology  $A$  has a significantly smaller success rate than topology  $B$

| Migration interval         | Ranking                                            |
|----------------------------|----------------------------------------------------|
| Small migration intervals  | $K_\mu \prec$ hypercube $\prec$ torus $\prec$ ring |
| Medium migration intervals | hypercube $\prec K_\mu \prec$ ring $\prec$ torus   |
| High migration intervals   | ring $\prec$ torus $\prec$ hypercube $\prec K_\mu$ |

improvement is found. This is with respect to randomized local search (**RLS**) working on this representation. **RLS** works like the  $(1+1)$  EA, but it only uses local mutations. As the mutation operator it uses jumps: an edge is selected uniformly at random and then it is moved to a (different) target position chosen uniformly at random. All edges in between the two positions are shifted accordingly.

On the considered instance **RLS** typically starts constructing a walk within one of these cycles, either by appending edges to the end of the walk or by prepending edges to the start of the walk. When the walk extends to  $v^*$  for the first time, a decision needs to be made. **RLS** can either extend the walk to the opposite cycle, Fig. 46.9. In this case, **RLS** can simply extend both ends of the walk until a Eulerian cycle is formed. The expected time until this happens is  $\Theta(m^3)$ , where  $m$  denotes the number of edges.

However, if another edge in the same cycle is added at  $v^*$ , the walk will evolve into one of the two cycles that make up the instance. It is not possible to add further edges to the current walk, unless the current walk starts and ends in  $v^*$ . However, the walk can be rotated so that the start and end vertex of the walk is moved to a neighbored vertex. Such an operation takes expected time  $\Theta(m^2)$ . Note that the fitness after a rotation is the same as before. Rotations that take the start and end closer to  $v^*$  are as likely as rotations that move it away from  $v^*$ . The start and end of the walk hence performs a fair random walk, and  $\Theta(m^2)$  rotations are needed on average in order to reach  $v^*$ . The total expected time for rotating the cycle is hence  $\Theta(m^4)$ .

Summarizing, if **RLS** makes the right decision then expected time  $\Theta(m^3)$  suffices in total. However, if rotations become necessary the expected time increases to  $\Theta(m^4)$ . Now consider an island model with  $m$  islands running **RLS**. If islands evolve independently for at least  $\tau \geq m^3$  generations, all mentioned decisions are made independently, with high probability. The probability of making a wrong decision is  $1/3$ , hence with  $m$  islands the probability that all islands make the wrong decision is  $3^{-m}$ . The expected time can be shown to be

$$\Theta(m^3 + 3^{-m} \cdot m^4).$$

The choice  $m := \log_3 m$  yields an expectation of  $\Theta(m^3)$ , and every value up to  $\log_3 m$  leads to a superlinear speedup, asymptotically speaking. Technically, the speedup is even exponential.

Interestingly, this good performance only holds if migration is used rarely, or if independent runs are used.

If migration is used too frequently, the island model rapidly loses diversity. If  $T$  is any strongly connected topology and  $\text{diam}(T)$  is its diameter, we have the following. If

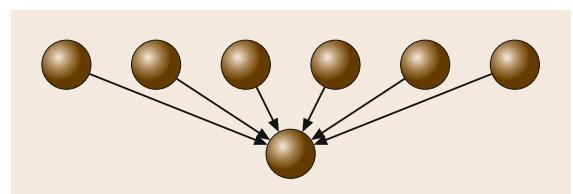

$$\tau \cdot \text{diam}(T) \cdot m = O(m^2),$$

then there is a constant probability that the island that first arrives at a decision at  $v^*$  propagates this solution throughout the whole island model, before any other island can make an improvement. This results in an expected running time of  $\Omega(m^4 / \log(m))$ . This is almost  $\Theta(m^4)$ , even for very large numbers of islands. The speedup is, therefore, logarithmic at best, or even worse. This natural example shows that the choice of the migration interval can make a difference between exponential and logarithmic speedups.

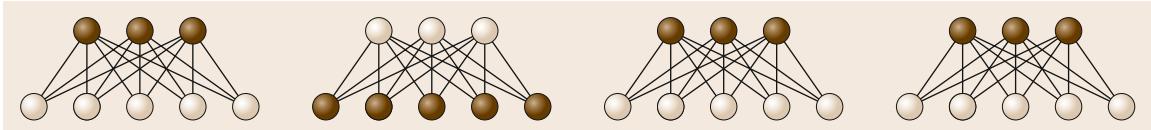

#### 46.4.4 Crossover Between Islands

It has long been known that island models can also be useful in the context of crossover. Crossover usually requires a good diversity in the population to work properly. Due to the higher diversity between different islands, compared to panmixia, recombining individuals from different islands is promising.

*Watson and Jansen* [46.52] presented and analyzed a royal road function for crossover: a function where crossover drastically outperforms mutation-based evolutionary algorithms. In contrast to previous theoretically studied examples [46.53–57], their goal was to construct a function with a clear building-block structure. In order to prove that a **GA** was able to assemble all building blocks, they resorted to an island model with a very particular migration topology. In their *single-receiver model* all islands except one evolve independently. Each island sends its migrants to a designated island called the *receiver* (Fig 46.10). This way, all sending islands are able to evolve the right building blocks, and the receiver is used to assemble all these building blocks to obtain the optimum.

**Fig. 46.10** The topology for *Watson and Jansen's* single-receiver model (after [46.52])

**Fig. 46.11** Vertex cover instance with bipartite graphs. The *brown vertices* denote selected vertices. In this configuration the second component shows a locally optimal configuration while all other components are globally optimal

This idea was picked up later on by Neumann et al. [46.7] in a more detailed study of crossover in island models. We describe parts of their results, as their problem is more illustrative than the one by Watson and Jansen. The former authors considered instances of the NP-hard *Vertex cover* problem. Given an undirected graph, the goal is to select a subset of vertices such that each vertex is either selected or neighbored to a selected vertex. We say that vertices are *covered* if this property holds for them. The objective is to minimize the number of selected vertices. The problem has a simple and natural binary representation where each bit indicates whether a corresponding vertex is selected or not.

Prior work by Oliveto et al. [46.58] showed that evolutionary algorithms with panmictic populations even fail on simply structured instance classes like copies of bipartite graphs. An example is shown in Fig. 46.11. Consider a single bipartite graph, i.e., two sets of vertices such that each vertex in one set is connected to every vertex in the other set. If both sets have different sizes, the smaller set is an optimal Vertex cover. The larger set is another Vertex cover. It is, in fact, a non-optimal local optimum which is hard to overcome: the majority of bits has to flip in order to escape. If the instance consists of several independent copies of bipartite graphs, it is very likely that a panmictic EA will evolve a locally optimal configuration on at least one of the bipartite graphs. Then the algorithm fails to find a global optimum.

Island models perform better. Assume the topology is the single-receiver model. In each migration a 2-point crossover is performed between migrants and the individual on the target island. All islands have population size 1 for simplicity. We also assume that the bipartite subgraphs are encoded in such a way that each subgraph forms one block in the bit string. This is a natural assumption as all subgraphs can be clearly identified as building blocks. In addition, Jansen et al. [46.59] presented an automated way of encoding graphs in a crossover-friendly way, based on the degrees of vertices.

The analysis in [46.7] shows the following. Assume that the migration interval is at least  $\tau \geq n^{1+\varepsilon}$  for some positive constant  $\varepsilon > 0$ . This choice implies that all islands will evolve to configurations where all bipartite graphs are either locally optimal or globally optimal. With probability  $1 - e^{-\mathcal{O}(m)}$  we have that for each bipartite graph at least a constant fraction of all sender islands will have the globally optimal configuration.

All that is left to do for the receiver island is to rely on crossover combining all present good building blocks. As two-point crossover can select one block from an immigrant and the remainder from the current solution on the receiver island, all good building blocks have a good chance to be obtained. The island model finds a global optimum within a polynomial number of generations, with probability  $1 - e^{-\mathcal{O}(\min\{n^{\varepsilon/2}, m\})}$ .

## 46.5 Speedups by Parallelization

### 46.5.1 A General Method for Analyzing Parallel EAs

We now finally discuss a method for estimating the speedup by parallelization. Assume that, instead of running a single EA, we run an island model where each island runs the same EA. The question is by how much the expected optimization time (i.e., the number of generations until a global optimum is found) decreases,

compared to the single, panmictic EA. Recall that this speedup is called weak orthodox speedup [46.14].

In the following we sometimes speak of the expected *parallel* optimization time to emphasize that we are dealing with a parallel system. If the number of islands and the population size on each island is fixed, we can simply multiply this time by a fixed factor to obtain the expected number of function evaluations.

*Lässig* and *Sudholt* [46.4] presented a method for estimating the expected optimization time of island models. It combines growth curves with a well-known method for the analysis of evolutionary algorithms. The *fitness-level method* or *method of f-based partitions* [46.60] is a simple, yet powerful technique. The idea is to partition the search space into non-empty sets  $A_1, A_2, \dots, A_m$  such that the following holds:

- for each  $1 \leq i < m$  each search point in  $A_i$  has a strictly worse fitness than each search point in  $A_{i+1}$  and
- $A_m$  contains all global optima.

The described ordering with respect to the fitness is often denoted

$$A_1 \lessdot_f A_2 \lessdot_f \cdots \lessdot_f A_m.$$

Note that  $A_m$  can also be redefined towards containing all search points of some desired quality if the goal is not global optimization.

We say that a population-based algorithm  $\mathcal{A}$  (including populations of size 1) is in  $A_i$  or *on fitness level i* if the best search point in the population is in  $A_i$ . Now, assume that we know that  $s_i$  is a lower bound on the probability that the algorithm finds a solution in  $A_{i+1} \cup \dots \cup A_m$  if it is currently in  $A_i$ . Then the reciprocal  $1/s_i$  is an upper bound on the expected time until this event happens. If the algorithm is *elitist* (i.e., it never loses the current best solution), then it will never decrease its current fitness level. A sufficient condition for finding an optimal solution is that all sets  $A_1, A_2, \dots, A_{m-1}$  are left in the described manner at least once. This implies the following bound on the expected optimization time.

### Theorem 46.1 Wegener [46.60]

Consider an elitist EA and assume a fitness-level partition  $A_1 \lessdot_f \cdots \lessdot_f A_m$  where  $A_m$  is the set of global optima. Let  $s_i$  be a lower bound for the probability that in one generation the EA finds a search point in  $A_{i+1} \cup \dots \cup A_m$  if the best individual in the parent population is in  $A_i$ . Then the expected optimization time is bounded by

$$\sum_{i=1}^{m-1} \frac{1}{s_i}.$$

The above bound applies to all elitist algorithms. It is generally applicable and often quite versatile, as

we can freely choose the partition  $A_1, \dots, A_m$ . The challenge is to find such a partition and to find corresponding probability bounds  $s_1, \dots, s_{m-1}$  for finding improvements. Many papers have shown that this method – applied explicitly or implicitly – yields tight bounds on the expected optimization time of EAs for various problems [46.32, 42, 48]. It can also be used as part of a more general analysis [46.61, 62].

We are being pessimistic in assuming that every fitness level has to be left. In reality, several fitness levels might be skipped. The fitness-level method often yields good bounds if not too many levels are skipped, and if the probability bounds  $s_i$  are good estimates for the real probabilities of finding a better fitness-level set. Note that the lower bound  $s_i$  must apply regardless of the precise search point(s) in  $A_i$  present in the population, hence we need to consider the worst-case probability of escaping from  $A_i$ .

Nevertheless, the fitness-level method often yields tight bounds. *Sudholt* [46.63] recently developed a lower-bound method based on fitness levels, which in each case shows that the upper bound is tight. Also, *Lehre* [46.64] recently presented an extension of the method to non-elitist algorithms. Asymptotically, the same bound as in Theorem 46.1 applies, if some additional conditions on the selection pressure and the population size are fulfilled. For the sake of simplicity, we focus on elitist algorithms in the following.

If  $s_i$  denotes the probability of a single offspring finding an improvement, this probability can be increased by using  $\lambda$  offspring in parallel. We have already seen in Sect. 46.1 how  $\lambda$  independent trials can increase or amplify a success probability  $p$  to  $1 - (1 - p)^\lambda$ . The same reasoning applies to the probability  $s_i$  for finding an improvement on the current best level. Figure 46.1 has shown how this probability increases with the number of trials. Figure 46.12 shows how the expected time for having a success decreases with the number of offspring. In fact, the curves in Fig. 46.12 are just reciprocals of those in the previous Fig. 46.1.

Figure 46.12 shows that the speedup can be close to linear (in a strict, non-asymptotic sense), especially for low success probabilities. As the probability of increasing the current fitness level  $i$  is at least  $1 - (1 - s_i)^\lambda$ , we obtain the following.

### Theorem 46.2

Consider an elitist EA creating  $\lambda$  offspring independently in each generation. Assume a fitness-level partition  $A_1 \lessdot_f \cdots \lessdot_f A_m$ , where  $A_m$  is the set of global optima. Let  $s_i$  be a lower bound for the probability that

in one generation a single offspring finds a search point in  $A_{i+1} \cup \dots \cup A_m$  if the best individual in the parent population is in  $A_i$ . Then the expected optimization time is bounded by

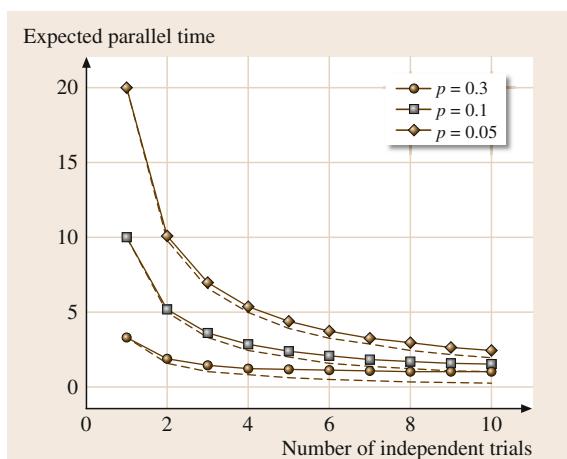

$$\sum_{i=1}^{m-1} \frac{1}{1 - (1 - s_i)^\lambda} \leq m - 1 + \frac{1}{\lambda} \sum_{i=1}^{m-1} \frac{1}{s_i}.$$

Note that the first bound for  $\lambda = 1$  reproduces the previous upper bound from Theorem 46.1. For the second bound we used

$$\frac{1}{1 - (1 - s_i)^\mu} \leq 1 + \frac{1}{\mu} \cdot \frac{1}{s_i}, \quad (46.2)$$

where the inequality was proposed by Jon Rowe (personal communication, 2011); it can be proven by a simple induction.

Our estimate of the probability for an improvement increases with the number of islands on the current best fitness level. In a spatially structured EA these growth curves are non-trivial. Especially with a sparse migration topology, information about the current best fitness level is typically propagated quite slowly. The increased exploration slows down exploitation. Still, even sparse topologies lead to drastically improved upper bounds, when compared to the simple bound for a sequential EA from Theorem 46.1. The precise bounds crucially depend on the particular topology.

**Fig. 46.12** Plots of the expected parallel time until an offspring population of size  $\lambda$  has a success, if each offspring independently has a success probability of  $p$ . The dashed lines indicate a perfect linear speedup

We first consider a setting where migration always transmits the current best fitness level and migration occurs in every generation. It is possible to adapt the results to account for larger migration intervals. One way of doing this is to redefine  $s_i$  to represent a lower bound of finding an improvement in a time period between migrations. Then we obtain an upper bound on the expected number of migrations. For the sake of simplicity, we only consider the case  $\tau = 1$  in the following.

The following theorem was presented in Lässig and Sudholt [46.6]; it is a refined special case of previous results [46.4]. The main proof idea is to combine the investigation of growth curves with the consideration of amplified success probabilities.

### Theorem 46.3 Lässig and Sudholt [46.6]

Consider an island model with  $\mu$  islands where each island runs an elitist EA. In every iteration each island sends copies of its best individual to all neighbored islands (i.e.,  $\tau = 1$ ). Each island incorporates the best out of its own individuals and its immigrants.

For every partition  $A_1 \prec_f \dots \prec_f A_m$  if  $s_i$  is a lower bound for the probability that in one generation an island in  $A_i$  finds a search point in  $A_{i+1} \cup \dots \cup A_m$  then the expected parallel optimization time is bounded by:

1.  $2 \sum_{i=1}^{m-1} \frac{1}{s_i^{1/2}} + \frac{1}{\mu} \sum_{i=1}^{m-1} \frac{1}{s_i}$  for every unidirectional ring (a ring with edges in one direction) or any other strongly connected topology,
2.  $3 \sum_{i=1}^{m-1} \frac{1}{s_i^{1/3}} + \frac{1}{\mu} \sum_{i=1}^{m-1} \frac{1}{s_i}$  for every undirected grid or torus graph with side lengths at least  $\sqrt{\mu} \times \sqrt{\mu}$ ,
3.  $m - 1 + \frac{1}{\mu} \sum_{i=1}^{m-1} \frac{1}{s_i}$  for the complete topology  $K_\mu$ .

Note that the bound for the complete topology  $K_\mu$  is equal to the upper bound for offspring populations, Theorem 46.2. This makes sense as an island model with a complete topology propagates the current best fitness level like an offspring population.

All bounds in Theorem 46.3 consist of two additive terms. The second term

$$\frac{1}{\mu} \sum_{i=1}^{m-1} \frac{1}{s_i}$$

represents a perfect linear speedup, compared to the upper bound from Theorem 46.1. The larger we choose the number of islands  $\mu$ , the smaller this term becomes. The first additive term is related to the growth curves of the current best fitness level in the island model. The

denser the topology, the faster information is spread, and the smaller this term becomes. Note that it is independent of  $\mu$ . It can be regarded as the term limiting the degree of parallelizability. We can increase the number of islands in order to decrease the second term

$$\frac{1}{\mu} \sum_{i=1}^{m-1} \frac{1}{s_i},$$

but we cannot decrease the first term by changing  $\mu$ .

This allows for immediate conclusions about cases where we obtain an asymptotic linear speedup over a single-island EA. For all choices of  $\mu$  where the second term is asymptotically no smaller than the first term, the upper bound is smaller than the upper bound from Theorem 46.1 by a factor of order  $\mu$ . This is an asymptotic linear speedup if the upper bound from Theorem 46.1 is asymptotically tight. (If it is not, we can only compare upper bounds for a sequential and a parallel EA.)

We illustrate this with a simple and well-known test function from pseudo-Boolean optimization. The algorithm considered is an island model where each island runs a  $(1+1)$  EA; the island model is also called parallel  $(1+1)$  EA. The function

$$\text{LO}(x) := \sum_{i=1}^n \prod_{j=1}^i x_j \quad (\text{LeadingOnes})$$

counts the number of leading ones in the bit string. We choose the canonic partition where  $A_i$  contains all search points with fitness  $i$ , i. e.,  $i$  leading ones. For any set  $A_i$ ,  $0 \leq i \leq n-1$  we use the following lower bound on the probability for an improvement.

An improvement occurs if the first 0-bit is flipped from 0 to 1 and no other bit flips. The probability of flipping the mentioned 0-bit is  $1/n$  as each bit is

flipped independently with probability  $1/n$ . The probability of not flipping any other bit is  $(1 - 1/n)^{n-1}$ . We use the common estimate  $(1 - 1/n)^{n-1} \geq 1/e$ , where  $e = \exp(1) = 2.718\dots$ , so the probability of an improvement is at least  $s_i \geq 1/(en)$  for all  $0 \leq i \leq n-1$ . Plugging this into Theorem 46.3, the second term is  $\frac{1}{\mu} \cdot en^2$  for all bounds. The first terms are

$$2n \cdot (en)^{1/2} = 2e^{1/2} n^{3/2}$$

for the ring,

$$3n \cdot (en)^{1/3} = 3e^{1/3} n^{4/3}$$

for the torus, and  $n$  for the complete graph, respectively.

For the ring, choosing  $\mu = O(n^{1/2})$  islands results in an expected parallel time of  $O(\frac{1}{\mu} \cdot n^2)$  as the second term is asymptotically not smaller than the first one. This is asymptotically smaller by a factor of  $1/\mu$  than the expected optimization time of a single  $(1+1)$  EA,  $\Theta(n^2)$  [46.42]. Hence, each choice of  $\mu$  up to  $\mu = O(n^{1/2})$  gives a linear speedup. For the torus we obtain a linear speedup for  $\mu = O(n^{2/3})$  in the same fashion. For the complete graph this even holds for  $\mu = O(n)$ . One can see here that the island model can decrease the expected parallel running time by significant polynomial factors.

Table 46.3 lists expected parallel optimization time bounds for several well-known pseudo-Boolean functions. The above analysis for LO generalizes to all unimodal functions. A function is called unimodal here if every non-optimal search point has a better Hamming neighbor, i. e., a better search point can be reached by flipping exactly one specific bit. ONEMAX( $x$ ) =  $\sum_{i=1}^n x_i$  counts the number of ones, hence modeling a simple hill climbing task. Finally, Jump <sub>$k$</sub>  [46.42] is a multimodal function of tunable difficulty. An EA

**Table 46.3** Upper bounds for expected parallel optimization times (number of generations) for the  $(1+1)$  EA and the corresponding island model with  $\mu$  islands in pseudo-Boolean optimization. The last but one column is for any unimodal function with  $d$  function values. The number of function evaluations in the island model is larger than the number of generations by a factor of  $\mu$

| Algorithm                          | ONEMAX                                   | LO                                        | Unimodal, $d$ values                      | Jump <sub><math>k</math></sub> , $k \geq 3$ |
|------------------------------------|------------------------------------------|-------------------------------------------|-------------------------------------------|---------------------------------------------|
| $(1+1)$ EA                         | $O(n \log n)$ [46.42]                    | $O(n^2)$ [46.42]                          | $O(nd)$                                   | $O(n^k)$ [46.42]                            |
| Island model on ring               | $O\left(n + \frac{n \log n}{\mu}\right)$ | $O\left(n^{3/2} + \frac{n^2}{\mu}\right)$ | $O\left(dn^{1/2} + \frac{dn}{\mu}\right)$ | $O\left(n^{k/2} + \frac{n^k}{\mu}\right)$   |
| Island model on torus              | $O\left(n + \frac{n \log n}{\mu}\right)$ | $O\left(n^{4/3} + \frac{n^2}{\mu}\right)$ | $O\left(dn^{1/3} + \frac{dn}{\mu}\right)$ | $O\left(n^{k/3} + \frac{n^k}{\mu}\right)$   |
| Island model on $K_\mu/(1+\mu)$ EA | $O\left(n + \frac{n \log n}{\mu}\right)$ | $O\left(n + \frac{n^2}{\mu}\right)$       | $O\left(d + \frac{dn}{\mu}\right)$        | $O\left(n + \frac{n^k}{\mu}\right)$         |

typically has to make a *jump* by flipping  $k$  bits simultaneously, where  $2 \leq k \leq n$ . The  $(1+1)$  EA has an expected optimization time of  $\Theta(n^k)$ , hence growing rapidly with increasing  $k$ .

One can see that the island model leads to drastically reduced parallel optimization times. This particularly holds for problems where improvements are hard to find.

We remark that Lässig and Sudholt [46.4] also considered parallel EAs where migration is not always successful in transmitting information about the current best fitness level. This includes the case where crossover is used during migration and crossover has a certain probability of being disruptive. We do obtain upper bounds on the expected optimization time if we know a lower bound  $p^+$  on the probability of a successful transmission. The bounds depend on  $p^+$ ; the degree of this dependence is determined by the topology. For simplicity we only focus on the deterministic case here.

### 46.5.2 Speedups in Combinatorial Optimization

The techniques are also applicable in combinatorial optimization. We review two examples here, presented in [46.6]. Scharnow et al. [46.32] considered the classical sorting problem as an optimization problem: given a sequence of  $n$  distinct elements from a totally ordered set, sorting is the problem of maximizing sortedness. Without loss of generality the elements are  $1, \dots, n$ ; then the aim is to find the permutation  $\pi_{\text{opt}}$  such that  $(\pi_{\text{opt}}(1), \dots, \pi_{\text{opt}}(n))$  is the sorted sequence.

The search space is the set of all permutations  $\pi$  on  $1, \dots, n$ . Two different operators are used for mutation. An exchange chooses two indices  $i \neq j$  uniformly at random from  $\{1, \dots, n\}$  and exchanges the entries at positions  $i$  and  $j$ . A jump chooses two indices in the same fashion. The entry at  $i$  is put at position  $j$  and all entries in between are shifted accordingly. For instance,

a jump with  $i = 2$  and  $j = 5$  would turn  $(1, 2, 3, 4, 5, 6)$  into  $(1, 3, 4, 5, 2, 6)$ .

The  $(1+1)$  EA draws  $S$  according to a Poisson distribution with parameter  $\lambda = 1$  and then performs  $S+1$  elementary operations. Each operation is either an exchange or a jump, where the decision is made independently and uniformly for each elementary operation. The resulting offspring replaces its parent if its fitness is not worse. The fitness function  $f_{\pi_{\text{opt}}}(\pi)$  describes the sortedness of  $(\pi(1), \dots, \pi(n))$ . As in [46.32], we consider the following measures of sortedness:

- INV( $\pi$ ) measures the number of pairs  $(i, j)$ ,  $1 \leq i < j \leq n$ , such that  $\pi(i) < \pi(j)$  (pairs in correct order),
- HAM( $\pi$ ) measures the number of indices  $i$  such that  $\pi(i) = i$  (elements at the correct position),
- LAS( $\pi$ ) equals the largest  $k$  such that  $\pi(i_1) < \dots < \pi(i_k)$  for some  $i_1 < \dots < i_k$  (length of the longest ascending subsequence),
- EXC( $\pi$ ) equals the minimal number of exchanges (of pairs  $\pi(i)$  and  $\pi(j)$ ) to sort the sequence, leading to a minimization problem.

The expected optimization time of the  $(1+1)$  EA is  $\Omega(n^2)$  and  $O(n^2 \log n)$  for all fitness functions. The upper bound is tight for LAS, and it is believed to be tight for INV, HAM, and EXC as well [46.32]. Theorem 46.3 yields the following. For INV, all topologies guarantee a linear speedup only in case  $\mu = O(\log n)$  and the bound  $O(n^2 \log n)$  for the  $(1+1)$  EA is tight. The other functions allow for linear speedups up to  $\mu = O(n^{1/2} \log n)$  (ring),  $\mu = O(n^{2/3} \log n)$  (torus), and  $\mu = O(n \log n)$  ( $K_\mu$ ), respectively (again assuming tightness, otherwise up to a factor of  $\log n$ ). Note how the results improve with the density of the topology. HAM, LAS, and EXC yield much better guarantees for the island model than INV. This is surprising as there is no visible performance difference for a single  $(1+1)$  EA. Theorem 46.3 yields the following results also shown in Tab. 46.4

**Table 46.4** Upper bounds for expected parallel optimization times for the  $(1+1)$  EA and the corresponding island model with  $\mu$  islands for sorting  $n$  objects

| Algorithm                          | INV                                          | HAM, LAS, EXC                                    |
|------------------------------------|----------------------------------------------|--------------------------------------------------|
| $(1+1)$ EA                         | $O(n^2 \log n)$ [46.32]                      | $O(n^2 \log n)$ [46.32]                          |
| Island model on ring               | $O\left(n^2 + \frac{n^2 \log n}{\mu}\right)$ | $O\left(n^{3/2} + \frac{n^2 \log n}{\mu}\right)$ |
| Island model on torus              | $O\left(n^2 + \frac{n^2 \log n}{\mu}\right)$ | $O\left(n^{4/3} + \frac{n^2 \log n}{\mu}\right)$ |
| Island model on $K_\mu/(1+\mu)$ EA | $O\left(n^2 + \frac{n^2 \log n}{\mu}\right)$ | $O\left(n + \frac{n^2 \log n}{\mu}\right)$       |

**Table 46.5** Worst-case expected parallel optimization times for the (1 + 1) EA and the corresponding island model with  $\mu$  islands for the SSSP on graphs with  $n$  vertices and  $m$  edges. The value  $\ell$  is the maximum number of edges on any shortest path from the source to any vertex and  $\ell^* := \max\{\ell, \ln n\}$ . The second lines show a range of  $\mu$ -values yielding a linear speedup, apart from a factor  $\ln(en/\ell)$

| Algorithm                            | Vertex-based mutation [46.32]                                                                                | Edge-based mutation [46.65]                                                                                                |

| (1 + 1) EA                           | $\Theta(n^2\ell^*)$ [46.34]                                                                                  | $\Theta(m\ell^*)$ [46.65]                                                                                                  |
| Island model on ring                 | $O\left(n^{3/2}\ell^{1/2} + \frac{n^2\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O((n\ell)^{1/2})$ | $O\left(m^{1/2}n^{1/2}\ell^{1/2} + \frac{m\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O((m/n \cdot \ell)^{1/2})$ |
| Island model on torus                | $O\left(n^{4/3}\ell^{1/3} + \frac{n^2\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O((n\ell)^{2/3})$ | $O\left(m^{1/3}n^{2/3}\ell^{1/3} + \frac{m\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O((m/n \cdot \ell)^{2/3})$ |
| Island model on $K_\mu/(1 + \mu)$ EA | $O\left(n + \frac{n^2\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O(n\ell)$                         | $O\left(n + \frac{m\ell \ln(en/\ell)}{\mu}\right)$<br>$\rightarrow \mu = O(m/n \cdot \ell)$                                |

An explanation is that INV leads to  $\binom{n}{2}$  non-optimal fitness levels that are quite easy to overcome. HAM, LAS, and EXC have only  $n$  non-optimal fitness levels that are more difficult. For a single EA both settings are equally difficult, leading to asymptotically equal expected times (assuming all upper bounds are tight). However, the latter setting is easier to parallelize than the former as it is easier to amplify small success probabilities.

We also consider parallel variants of the (1 + 1) EA for the single source shortest path problem (SSSP) [46.32]. An SSSP instance is given by an undirected connected graph with vertices  $\{1, \dots, n\}$  and a distance matrix  $D = (d_{ij})_{1 \leq i,j \leq n}$ , where  $d_{ij} \in \mathbb{R}_0^+ \cup \{\infty\}$  defines the length value for given edges from node  $i$  to node  $j$ . We are searching for shortest paths from a node  $s$  (without loss of generality  $s = n$ ) to each other node  $1 \leq i \leq n - 1$ .

A candidate solution is represented as a *shortest paths tree*, a tree rooted at  $s$  with directed shortest paths to all other vertices. We define a search point  $x$  as vector of length  $n - 1$ , where position  $i$  describes the predecessor node  $x_i$  of node  $i$  in the shortest path tree. Note that infeasible solutions are possible if the predecessors do not encode a tree. An elementary mutation chooses a vertex  $i$  uniformly at random and replaces its predecessor  $x_i$  by a vertex chosen uniformly at random from  $\{1, \dots, n\} \setminus \{i, x_i\}$ . We call this a vertex-based mutation. Doerr et al. [46.65] proposed an edge-based mutation operator. An edge is chosen uniformly at random, and the edge is made a predecessor edge for its end node.

The (1 + 1) EA uses either vertex-based mutations or edge-based ones. It creates an offspring using  $S$  elementary mutations, where  $S$  is chosen according to

a Poisson distribution with  $\lambda = 1$ . The result of an offspring is accepted in case no distance to any vertex has gotten worse.

Applying Theorem 46.3 along with a layering argument as described at the end of Sect. 46.3.4 yields the bounds on the expected parallel optimization time shown in Table 46.5.

The upper bounds for the island models with constant  $\mu$  match the expected time of the (1 + 1) EA if  $\ell = O(1)$  or  $\ell = \Omega(n)$  as then  $\ell \ln(en/\ell) = \Theta(\ell^*)$ . In other cases, the upper bounds are off by a factor of  $\ln(en/\ell)$ . Table 46.5 also shows a range of  $\mu$ -values for which the speedup is linear (if  $\ell = O(1)$  or  $\ell = \Omega(n)$ ) or almost linear, that is, when disregarding the  $\ln(en/\ell)$  term.

Note how the possible speedups significantly increase with the density of the topology. The speedups also depend on the graph instance and the maximum number of edges  $\ell$  on any shortest path. For a single (1 + 1) EA edge-based mutations are more effective than vertex-based mutations [46.65]. Island models with edge-based mutations cannot be paral-

**Table 46.6** Asymptotic bounds for expected parallel running times and expected sequential running times for the parallel (1 + 1) EA with adaptive population models

|                                 | Scheme | Sequential         | Parallel           |
|---------------------------------|--------|--------------------|--------------------|
| ONEMAX                          | A      | $\Theta(n \log n)$ | $O(n \log n)$      |
|                                 | B      | $\Theta(n \log n)$ | $O(n)$             |
| LO                              | A      | $\Theta(n^2)$      | $\Theta(n \log n)$ |
|                                 | B      | $\Theta(n^2)$      | $O(n)$             |
| Unimodal $f$ with $d f$ -values | A      | $O(dn)$            | $O(d \log n)$      |
|                                 | B      | $O(dn)$            | $O(d + \log n)$    |
| Jump $_k$ with $k \geq 2$       | A      | $O(n^k)$           | $O(n \log n)$      |
|                                 | B      | $O(n^k)$           | $O(n + k \log n)$  |

lized as effectively for sparse graphs as those with vertex-based mutations if the graph is sparse, i.e.,  $m = o(n^2)$ . Then the number of islands that guarantees a linear speedup is smaller for edge-based mutations than for vertex-based mutations. The reason is that with a more efficient mutation operator there is less potential for further speedups with a parallel EA.

### 46.5.3 Adaptive Numbers of Islands

Theorem 46.3 presents a powerful tool for determining the number of islands that give an asymptotic linear speedup. However, it would be even more desirable to have an adaptive system that automatically finds the ideal number of islands throughout the run.

In [46.5] Lässig and Sudholt proposed and analyzed two simple adaptive schemes for choosing the number of islands. Both schemes check whether in the current generation some island has found an improvement over the current best fitness in the system. If no island has found an improvement, the number of islands is doubled. This can be implemented, for instance, by copying each island. New processors can be allocated to host these islands in large clusters or by using cloud computing.

If some island has found an improvement, the number of islands is reduced by removing selected islands from the system and de-allocating resources. Both schemes differ in the way they decrease the number of islands. The first scheme, simply called Scheme A, only keeps one island containing a current best solution. Scheme B halves the number of islands. Both schemes use complete topologies, so all remaining islands will contain current best individuals afterwards.

Both mechanisms lead to optimal speedups in many cases. Doubling the number of islands may seem aggressive, but the analysis shows that the probability of allocating far more islands than necessary is very very small. The authors considered the expected sequential optimization time, defined as the number of function evaluations, to measure the total effort over time. With both schemes it is guaranteed that the expected sequential time does not exceed the simple bound for a sequential EA from Theorem 46.1, asymptotically. The expected parallel times on each fitness level can, roughly speaking, be replaced by their logarithms.

The following is a slight simplification of results in [46.5].

---

### Theorem 46.4 Lässig and Sudholt [46.5]

Given an  $f$ -based partition  $A_1, \dots, A_m$  and lower bounds  $s_1, \dots, s_{m-1}$  on the probability of a single island finding an improvement, the expected sequential times for island models using a complete topology and either Scheme A or Scheme B are bounded by

$$3 \sum_{i=1}^{m-1} \frac{1}{s_i} .$$

If each set  $A_i$  contains only a single fitness value then also the expected parallel time is bounded by

$$4 \sum_{i=1}^{m-1} \log\left(\frac{2}{s_i}\right) .$$

---

Actually, for Scheme A we can obtain slightly better constants than the ones stated in Theorem 46.4. However, with a more detailed analysis one can show that Scheme B can perform much better than Scheme A. Lässig's and Sundholt's work [46.5] contains a more refined upper bound for Scheme B. We only show a special case where the fitness levels become increasingly harder. Then it makes sense to only halve the number of islands when an improvement is found, instead of resetting the number of islands to 1.

---

### Theorem 46.5 Lässig and Sudholt [46.5]

Given an  $f$ -based partition  $A_1, \dots, A_m$ , where each set  $A_i$  contains only a single fitness value and for the probability bounds it holds  $s_1 \geq s_2 \geq \dots \geq s_{m-1}$ . Then the expected parallel running time for an island model using a complete topology and Scheme B is bounded by

$$3(m-2) + \log\left(\frac{1}{s_{m-1}}\right) .$$

---

Example applications for a parallel (1 + 1) EA in Table 46.6 show that Scheme B can automatically lead to the same speedups as when using an optimal number of islands. This holds for ONEMAX, LO, and the general bound for unimodal functions. For  $\text{Jump}_k$  it also holds in the most relevant cases, when  $k = O(n/\log n)$ , as then the expected parallel time is  $O(n)$ .

We conclude that simply doubling or halving the number of islands represents a simple and effective mechanism for finding optimal parameters adaptively.

## 46.6 Conclusions

Parallel evolutionary algorithm can effectively reduce computation time and at the same time lead to an increased exploration and better diversity, compared to sequential evolutionary algorithms.

We have surveyed various forms of parallel **EAs**, from independent runs to island models and cellular **EAs**. Different lines of research have been discussed that give insight into the working principles behind parallel **EAs**. This includes the spread of information, growth curves for current best solutions, and takeover times.

A recurring theme was the possible speedup that can be achieved with parallel **EAs**. We have elaborated on the reasons why superlinear speedups are possible in practice. Rigorous runtime analysis has given examples where parallel **EAs** excel over sequential algorithms, with regard to the number of generations or the number of function evaluations until a global optimum is found. The final section has covered a method for estimating the expected parallel optimization time of island models. The method is easy to apply as we can automatically transfer existing analyses for sequential **EAs** to a parallel version thereof. Examples have been given for pseudo-Boolean optimization and combinatorial optimization. The results have also led to the discovery of a simple, yet surprisingly powerful adaptive scheme for choosing the number of islands.

There are many possible avenues for future work. In the light of the development in computer architecture, it is important to develop parallel **EAs** that can run effectively on many cores. It also remains a crucial issue to increase our understanding of how design choices and parameters affect the performance of parallel **EAs**. Rigorous runtime analysis has emerged recently as a new line of research that can give novel insights in this respect and opens new roads. The present results should be extended towards further algorithms, further problems, and more detailed cost models that reflect the costs for communication in parallel architectures. It would also be interesting to derive further rigorous results on takeover times in settings where propagation through migration is probabilistic. Finally, it is important to bring theory and practice together in order to create synergetic effects between the two areas.

### 46.6.1 Further Reading

This book chapter does not claim to be comprehensive. In fact, parallel evolutionary algorithms represent

a vast research area with a long history. Early variants of parallel evolutionary algorithms were developed, studied, and applied more than 20 years ago. We, therefore, point the reader to references that may complement this chapter. *Paz* [46.66] presented a review of early literature and the history of parallel **EAs**. The survey by *Alba* and *Troya* [46.37] contains detailed overviews of parallel **EAs** and their characteristics.

This chapter does not cover implementation details of parallel evolutionary algorithms. We refer to the excellent survey by *Alba* and *Tomassini* [46.38]. This survey also includes an overview of the theory of parallel **EAs**. The emphasis is different from this chapter and it can be used to complement this chapter.

*Tomassini's* text book [46.67] describes various forms of parallel **EAs** like island models, cellular **EAs**, and coevolution. It also presents many mathematical and experimental results that help understand how parallel **EAs** work. Furthermore, it contains an appendix dealing with the implementation of parallel **EAs**.

The book edited by *Alba* et al. [46.39] takes a broader scope on parallel models that also include parallel evolutionary multiobjective optimization and parallel variants of swarm intelligence algorithms like particle swarm optimization and ant colony optimization. The book contains a part on parallel hardware as well as a number of applications of parallel metaheuristics.

*Alba's* edited book on parallel metaheuristics [46.40] has an even broader scope. It covers parallel variants of many common metaheuristics such as genetic algorithms, genetic programming, evolution strategies, ant colony optimization, estimation-of-distribution algorithms, scatter search, variable-neighborhood search, simulated annealing, tabu search, greedy randomized adaptive search procedures (**GRASP**s), hybrid metaheuristics, multiobjective optimization, and heterogeneous metaheuristics.

The most recent text book was written by *Luque* and *Alba* [46.19]. It provides an excellent introduction into the field, with hands-on advice on how to present results for parallel **EAs**. Theoretical models of selection pressure in distributed **GAs** are presented. A large part of the book then reviews selected applications of parallel **GAs**.

# 47. Learning Classifier Systems

Martin V. Butz

Learning Classifier Systems (**LCSs**) essentially combine fast approximation techniques with evolutionary optimization techniques. Despite their somewhat misleading name, **LCSs** are not only systems suitable for classification problems, but may be rather viewed as a very general, distributed optimization technique. Essentially, **LCSs** have very high potential to be applied in any problem domain that is best solved or approximated by means of a distributed set of local approximations, or predictions. The evolutionary component is designed to optimize a partitioning of the problem domain for generating maximally useful predictions within each subspace of the partitioning. The predictions are generated and adapted by the approximation technique. Generally any form of spatial partitioning and prediction are possible – such as a Gaussian-based partitioning combined with linear approximations, yielding a Gaussian mixture of linear predictions. In fact, such a solution is developed and optimized by **XCSF** (**XCS** for function approximation). The **LCSs XCS** (X classifier system) and the function approximation version **XCSF**, indeed, are probably the most well-known **LCS** architectures to date. Their optimization technique is very-well balanced with the approximation technique: as long as the approximation technique yields reasonably good solutions and evaluations of these solutions fast, the evolutionary component will pick-up on the evaluation signal and optimize the partitioning. This chapter

provides historical background on **LCSs**. Then **XCS** and **XCSF** are introduced in detail providing enough information to be able to implement, understand, and apply these systems. Further **LCS** architectures are surveyed and their potential for future research and for applications is discussed. The conclusions provide an outlook on the many possible future **LCS** applications and developments.

Learning classifier systems (**LCSs**) are machine learning algorithms that combine gradient-based approximation with evolutionary optimization. Due to this flexibility, **LCSs** have been successfully applied to classification and data mining problems, reinforcement learning (**RL**) problems, regression problems, cognitive map learning, and even robot control problems.

The main feature of **LCSs** is their innovative combination of two learning principles; whereas gradient-based approximation adapts local, predictive approximations of target function values, evolutionary optimization structures individual classifiers to enable the formation of effectively distributed and accurate approximations. The two learning methods interact bidirectionally in

that the gradient-based approximations yield local fitness quality estimates of the generated approximations, which the evolutionary optimization technique uses for optimizing classifier structures. Concurrently, the evolutionary optimization technique is generating new classifier structures, which again need to be evaluated by the gradient-based approach in competition with the other, locally overlapping, interacting classifiers.

Due to the innovative combination of two learning and optimization techniques, **LCS**s are often perceived as being hard to understand. Facet-wise analyses of the individual **LCS** components and their interactions, however, give both mathematical scalability bounds for learning and an intuitive understanding of the systems in general. Moreover, the currently most common **LCS**, which is the **XCS** classifier system (note that the *X* in **XCS** does not really encode any particular acronym according to the system creator Wilson), is comparatively easy to understand, to tune, and to apply. Thus, the core of this chapter focuses on **XCS**, gives a facet-wise overview of its functionality, details several enhancements, and highlights various successful application domains. However, **XCS** is also compared with other **LCS** architectures and **LCS**s in

general are compared with other machine learning techniques.

This chapter starts with a historical perspective, providing information on the beginnings of **LCS**s and establishing some terminology background. We then introduce the **XCS** classifier system providing a detailed system overview as well as theoretical and facet-wise conceptual insights on its performance. Also tricks and tweaks are discussed to tune the system to the problem at hand. Next, the **XCS** counterpart for regression problems, **XCSF**, is introduced. Focusing then on the application-side, **LCS** applications to data mining tasks and to behavioral learning and cognitive modeling tasks are surveyed. We cover various **LCS** architectures that have been successfully applied in the data mining realm. With respect to behavioral learning, we point out the relation of **LCS**s to reinforcement learning. Moreover, we cover anticipatory learning classifier systems (**ALCS**s) – which learn predictive schema models of the environment rather than reward prediction maps – and we introduce the modified **XCSF** version that can effectively learn a redundant forward-inverse kinematics model of a robot arm. A summary and conclusions wrap up the chapter.

## 47.1 Background

Learning classifier systems (**LCS**) were proposed over 30 years ago by *Holland* [47.1–3]. Originally, *Holland* and *Reitman* actually called **LCS**s *cognitive systems* [47.4], focusing on problems related to reinforcement learning (**RL**) [47.5, 6]. His cognitive system developed a *memory of classifiers*, where each classifier consisted of a condition part (*taxon*), an action part (originally consisting of a *message*, and an *effector bit*), a payoff prediction part, and several other parameters that stored the age, the application frequency, and the *attenuation* of the classifier.

Concurrently with the development of temporal difference learning techniques in **RL** – such as the now well-known state-action-reward-state-action (**SARSA**) algorithm [47.6] – *Holland* and *Reitman* introduced the *bucket brigade* algorithm [47.4, 7], which also distributes reward backwards in time with a discounting mechanism. In addition, the *attenuation* parameter in a classifier realized something similar to an *eligibility trace* in **RL** – distributing a currently encountered reward also to classifiers that were active several time steps ago and that thus indirectly led to gaining the cur-

rently experienced reward. Meanwhile, *Holland*'s cognitive system applied a genetic algorithm (**GA**) [47.1, 8] as its second learning mechanism. The **GA** modified the *taxa* in *Holland* and *Reitman*'s cognitive system.

In sum, the first actual **LCS** implementation, i. e., the *cognitive system* by *Holland* and *Reitman* [47.4], was ahead of its time. It implemented various reward-related ideas that were later established in the reinforcement learning community – and can now partially be regarded as standard **RL** techniques. However, the combination with **GAs** yielded a highly interactive and very complex system that was and still is hard to analyze. Thus, while proposing a highly innovative cognitive learning approach, the applicability of the system remained limited at the time.

### 47.1.1 Early Applications

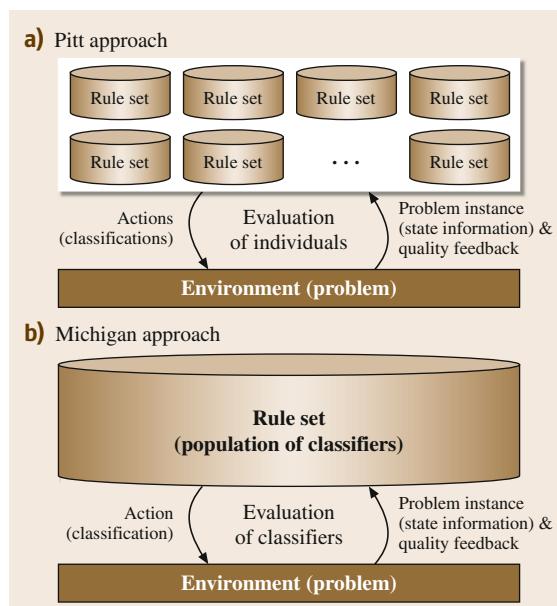

Nonetheless, early applications of **LCS**s were published in the 1980s. *Smith* developed a poker decision making system [47.9] based on *De Jong*'s approach to **LCS**s [47.10]. *Booker* worked on animal-like

automation based on the cognitive systems architecture [47.11]. Wilson proposed and worked on the *animat problem* with **LCS** architectures derived from Holland and Reitman's cognitive systems approach [47.12, 13]. Goldberg solved a gas pipeline control task with a simplified version of the cognitive system architecture [47.8, 14]. Despite these successful early applications, a decade passed until a growing research community developed that worked on learning classifier systems.

### 47.1.2 The Pitt and Michigan Approach

Two fundamentally different **LCS** approaches were pursued from early on. The Pitt approach was fostered by the work of De Jong et al. [47.10, 15, 16]. On the other hand, the Michigan approach developed in the further years at Michigan under the supervision of John H. Holland [47.11, 14, 17, 18]. Diverse perspectives on the Michigan approach can be found in [47.19].

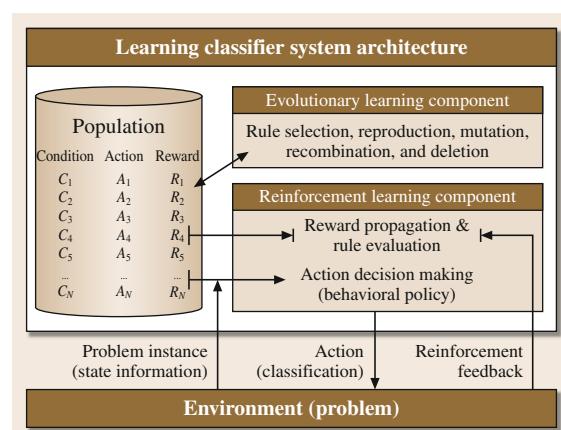

The essential difference between the two approaches is that in the Pitt approach rule sets are evolved where each particular rule set constitutes an individual for the **GA**. In contrast, in the Michigan approach one set of rules is evolved and each rule is an individual for

**Fig. 47.1a,b** While the Pitt approach to **LCS**s evolves a population of sets of rules, in the Michigan approach there is only one set of rules (i.e., the population) that is evolved

the **GA**. As a consequence, the Pitt-style **LCS**s are much closer to general **GAs** because each individual constitutes an overall problem solution. In the Michigan-style **LCS**s, on the other hand, each individual only applies in a subspace of the overall problem and only the whole set of rules that evolves constitutes the overall problem solution. Figure 47.1 illustrates this fundamental contrast between the two approaches.

As a consequence of this contrast, Pitt-style **LCS**s usually apply rather standard **GA** approaches. The whole population of rule sets is evolved. For fitness evaluation purposes, each set of rules needs to be evaluated in the problem environment addressed. On the other hand, Michigan-style **LCS**s need to continuously interact with an environment to sufficiently evaluate all the rules in the rule set – essentially exploring all the environmental subspaces to make sure all rules can develop a sufficiently useful fitness estimate. This continuous interaction and the typical interacting components of Michigan-style **LCS**s are illustrated in further detail in Fig. 47.2. Due to the continuously developing fitness estimates, often a more steady-state, niched **GA** is applied online in Michigan-style **LCS**s. The undertaken updates then depend directly on the current interaction and thus on the current subset of rules relevant in the experienced interaction. The steady-state, niched **GA** optimizes the internal knowledge base iteratively depending on the incoming learning samples.

**Fig. 47.2** **LCS**s consist of a knowledge base (population of classifiers), a genetic algorithm for rule structure evolution, and a reinforcement learning component for rule evaluation, reward propagation, and decision making. The system interacts with its environment or problem iteratively learning online

In summary, Pitt-style **LCSs** evaluate and optimize their rule sets globally based on sets of problem instances. They usually learn *offline*. Michigan-style **LCSs** evaluate and optimize their set of rules online while interacting with the problem, iteratively perceiving problem instances. The major qualities of Pitt-style **LCSs** are that they evolve competing global problem solutions in the form of sets of rules. Evolutionary rule structure optimization is used – typically evolving small sets of rules (10 s). Michigan-style **LCSs**, on the other hand, are designed to develop one distributed, locally optimized problem solution by combining local gradient-based approximation techniques with steady-state, niched **GAs**. In consequence, typically larger, more distributed sets of rules develop yielding problem solutions with potentially 1000 s of rules.

### 47.1.3 Basic Knowledge Representation

Because an exemplary knowledge representation was already discussed for the early *cognitive system* implementation of [47.4], we now provide a general sketch of the knowledge representation typically found in Michigan-style **LCSs**.

The knowledge representation of an **LCS** consists of a finite *population of classifiers* (that is, a finite set of rules). This population of classifiers essentially represents the current knowledge of the **LCS** about the problem the system is applied to. Each rule – or *classifier* – usually consists of a *condition* and an *action part*, as well as a *prediction* and a *fitness estimate*. The condition part specifies the problem subspace in which the classifier is applicable. When the condition part is satisfied given a particular problem instance, a classifier is said to *match* that problem instance. The action part specifies an action that may be executed, or a classification that may be tested. The prediction specifies the expected reward, or feedback value, given the specified action was executed under the specified contextual conditions. The fitness estimates the value of this classifier relative to other, competing classifiers. In the early approaches, fitness was often simply equal to the prediction value. In the currently established **LCSs**, fitness typically estimates the accuracy of the prediction.

Michigan-style **LCSs** usually learn online about a problem, iteratively perceiving or actively generating problem instances. Given a particular problem instance, first, the system forms a *match set* of those classifiers in the population whose conditions match. Next, the system decides on an action or classification and ex-

ecutes it. Classifiers in the match set that specify the executed action constitute the current *action set*. After feedback is received, the predictions of the classifiers in the action set are adjusted. From the classifier prediction estimates, a fitness estimate is derived for each classifier. Finally, the steady-state **GA** is applied to the match set or the population as a whole. The **GA** modifies classifier structures by reproducing, mutating, and recombining well-performing classifiers and by deleting ill-performing ones. In contrast to the Michigan approach, Pitt-style **LCSs** evaluate their sets of rules typically independently of each other in the provided problem. The **GA** exchanges rules and rule-structures within and across the sets of rules.

A Michigan-style **LCS** consequently is an interactive, online learning system. It maintains a population of classifiers as its knowledge base. It applies a niched, steady-state genetic algorithm for gradual rule structure evolution; it applies a gradient-based learning component for rule evaluation – yielding prediction and fitness estimates. Michigan-style **LCSs** are often applied in **RL** scenarios in which reward estimates need to be propagated and action decisions are made based on the learned reward prediction estimates. In this case, typically techniques similar to **SARSA** learning or Q-learning are applied. Figure 47.2 shows the basic components of a Michigan-style **LCS** as well as their interactions.

The earliest Michigan-style **LCS** implementation is the introduced cognitive system **CS1** [47.4]. After various early applications of **LCSs**, **Wilson** set a milestone in **LCS** research by introducing the zeroth level classifier system **ZCS** [47.20] and the now most prominent and well-known **LCS**: the **XCS** classifier system [47.21]. Both systems were explicitly compared to the very well-known Q-learning [47.22] technique from the **RL** community, offering with **ZCS** and **XCS** two learning classifier systems that can learn Q-value functions with a compact highly generalized rule-based representation.

In the following, we now first give a precise introduction to the **XCS** classifier system. We then also introduce the real-valued version for solving regression problems, with a Gaussian mixture of linear approximations, i. e., **XCSF**. After that, we provide spot-lights on various current application domains where various types of **LCSs**, including **XCS(F)**, have produced highly competitive problem solutions, when compared to other machine learning techniques and regression algorithms.

## 47.2 XCS

Wilson introduced the **XCS** classifier system in 1995 [47.21]. The two main novel features of **XCS** in comparison to earlier Michigan-style **LCS**s are its accuracy-based fitness estimation and its niche-based application of the evolutionary component. The introduction of accuracy-based fitness essentially decoupled the classifier fitness estimate from the reward prediction, enforcing that **XCS** learned *complete* payoff landscapes rather than only estimates for those subspaces where high reward is encountered. In addition, Wilson related **XCS** directly to Q-Learning [47.21, 22]. Much later, even a relation to Kalman filtering and general regression tasks was made mathematically explicit [47.23, 24]. The niche-based **GA** reproduction combined with population-wide deletion enabled a much more focused **GA**-based optimization of classifier structures as well as the generalization of classifier structures based on the sampling distribution [47.25]. In consequence, **XCS** is an **LCS** that is designed to evolve not only the best solution to a problem, but it evolves all alternative solutions with associated Q-value estimations and variance estimations of the respective Q-value estimates. Due to its **GA** design and fitness definition, **XCS** strives to approximate the full Q-table of a problem with a maximally accurate and maximally compact classifier-based representation.

Despite its original strong relation to Q-learning and **RL** in general, **XCS** has also been applied successfully to classification problems and regression problems. In the former case, **XCS** identifies locally relevant features for the generation of maximally accurate classification estimates. In the latter case, **XCS** optimizes the distribution and structure of local, typically linear estimators for a maximally accurate approximation of the function surface. Thus, despite its original strong relation to **RL**, **XCS** is a much more generally applicable learning system that can solve single-step classification or regression problems as well as multi-step **RL** problems, which are typically defined as Markov decision processes.

### 47.2.1 System Overview

**XCS** evolves one population of classifiers. Classifier structures are optimized by means of a steady-state **GA**. A classifier consists of a condition part  $C$ , an action part  $A$ , reward prediction  $r$ , reward prediction error  $\varepsilon$ , and fitness  $f$  estimates. While the condition and action

structures are iteratively optimized by the steady-state **GA**, the estimates are adjusted using the Widrow–Hoff delta rule [47.26] based on an approximation of the Q-value signal.

While condition and action parts can be generally represented in any way desired [47.25], in this overview we focus on binary problems and a ternary representation of the condition part. Conventionally, the condition part  $C$  is coded by  $C \in \{0, 1, \#\}^L$ , where the  $\#$  symbol matches zero and one. Condition  $C$  essentially specifies a hypercube within which the classifier *matches* and can be said to cover a certain *volume* of the complete problem space. Action part  $A \in \mathcal{A}$  defines an action or classification from a provided finite set of possible actions  $\mathcal{A}$ . Reward prediction  $r \in \mathbb{R}$  estimates the moving average of the received reward in the recent activations of the classifier. Reward prediction error  $\varepsilon$  estimates the moving average of the absolute error of the reward prediction. Finally, fitness  $f \in [0, 1]$  estimates the moving average of the relative accuracy of the classifier compared to the competing classifiers in the activated match sets (or action sets). The larger the fitness estimate, the on average larger the accuracy of a classifier in comparison to all classifiers that encode the same action and whose condition parts define overlapping subspaces.

Each classifier also maintains several additional parameters. The *action set size estimate*  $as$  estimates the moving average of the action sets the classifier was part of. It is updated similarly to the reward prediction  $r$ . A *time stamp*  $ts$  specifies the last time the classifier was part of a **GA** competition. An *experience counter*  $exp$  specifies the number of applied parameter updates. The numerosity  $num$  specifies the number of (micro-) classifiers, this macro-classifier actually represents – mainly for saving computation time.

Learning usually starts with an empty population. The problem faced is sampled iteratively, encountering particular problem instances  $s \in S$ . The set of all matching classifiers in the classifier population  $[P]$  is termed the *match set*  $[M]$ . If some action in  $\mathcal{A}$  is not represented in  $[M]$ , a *covering mechanism* is applied. Covering creates classifiers that match  $s$  (inserting  $\#$ -symbols in the new  $C$  with a probability  $P_{\#}$  at each position) and that specify the unrepresented actions.  $[M]$  essentially contains all the knowledge of **XCS** about the current problem instance. Given  $[M]$ , **XCS** estimates the payoff for each possible action forming a *prediction ar-*

ray  $P(\mathcal{A})$ ,

$$P(A) = \frac{\sum_{\text{cl.} A=A \wedge \text{cl} \in [M]} \text{cl.} r \cdot \text{cl.} f}{\sum_{\text{cl.} A=A \wedge \text{cl} \in [M]} \text{cl.} f}, \quad (47.1)$$

where classifier parameters are addressed using the dot notation.  $P(A)$  computes the fitness-averaged Q-value estimates for each action in the current state  $s$ . Thus,  $P(A)$  can be used to decide on the currently most promising action.

Any action selection policy may be applied, such as choosing the action with the largest Q-value expectation. Because XCS relies on exploring the complete problem spaces, however, it is important that all actions are applied sufficiently frequently. Alternatively, also the prediction error estimates may be considered for action selection – choosing, for example, that action with the highest fitness-averaged  $\varepsilon$  value with the aim of maximizing information gain (see also more elaborate techniques surveyed recently in the computational intelligence literature [47.27]).

After the choice of an action  $A$ , an *action set*  $[A]$  is formed, which contains all classifiers in  $[M]$  that specify the chosen action. Moreover, the chosen action is executed, feedback is received in the form of scalar reward  $R \in \mathbb{R}$ , and the next problem instance may be perceived. In conjunction with the maximum  $P(A)$  derived from the resulting match set, the  $[A]$  formed is updated according to the estimated Q-value signal, which is  $R + \gamma \max_{A \in \mathcal{A}} P(A)$ . Moreover, the steady-state GA may be applied, reproducing two classifiers in  $[A]$ , but choosing classifiers from  $[P]$  for deletion. In classification problems – often also termed *single-step problems* – the Q-learning

update only considers the immediate reward  $R$ . Figure 47.3 illustrates the iterative learning process applied in XCS.

### Rule Evaluation

To evaluate the classifiers, it is crucial to update their parameter estimates and derive a relative fitness estimate. Parameter updates are applied iteratively in respective action sets. Usually, the prediction error is updated before the prediction and the fitness. Other parameters may be updated in any order.

In particular, the reward prediction error  $\varepsilon$  of each classifier in  $[A]$  is updated by

$$\varepsilon \leftarrow \varepsilon + \beta(|\rho - R| - \varepsilon), \quad (47.2)$$

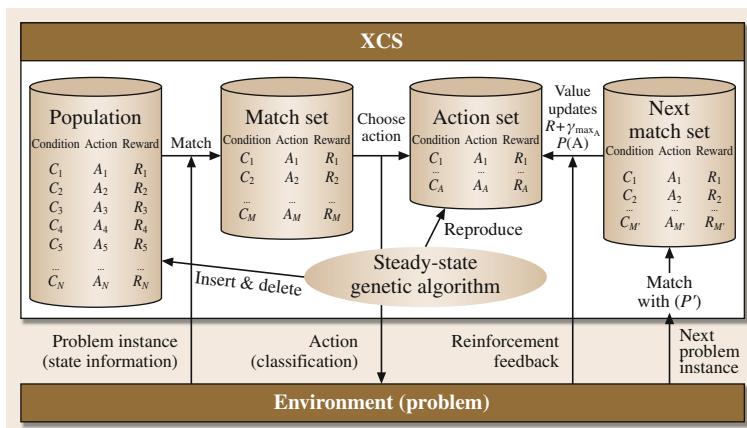

where  $\rho = R$  in classification problems and

$$\rho = R + \gamma \max_{A \in \mathcal{A}} P(A)$$

in multi-step reinforcement learning problems. Parameter  $\beta \in [0, 1]$  specifies a learning rate, which is typically set to values between 0.05 and 0.2. The higher the value of  $\beta$  is, the more the  $\varepsilon$  value depends on the most recent problem interactions. Next, the reward prediction  $r$  of each classifier in  $[A]$  is updated by

$$r \leftarrow r + \beta(\rho - r). \quad (47.3)$$

Note that XCS essentially applies Q-learning updates, where Q-values are not approximated by a tabular entry but by a collection of rules expressed in the prediction array  $P(\mathcal{A})$  [47.21].

**Fig. 47.3** The XCS classifier system learns iteratively online. With each iteration it forms a match set given the current problem instance. Next, it chooses an action or classification and applies it. After the perception of feedback, the classifiers in the corresponding action set  $[A]$  are updated and the steady-state GA is applied. After that, the next problem iteration proceeds

To update the fitness estimate of each classifier in  $[A]$ , a current scaled relative accuracy  $\kappa'$  is determined.

$$\kappa = \begin{cases} 1 & \text{if } \varepsilon < \varepsilon_0 \\ \alpha \left(\frac{\varepsilon_0}{\varepsilon}\right)^v & \text{otherwise} \end{cases}, \quad (47.4)$$

$$\kappa' = \frac{\kappa \cdot \text{num}}{\sum_{\text{cl} \in [A]} \text{cl.}\kappa \cdot \text{cl.}\text{num}}. \quad (47.5)$$

$\kappa'$  essentially measures the current inverse error of a classifier.  $\varepsilon_0$  specifies the targeted error below which a classifier is considered maximally accurate.  $\kappa'$  then determines the current relative accuracy with respect to all other classifiers in the current action set  $[A]$ . Thus, each classifier in  $[A]$  competes for a limited fitness resource, which is distributed relative to the current accuracy estimates  $\kappa$ . Finally, the fitness estimate  $f$  is updated given the current  $\kappa'$  by

$$f \leftarrow f + \beta(\kappa' - f). \quad (47.6)$$

In effect, fitness reflects the moving average, set-relative accuracy of a classifier. As before,  $\beta$  controls the sensitivity of the fitness estimates to changes in the population.

The action set size estimate  $as$  is updated similarly to the reward prediction  $R$  but with respect to the current action set size  $|[A]|$

$$as \leftarrow as + \beta(|[A]| - as), \quad (47.7)$$

resulting in an action set size adaptation to changes  $|[A]|$  in an order similar to the fitness changes. Parameters  $r$ ,  $\varepsilon$ , and  $as$  are updated using the *moyenne adaptive modifiée* technique [47.28]. This technique sets parameter values directly to the average of the so far encountered cases until the resulting update is smaller than  $\beta$  (which is the case after  $1/\beta$  updates). Finally, the experience counter  $exp$  is increased by one. If the **GA** is applied, the time stamps  $ts$  of all classifiers in  $[A]$  are set to the current iteration time  $t$ .

### Rule Evolution

XCS applies a steady-state genetic algorithm (**GA**) for rule evolution. Given a current action set  $[A]$ , the **GA** is invoked if the average time since the last **GA** application (stored in parameter  $ts$ ) in  $[A]$  is larger than threshold  $\theta_{GA}$ . This mechanism is applied to ensure sufficient evaluation of classifiers, as well as to control

unbalanced sampling. The higher the threshold  $\theta_{GA}$  is, the slower evolution proceeds, but also the less prone XCS is to unbalanced problem sampling [47.29].

The steady-state **GA** first selects two parental classifiers for reproduction in  $[A]$ . While this selection process was done by proportionate selection based on fitness in the original **XCS**, more recently it was shown that tournament selection can improve the robustness of the system highly significantly [47.30]. Tournament selection in **XCS** chooses the classifier with the highest fitness from a tournament of randomly chosen classifiers from  $[A]$ . The tournament size is usually set relative to the current action set size  $|[A]|$  to  $\tau \cdot |[A]|$ . Two classifiers are selected in two independent tournaments. The selected classifiers are reproduced generating the offspring. Crossover and mutation are applied to the offspring. The parents stay in the population. Mutation usually changes each condition and action symbol randomly with a certain probability  $\mu$ . Crossover exchanges condition and action symbols. Often, simple uniform crossover is applied (exchanging each symbol with a probability of 0.5). However, also more sophisticated estimation of distribution (**EDAs**) algorithms have been applied for more effective building block processing [47.31].

The offspring parameters are initialized by setting prediction  $R$ ,  $\varepsilon$ ,  $f$ , and  $as$  to the parental values. Fitness  $f$  is often decreased to 10% of the parental fitness. Experience counter  $exp$  and numerosity  $num$  are set to one.

The resulting offspring classifiers are finally added to the population. In this case, **GA subsumption** may be applied [47.32] to stress generalization. **GA subsumption** searches for another classifier in  $[A]$  that may subsume an offspring classifier. This classifier must have a more general condition than the offspring classifier, its error estimate must be below  $\varepsilon_0$ , and its experience counter must be sufficiently high ( $exp > \theta_{sub}$ ). If such a classifier is found, the offspring is *subsumed*, increasing the numerosity of the more general classifier by one and discarding the offspring.

The population of classifiers  $[P]$  is maximally of finite size  $N$ . When this size is exceeded after offspring insertion, classifiers are deleted from  $[P]$ . Fitness proportionate selection is applied depending on the action set size estimates  $as$ . Note that tournament selection is not suitable in this case because a balance in the action set sizes is most desirable. The likelihood of deletion of a classifier is further increased by a factor  $\bar{f}/f$  if this classifier is *experienced*  $exp > \theta_{del}$  and additionally if its fitness  $f$  is below a fraction  $\delta$  of the average fitness  $\bar{f}$  in the population.

### 47.2.2 When and How XCS Works

From the description above it may seem hard to understand why **XCS** learns successfully. This section provides intuition about when and how **XCS** works and points to relevant literature that quantifies the sketched-out intuition.

The two interacting learning components, which are gradient-based rule evaluation and evolutionary-based rule evolution, are strongly interactive. From an evolutionary point of view, several evolutionary pressures yield particular learning biases. Since reproduction is designed to maximize fitness, **XCS** strives to develop maximally accurate classifiers applying a *fitness pressure* [47.33]. Meanwhile, rules are selected in  $[A]$  for reproduction but they are selected in  $[P]$  for deletion. Since the classifier conditions in  $[A]$  will on average cover a larger subspace, i. e., they have a larger *volume* than the average condition volumes of classifiers in  $[P]$ , more general classifiers will be reproduced on average (when ignoring the fitness pressure for the moment), yielding a sampling-dependent *generalization pressure* [47.33]. In consequence, it has been put forward that **XCS** strives to evolve a *complete problem solution* that is represented by *maximally general classifiers* that are meanwhile *maximally accurate* (error below the threshold  $\varepsilon_0$ ). The resulting problem solution representation was previously termed the *optimal solution representation*  $[O]$  [47.34].

While these evolutionary pressures generally describe how the **GA** in **XCS** works, successful rule evolution still relies on sufficiently accurate fitness signals. Thus, rule evaluation needs to have enough time to estimate rule fitness before expected rule deletion. This leads to a *covering bound*, which quantifies the need for a sufficiently large population size given a particular initial condition volume. Moreover, each particular problem can be assumed to have a certain complexity in terms of subspace sizes that need to be separated for learning to take place, that is, for decreasing the error below the average deviation of the payoff signal to perceive an initial fitness signal towards higher accuracy. In consequence, the subspace size requires the generation of classifiers with condition volumes of maximally that size, consequently yielding a *schema bound* on the population size to be able to cover the full problem space with such condition volumes. Finally, better classifiers with a certain condition volume need to be able to grow, that is, have reproductive opportunities before deletion can be expected, consequently yielding a *reproductive opportunity bound*.

Together these bounds give estimates on the necessary initial condition volumes and the resulting maximal population size necessary to cover a problem space. For example, given the need for an initial classifier volume of 0.01 of the encountered problem space, the population size  $N$  should be set to about  $10/0.01 = 1000$  to assure proper rule evolution. Given that these factors are satisfied, better classifiers are assured to be identified and to grow in the population with high probability. For binary and for real-valued problem domains, these considerations have been quantified, showing that **XCS** is an approximate polynomial-time learning algorithm in problem domains with bounded complexity [47.25, 35].

The considerations above ensure the theoretic growth of better classifiers. However, the evolutionary component may still destroy relevant classifier structures due to mutation and crossover. Thus, neither mutation nor crossover may be overly disruptive. In extreme cases, where highly unstructured subspaces may need to be identified and recombined, estimation of distribution algorithms can help to identify these subspaces [47.31, 36]. In most cases, though, a sufficiently low mutation rate and uniform crossover suffice to learn successfully. However, clearly mutation is mandatory to detect more accurate classifier structures over time. Thus, a good compromise is necessary to ensure that offspring is usually mutated but its structure is not fully destructed. In the binary domain, for example, the mutation probability is consequently often set to  $1/l$ , where  $l$  is the number of bits of a problem instance. This is a typical choice for the mutation strength used in genetic algorithms – essentially setting the expected number of attributes that will be mutated to one.

### 47.2.3 When and How to Apply XCS

From the reflections above it becomes clear that **XCS** is designed to learn the target function of a problem by a population of locally accurate predictors, that is, classifiers. This target function may be the Q-value function in **RL** problems, a *correctness* function in classification problems, or also any other type of function. **XCS** is best suited to be applied in problem domains that can be partitioned into subspaces within which simple predictions yield accurate values. Moreover, **XCS** is even better suited to be applied to problems where regularities in the target function can be well-represented in classifier conditions, that is, subspaces in which the

function values are approximately equal should be compactly representable with few classifiers. Overall, **XCS** thus strives to develop distributed problem solutions in the form of a set of locally partially overlapping classifier structures, which cover the whole sampled problem space in a generalized way.

As long as a condition representation can be chosen that identifies expectable regularities in a data set or also in a reinforcement learning problem well, **XCS** is a good candidate to optimize these local condition structures iteratively online. However, also in offline, data mining-based classification problems **XCS** was applied successfully and it was shown that the generalization and accuracy performance **XCS** yield is comparable to other state-of-the art machine learning algorithms [47.25, 37], such as decision tree learners, instance-based classifiers, or support vector machines. Thus, **XCS** may be applied to multi-step Q-learning problems but also to single-step classification problems and general regression problems. Online generalization and optimal condition structuring for accurate predictions are the major features of **XCS**. From a regression perspective, **XCS** is a non-parametric regression algorithm that strives to minimize the expected absolute function approximation error, or also the expected squared function approximation error as put forward elsewhere [47.24].

The two components, (a) gradient-based rule prediction approximation and evaluation and (b) evolutionary rule structure evolution, are the key to successful **XCS** applications. With respect to rule structure evolution, also the **XCS** system strongly depends on distance representations, which can be compared with general kernel representations as used in support vector machines and elsewhere [47.38, 39]. As long as the represented kernel-based condition structures can be meaningfully modified by genetic operators, evolution and thus also **XCS** can be applied. Meanwhile, also sensible value predictions need to be generated. Gradient-based methods work best to approximate these predictions, whether the prediction is a single value, is computed linearly or polynomially from input, or its structured otherwise depends on the problem at hand and the gradient-based approximation approach available. The more the prediction structure fits with the regularities in the target function, the faster and more robust learning can be expected. While such structural considerations can improve system performance, the successful applications of **XCS** to various problem domains show that successful learning is usually not precluded by suboptimal structural choices.

#### 47.2.4 Parameter Tuning in **XCS**

While **XCS** does, indeed, specify many parameters, only few parameters are really crucial. All other parameter values can typically be set to standard values. Here we discuss some rules of thumb for tuning the critical parameter settings and also provide standard settings. While the following recommendations have not been published elsewhere so far, they can be derived from observations and other recommendations found in the literature [47.25, 35, 40].

The two most important parameters are the maximal population size  $N$  and the strived-for error threshold  $\varepsilon_0$ . The larger the population size  $N$  is, the more capacity **XCS** has for learning and thus the more complex problems **XCS** can learn. On the other hand, the larger  $N$  is, the slower **XCS** learns, because it reproduces and deletes only two classifiers in a typical learning iteration. Parameter  $\varepsilon_0$  specifies the targeted approximation error. In continuous function approximation problems, smaller  $\varepsilon_0$  values demand finer problem space partitions and thus larger population sizes to cover the whole problem space and to enable reproductive opportunities (see above). Moreover,  $\varepsilon_0$  can partially determine the fitness signal available to **XCS**: if  $\varepsilon_0$  is chosen very small, (47.4) will yield values very close to zero for all highly inaccurate classifiers. Thus, overly small  $\varepsilon_0$  values should be avoided. In noisy problems,  $\varepsilon_0$  should thus also not be chosen much smaller than the standard deviation of the noise expected in the function value signal.

Without much knowledge of a problem, one may start with a rather small population size  $N$  – say 1000 – and evaluate learning progress in this setting with a desired  $\varepsilon_0$ . If the generated approximation error over time does not decrease, then  $\varepsilon_0$  should be set to about 1/10 of the encountered error. Next, the population size  $N$  should be progressively increased, for example, to  $N = 5000$  or more. If still no error decrease is observed, further analysis is necessary. If the population is filled with classifiers but the match set sizes are very small (below 5), better classifiers probably do not receive enough reproductive opportunities. In this case, first the initial condition volume should be increased – for example, in the binary domain the probability  $P_{\#}$  would need to be increased (up to close to 1). If the match set still decreases to sizes below 5, the problem is rather hard, requiring a further population size increase. On the other hand, if the match set sizes are very large (above 100), then over-generalization takes place and **XCS** apparently does not pick up the fitness signal. In this case,

the initial condition volume should be decreased. If this does not help, then the **GA** application rate should be decreased to enforce a more accurate classifier evaluation before evolution applies. This can be accomplished by increasing the threshold  $\theta_{GA}$  to say 100, 500, or even higher. An increase in  $\theta_{GA}$  can also be crucial in problems where the problem domain is sampled highly unevenly, as is studied in detail elsewhere [47.29].

Several other parameter settings may be checked as well; the mutation rate should not be set overly high. As stated above, in the binary problem domain,

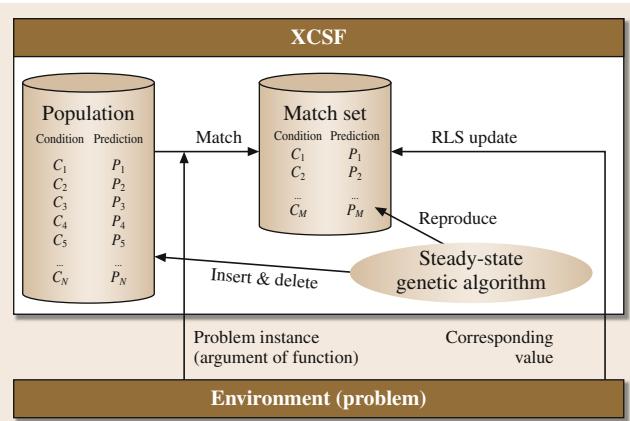

for example, a mutation rate of  $\mu = 1/l$ , where  $l$  denotes the condition size, is a good rule of thumb. Crossover can mostly be applied without restrictions ( $\chi = 1.0$ ) – especially when tournament selection for reproduction is chosen because in this case disruption is often prevented by choosing two equal classifiers. Other parameters can be safely set to somewhat standardized values. A typical initial parameter setting for **XCS** is:  $N = 1000$ ,  $\varepsilon_0 = 0.1$ ,  $\mu = 1/l$ ,  $\chi = 1$ ,  $\alpha = 1$ ,  $\beta = 0.2$ ,  $\nu = 5$ ,  $\theta_{GA} = 25$ ,  $\gamma = 0.9$ ,  $\theta_{del} = 20$ ,  $\delta = 0.1$ ,  $\theta_{sub} = 20$ ,  $P_{\#} = 0.5$ , and  $\tau = 0.4$ .

### 47.3 XCSF

The **XCS** classifier system for real-valued inputs was introduced by *Wilson* in 1999, introducing Michigan-style **LCSs** to the real-valued problem domain [47.41, 42]. It was further enhanced to approximate continuous real-valued function surfaces in 2001/2002 [47.43], yielding an iterative online learning non-parametric regression system. **XCS** for function approximation (**XCSF**) essentially enhances and modifies **XCS** by

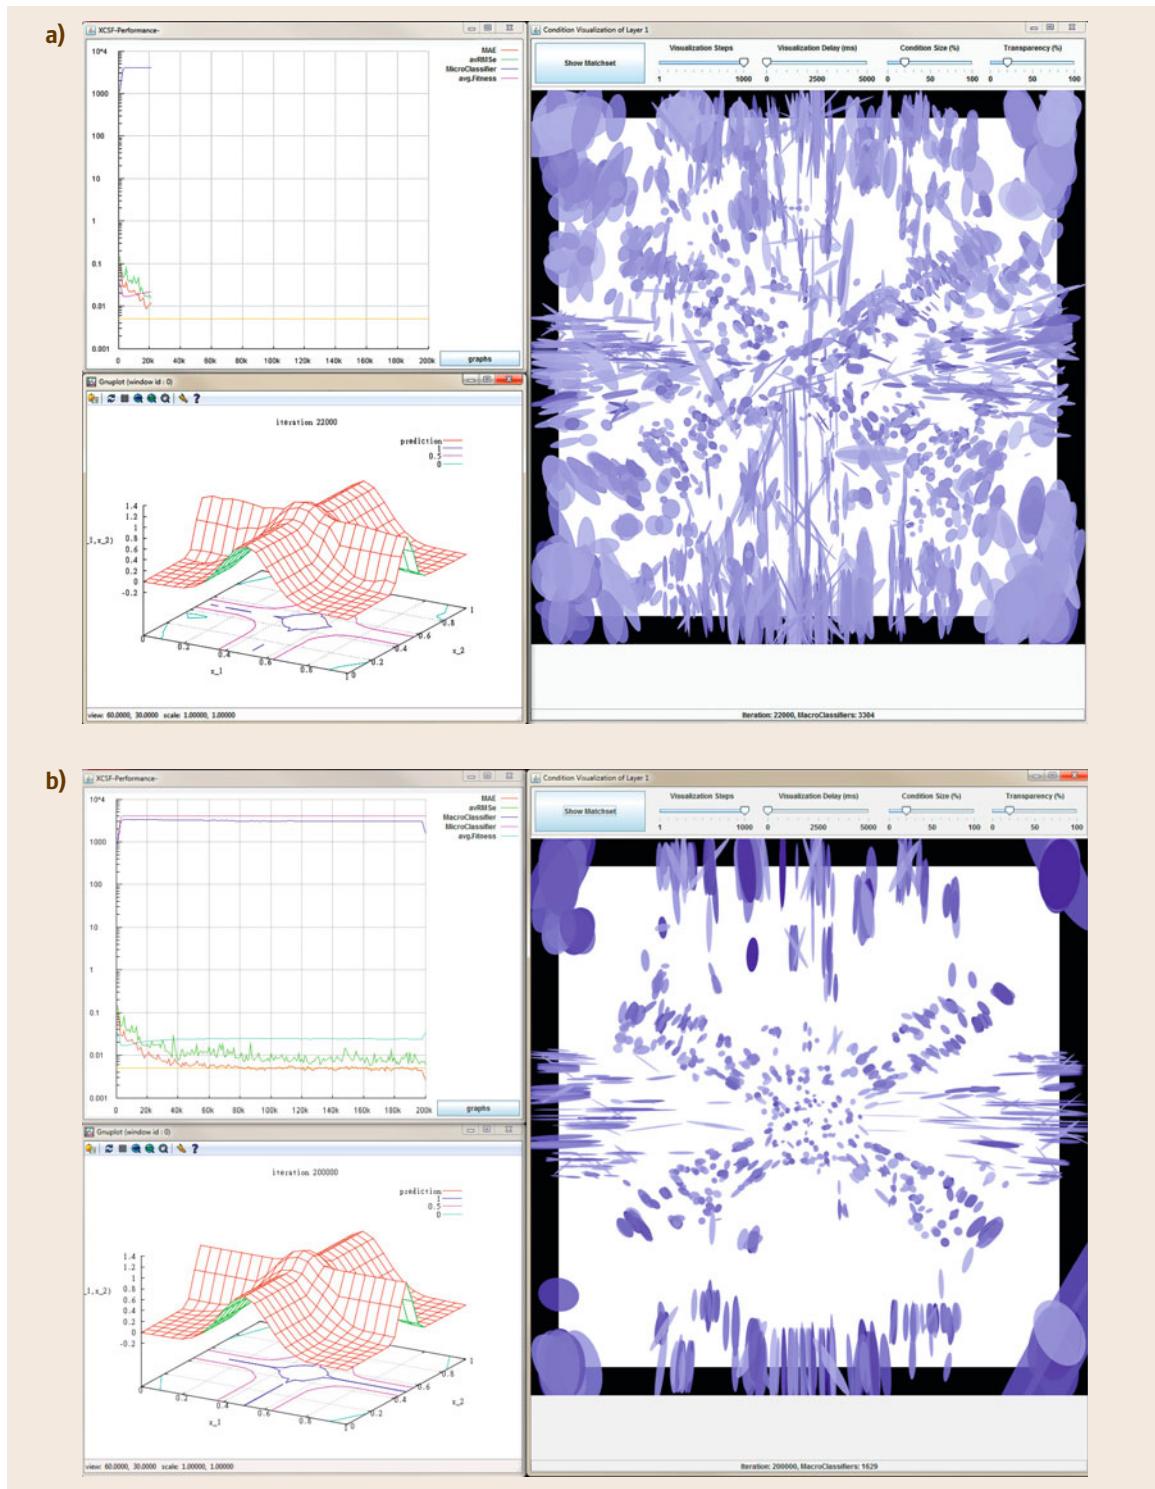

changing its classifier condition structure to accept real-valued input. Moreover, the prediction part no longer predicts single values, but it computes its prediction from the input using linear approximation techniques, such as recursive least squares (**RLS**) [47.44]. Finally, the action part of the system is removed, applying the parts of the algorithm that were previously applied to [A] to the match set [M] in **XCSF**. Figure 47.4 illustrates the iterative learning process in **XCSF**.

**XCSF** is thus a regression system that solves function approximation problems by developing partially overlapping locally weighted projections in the form of a population of classifiers. In this form, **XCS** develops problem solutions that are similar to those developed by the locally-weighted projection regression algorithm (**LWPR**), which is rather well-known in the robotics community [47.45]. A comparative study has shown that **XCSF** can outperform **LWPR** in various problem domains [47.46], often yielding better problem space partitionings, as well as more accurate function value approximations with a comparable number of individual locally linear approximators (i. e., classifiers). In **XCSF**, each classifier specifies in its condition the subspace within which it is applicable. Thus, the condition may be compared with a receptive field determining the neural activity of the classifier. Moreover, each classifier specifies a linear approximator weighted within its subspace. In effect, the function approximation problem is approximated by locally-weighted, overlapping linear approximations. While typically the weighting is

**Fig. 47.4** The **XCSF** classifier system learns linear value predictions and usually does not specify actions. The feedback is the actual function value, which is used to update the linear approximators of the matching classifiers. The consequent error and fitness estimation updates are then considered in the evolutionary component for further optimization of the condition structures

**Fig. 47.5a,b** Screenshots of the **XCSF** program learning to approximate the crossed ridge function. Current performance values are plotted on the *top left*. The current approximation surface is approximated on the *bottom left*. On the *right-hand side* the classifier condition structures are plotted. For visualization purposes, the receptive field sizes are plotted smaller than their actual size. *Darker* classifier conditions have higher fitness values ►

fitness-dependent, also a weighting based on the distance to the center of the classifier condition can be applied.

With this structure it has been shown that **XCSF** is very well suited for developing any type of kernel structure [47.47]. In effect, various condition structures have been applied, including rectangular structures with and without rotation and with various forms of representation [47.35, 48, 49]. Moreover, the linear approximations may be enhanced to polynomial approximations and others [47.50]. Finally, it is also possible to cluster a contextual space with conditions, while approximating linear (or other) predictions given totally different inputs. For example, the velocity kinematics of an arm can be predicted locally dependent on the angular arm constellation for redundancy resolution [47.51] (see further details below). Thus, **XCSF** is a highly flexible system with which other modifications in the condition and prediction parts of the classifiers may still yield highly vital system applications.

As an example, we applied **XCSF** to the *crossed ridge* function – a function that has been used as a benchmark in the neural computation and machine

learning community for many years [47.45, 52]. The function contains a mix of linear and non-linear subspaces. It is specified in two dimensions as follows

$$f_1(x_1, x_2) = \max \{ \exp(-10x_1^2), \exp(-50x_2^2), \\ 1.25 \exp(-5(x_1^2 + x_2^2)) \} . \quad (47.8)$$

We ran **XCSF** with a maximum population size  $N = 4000$  and a target error  $\epsilon_0 = 0.005$  on this function, applying a condensation mechanism late in the run. Figure 47.5 shows that **XCSF** is able to yield a good function approximation very early in the run. The evolving classifier structures learn to suitably partition the problem space into local subspaces. In consequence, a smooth overall approximation surface is generated. Note how the inverse exponential hill in the center is approximated with nearly circular receptive fields, while the fields are selectively elongated in the  $x_1$  or  $x_2$  dimension due to the non-linearities caused by the ridges extending to the four sides. Towards the corners of the input space, the function flattens out so that the receptive fields become increasingly wider.

## 47.4 Data Mining

Data mining is a rather large field of research that generally addresses the challenge of extracting knowledge from data. In the **LCS** realm, the addressed data usually consists of a set of data instances, where each instance specifies a set of features and a corresponding class the data instance belongs to. **LCSs** then typically learn to mine the data by predicting the class likelihoods of unseen data instances, as well as by identifying the most relevant features and feature interactions for classification. Particularly Pitt-style **LCSs** have proven to be highly valuable in data mining applications. However, also the **XCS** classifier system was successfully applied in this domain.

The **XCS** system was also converted to an offline learning system; the sUervised classifier system (**UCS**) algorithm [47.53] determines classifier predictions and resulting fitness values in a supervised manner. Meanwhile, the other learning aspects of **UCS** were derived from **XCS**. Both, **XCS** and **UCS** have shown effective if not even superior prediction accuracies in various data mining tasks – most of them taken from the UCI machine learning database repository [47.54]. When applying always the same standard setting and comparing with various other decision making algo-

rithms, such as support-vector machines, decision tree learning, naive Bayes classifiers, and others implemented in the WEKA machine learning tool [47.55], **XCSF** outperformed these competing techniques in many cases – often depending on the problem at hand [47.25]. A similar performance was achieved with **UCS**, outperforming **XCS** in some cases due to its more accurate classifier prediction estimates. **XCS** was also further enhanced to be able to deal with highly unbalanced datasets in data mining domains by automatically adjusting the threshold that controls the frequency of **GA** applications  $\theta_{GA}$  [47.29].

Pitt-style **LCSs** have been evaluated and applied to data mining problems even more extensively. The typical offline-learning scenario faced in data mining particularly suits the Pitt approach. However, also the fact that often very compact rule sets are strived for is advantageous for the Pitt approach. More than 10 years ago, the GALE architecture [47.56, 57] yielded very good performance results on a collection of datasets from the UCI repository. GALE distributes its evolutionary process adding additional niching biases due to a grid-based spatial distribution of individuals. A comparative study of GALE, **XCS**,

and other machine learning algorithms can be found in [47.58].

The GAassist architecture [47.59, 60] develops a priority list of classification rules. The advantage of GAassist is its developing compactness. A comparative analysis with XCS is provided in [47.61]. Later, the architecture was enhanced with ensemble learning techniques [47.62] and memetic algorithms [47.63], proving high scalability and fast learning of very compact rule sets.

Recently, many efficiency enhancement techniques from the **GA** literature (cf. [47.64]) and from other fields, including bioinformatics and systems biology [47.65] were applied to various **LCSs**. These techniques can help tremendously to improve the learning speed of **LCSs**, particularly in data mining realms. For

example, *windowing techniques* select subsets of data instances to speed up the classifier evaluation process. *Fitness surrogates* were used to make the fitness estimation even cheaper [47.66]. *Hybrid methods* were already mentioned above; they combine traditional **GA** operators with informed ones, as is done when applying memetic algorithms, which locally improve the developing classifier structures when applied to **LCSs**. In combination, such techniques can yield **LCSs** that not only produce highly accurate classification performance and good generalizations, but they also offer solution interpretability allowing mining of the knowledge developed in the **LCS** rules, and they generate these results without requiring much computational time – which is often comparable to the time needed by much simpler machine learning techniques.

## 47.5 Behavioral Learning

While the application of **LCSs** to data mining problems will certainly still produce many further impressive results and promises to yield novel, deep insights into data structures, **LCSs** were originally designed as cognitive systems. Thus, in the following we will focus on **LCSs** as cognitive systems, their structures, and their potential as neural cognitive models. As had been sketched out above, the **XCS** classifier system in particular was compared with Q-learning in **RL**. We start from this perspective and detail various successful applications of **XCS** in reinforcement learning problems. Next, **ALCSs** are surveyed. **ALCSs** learn generalized cognitive maps that are suitable to apply Sutton's Dyna algorithm and value iteration techniques in general. A strong relation to factored **RL** techniques was pointed out recently in this respect [47.67]. Finally, robotics applications of **LCSs** are discussed and their potential is revealed.

### 47.5.1 Reward-Based Learning with **LCSs**

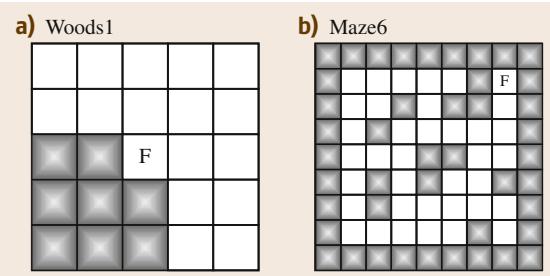

From the beginning [47.2] a big appeal to **LCSs** lay in the fact that they are designed for reward-based learning. Once the original bucket-brigade algorithm was replaced by Q-learning techniques, a theory developed in the **RL** community also applied to **LCSs** to a certain extent.

In **XCS**, in particular, it was shown that the system approximates the Q-value function by a collection of classifiers. The prediction array (47.1) calculation essentially approximates the current Q-value estimates for the current state in the environment. The fitness

weighting based on the relative accuracies, which are normalized to one, assures that these Q-value estimates on average do not over or underestimate the expected Q-value. Moreover, since Q-learning is an off-policy learning technique, **XCS** is well-suited to be combined with it because also **XCS** benefits from exploring all possible state-action combinations in the long run – striving to develop an approximation of the complete Q-value function in the problem space.

As a result, **XCS** has been successfully applied to learning optimal paths in various maze environments. Starting from the Woods1 and Woods2 environments proposed by Wilson [47.20, 21], XCS's performance and generalization capabilities have been investigated in various mazes [47.68]. For illustrative purposes such mazes are shown in Fig. 47.6. These maze environments provide information about the surrounding grid cells, indicating whether they are either free or occupied by an obstacle or by food. Reaching the latter cell usually results in a reward trigger. Movements are typically possible to the eight surrounding cells, yielding a rather large action space. The point of providing sensory state information rather than cell IDs or coordinates is that **XCS** is then able to exhibit its generalization capabilities. It essentially manages to generalize over the sensory state space ignoring irrelevant bits and generalizing over the states with respect to state-action combinations that yield the same reward.

Performance in many of these environments has yielded extreme generalization capabilities. For exam-

**Fig. 47.6a,b** Two highly typical maze environments used as benchmarks in the **LCS** literature for generalized reinforcement learning. Woods1 is a toroidal maze. In Maze6 the food location is much harder to find. In both cases, the **LCS**-controlled agent perceives information about the eight neighboring cells encoding free, blocked, and food cells by means of two bits. The agent can execute movements to each of these cells. Movements to blocked cells yield no reward. A movement to the food cell triggers reward and a reset of the agent

ple, in the Maze6 environment (Fig. 47.6) up to 90 irrelevant bits were introduced, which changed randomly while interacting with the environment. While learning was slightly delayed and a larger population size was needed for successful learning, the optimal Q-value function was still extracted from iterative interactions [47.25]. Thus, **XCS** learned the optimal Q-value function in a problem space that contained more than  $10^{30}$  potential sensory state encodings. Also rather noisy action outcomes did not preclude learning success. Later, it was shown that highly effective generalizations are even possible when each bit in the sensory encoding is relevant. In [47.36] the encoding for each bit was changed to a nested Boolean function, such as the parity function. **XCS** was still able to learn the optimal Q-value function, while Q-learning without generalization failed miserably due to the large state space. Thus, **XCS** is able to identify those aspects of the available sensory information that are relevant for accurate reward predictions.

To successfully apply **XCS** in these scenarios, one crucial modification was necessary to stabilize the Q-values and thus the derived fitness values: the update of the classifier predictions had to be further modified by the error gradient factor, converting (47.3) to

$$r \leftarrow r + \beta(\rho - r) \frac{f}{\sum_{cl \in [A-1]} cl.f} . \quad (47.9)$$

The exact derivation of this equation can be found in the literature [47.69]. The gradient term essentially re-

sults in much more stable performance and successful learning and generalization in problems that require the establishment of long reward chains. It stabilizes the reward learning by down-scaling updates of inaccurate and unreliable classifiers. Consequently, these rules do not tend to over-estimate reward, and thus learning progress is stabilized. As a further consequence, **XCS** with gradient-based reward predictions updates was also successfully applied to blocks world problems, in which even more generalizations are possible [47.25].

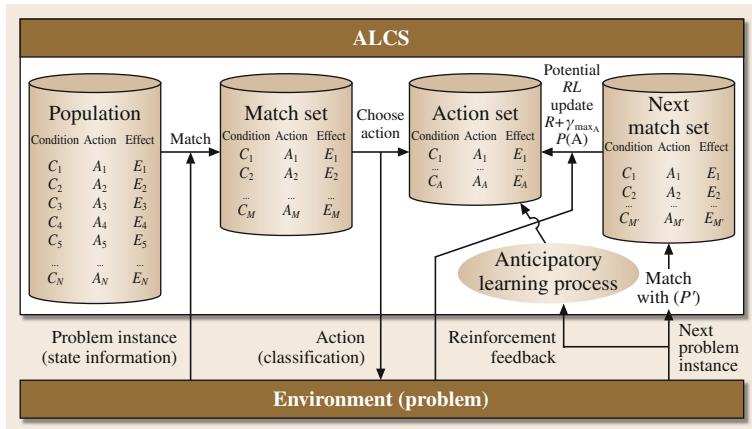

The generalization capabilities of **LCS**s reached even as far as being successfully applied to control simple light following behavior on a real robot platform [47.70, 71]. In this case, however, reward learning was maximized and no complete Q-value function approximation developed. Nonetheless, this work constituted one of the first successful application in the robotics domain.

Besides condition-action Michigan-style **LCS**s, such as the **XCS**, other Michigan-style **LCS** techniques have been applied for behavioral learning and also for learning cognitive maps. Such anticipatory learning classifier systems are surveyed in the following.

#### 47.5.2 Anticipatory Learning Classifier Systems

Anticipatory learning classifier systems (**ALCS**s) are learning systems that learn a generalized predictive model or *cognitive map* [47.72] of the encountered environment online. **ALCS**s are typical Michigan-style **LCS**s. However, in contrast to the usual classifier structure, classifiers in **ALCS**s have a state prediction or *anticipatory* part that predicts the environmental changes in the environment caused when executing the specified action in the specified context. As in **XCS**, **ALCS**s derive classifier fitness estimates from the accuracy of their predictions. However, the accuracy of the anticipatory state predictions are considered, rather than the accuracy of the reward prediction. Figure 47.7 illustrates the typical structures and learning processes that apply in an **ALCS** architecture.

*Rick Riolo* originally proposed an **ALCS** that generated its cognitive map mediated by a *message list* storage system, which was also used in Holland's original classifier system architecture [47.73]. However, this approach appeared to not be sufficiently elegant to enable any serious learning. Starting with *Stolzmann*'s anticipatory classifier system [47.74], various **ALCS** architectures were developed. Particularly in maze problems, optimal behavior was achieved with

**Fig. 47.7** Instead of the condition-action-reward prediction rules in typical LCSs, ALCSs encode and develop condition-action-effect rules. Typically, the structural optimization of these rules is done by a combination of evolutionary and heuristic techniques

various ALCSs [47.75–79]. To prevent the development of overgeneral models for concurrent reward learning, the reward learning process was often decoupled, yielding a system that learns a cognitive map based on LCS principles, and, additionally, a state value estimation system. In combination, DYNA-based learning techniques [47.80] were applied to improve the state value estimations also offline. These techniques allowed the simulation of animal-like behavioral patterns, such as reward adaptations based on knowledge about the behavioral consequences in rats in a T-maze environment [47.81], as well as in controlled devaluation or satiation experiments [47.82]. In these studies it was also pointed out that ALCSs do not only allow DYNA-based reward learning updates, but also enable the application of search and planning techniques for improving behavioral performance of the system. Even curiosity mechanisms have been added [47.83] to speed up the learning progress. Most approaches, however, never generalized the list of states with associated rewards.

The combination of the ACS2 system with the XCS system for state-value estimations, terming the resulting system XACS (x-anticipatory classifier system), may be the one with the most current potential for future research [47.84]. XACS essentially applies two LCS learning mechanisms: one being an ALCS architecture in the form of ACS2, which learns a cognitive model of the encountered environment, and the other one being the XCS system, which learns state-value estimations in this case. Figure 47.8 illustrates the components in the XACS architecture and their interactions.

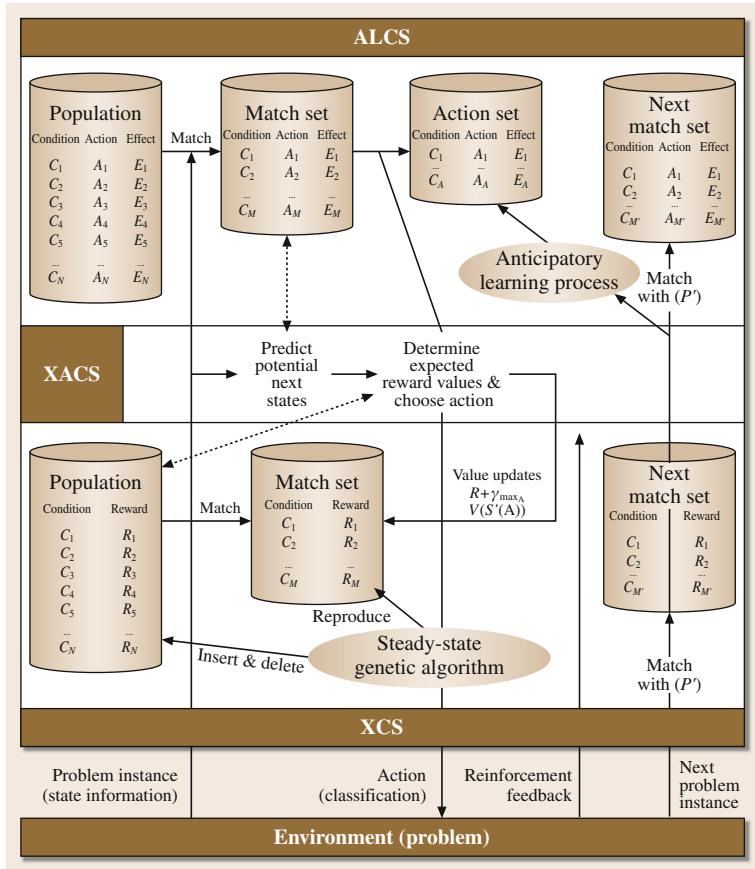

XACS has been shown to develop optimal behavior in blocks world problems in which other approaches failed to yield proper generalizations and resultingly

optimal behavior control. Moreover, the reward-based generalization mechanism in XACS is directly based on the XCS classifier system, thus enabling the incorporation of any tools and representations developed for XCS so far. The generalizations that were developed confirmed the identification of task-relevant perceptual attributes. In the XCS components, reward-distinguishing attributes were identified. In the ACS2 component, on the other hand, state prediction-relevant components were detected. In consequence, generalized detectors for prediction with respect to reward and state could be distinguished. The implementation of other anticipatory mechanisms in XACS, such as task-dependent attentional mechanisms, further interactions of the learning components, and multiple behavioral modules for the representation of multiple motivations (or needs) [47.84] are still open issues in the LCS realm. Further research with ALCSs is expected to yield highly promising, cognitive learning architectures.

### 47.5.3 Controlling a Robot Arm with an LCS

We end this section of behavioral learning with the XCSF system. Over the last decade or so it has become increasingly clear that XCS is extremely well suited to partition a contextual space for the generation of accurate predictions. Predictions, however, do not necessarily need to be reward predictions. Behavioral consequences serve just as well as a target for predictions. The forward kinematics mapping in the robotics domain [47.85] offers even another potential target for learning.

Consequently, XCSF was modified to learn the forward velocity kinematics of a robotic arm in simu-

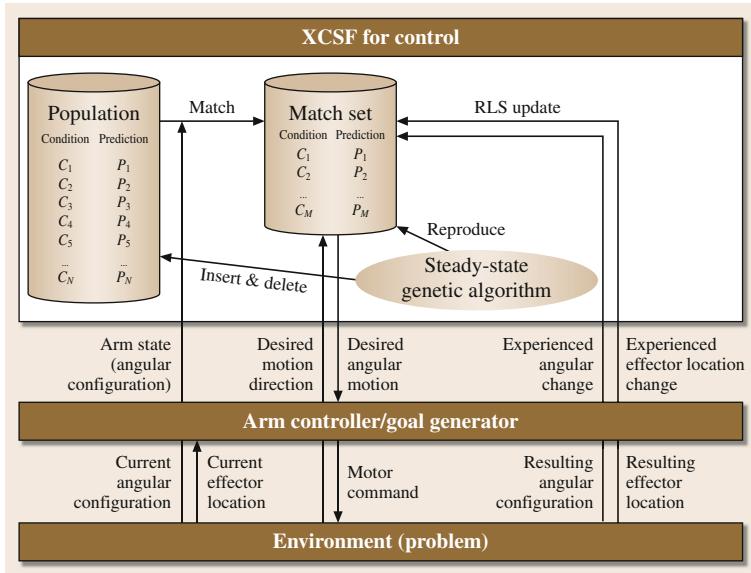

**Fig. 47.8** The **XACS** system combines the model learning capabilities of **ALCS**s with the generalizing reinforcement learning capabilities of **XCS**. Consequently, generalizations in the two system components are targeted towards a compact representation for accurate predictions and for reward predictions, respectively. The combined system enables the application of lookahead planning and search techniques for behavioral control as well as of reinforcement learning techniques and combinations thereof

lation [47.86]. To do so, **XCSF** projects its condition parts into the joint angle space of the robotic arm. However, its locally linear predictions receive as input small joint movements, that is, changes in joint space and predict the consequent change in task space, that is, changes of the end-effector location. This mapping has the great advantage that it is locally linear so that given a current joint angle constellation of the arm not only location changes of joint angle movements can be predicted but also directional motion of the end-effector can be invoked by inverting the locally linear forward velocity mappings. Seeing that those are linear, the inversion can be rather easily done using linear algebra techniques. Given a redundant arm system – one that has more degrees of freedom (i.e., joint angles to manipulate) than actual locations to move to – it is possible to add additional constraints to the arm motion. For example, the arm can be driven to maintain a *relaxed* arm posture while pursuing a certain goal or it may be forced to prevent moving a certain joint

angle at all [47.87]. Recent advancements in the exploration strategy, which can be self-induced by the **XCSF** controller during learning, have shown that **XCSF** is able to learn to control all seven degrees of freedom of a humanoid arm highly effectively – flexibly adhering to different constraints while pursuing motions to certain goal locations. Moreover, mappings could be learned in different reference frame representations. For example, end-effector locations were either represented in a Cartesian coordinate system or in a distance plus angles encoding. **XCSF** learned different classifier structures due to the differences in the linearities encountered. Nonetheless, **XCSF** yielded equally good arm control in both cases [47.51]. Figure 47.9 illustrates the **XCSF** setup for arm control.

These results confirmed that **XCSF** may very well be further developed into a cognitive system architecture for behavioral control. While this type of architecture was probably not the one envisioned by Holland originally, it may still prove highly valuable. Various

**Fig. 47.9** In the published robot arm control applications, **XCSF** clusters the contextual configuration state of the arm and learns linear approximations of the average Jacobian in the respective subspaces. In consequence, the system can generate both forward predictions of movement consequences as well as inverse control commands when directional movements of the arm are desired

neuroscientific evidence points out that similar forward-inverse predictive-control structures may be found in the cerebellum [47.88, 89]. Only more detailed knowledge on cortical and cerebellar structures may allow the direct comparison of the shapes and orientations of the receptive fields developed by the **XCSF** system and potential cortical and neural structures found in the brain.

While the brain may not implement actual evolutionary techniques literally, as **XCSF** does, it appears plausible that local competitions take place [47.90]. Moreover, it is known that neurons populate novel information sources once available – as **XCSF** does. Further research in neural computation with **LCSs** may prove highly valuable.

## 47.6 Conclusions

While **LCSs** have been applied to a wide variety of problems, still there are many potential developments that have not been further evaluated. In the following, potential future research directions are summarized.

At the moment nearly all **LCSs** are flat in that they develop one population of classifiers (or competing sets of classifiers in the Pitt-style system). All of the classifiers, however, apply to the same problem granularity. Ever since the introduction of **LCSs** by Holland, the development of *default hierarchies* was envisioned. However, so far it was never convincingly or rigorously accomplished [47.19]. Default hierarchies refer to classifier systems in which general rules predict one thing but more specialized rules predict exceptions of the general rule. The emergent development of default hierarchies in **LCSs** remains an open challenge.

With the most recent understanding of **LCSs** and the **XCS** system in particular, it seems that at least

the development of a hierarchically-structured **LCS** architecture is within our grasp. We expect such a hierarchical **LCS** to progressively refine its predictions in a hierarchical way. Default rules may gain a certain level of accuracy, but more specialized rules may identify exceptions of the default prediction. Alternatively, the more specialized rules may also simply add further accuracy to the default predictions where and when necessary. In the latter case, a hierarchical predictive system may develop that allows the progressive refinement of activated predictions until the finest prediction granularity in the hierarchical representation is reached.

When developing hierarchical **LCSs**, also network **LCSs** seem to be of vital importance. For example, when developing classifier structures in spatial domains that are intricately structured, a network structure may provide additional hints on the connectivity of

the space. Especially the case where **XCSF** learns velocity kinematics, or generally, contextually-dependent sensory-motor contingencies – as sketched out in the section on controlling a robot arm with **XCSF** above – a network structure can give additional hints on how the sensorimotor space is structured and may be traversed. Networks of **LCS** classifiers may allow the application of lookahead planning and goal-oriented control – as was pursued in early work in [47.91].

A network structure may also enable the speed-up of the **XCS** matching process. For example, when a problem space is sampled by means of a random walk process, overlapping classifiers may be directly identified within a classifier structure instead of applying a global matching process in each iteration. Also, when **XCSF** is used for goal-directed control – as mentioned above with respect to velocity kinematics – this may improve the efficiency of the system tremendously. Furthermore, given a hierarchically network structured **LCS** system matching may proceed from coarse-to-fine-grained levels. All these processes may speed up the matching, which is often considered a bottleneck in **LCS** research and has been improved by means of numerous approaches over the recent years [47.92, 93].

Besides these additions, also **ALCS**s may be pursued further, as sketched out above. From a cognitive modeling perspective, **ALCS**s essentially learn generalized schemata or production rules [47.94–96], which specify the expected state changes perceived after the execution of the specified action. Such rules may be applied by the cognitive science community for learning, for example, **ACT-R** structures [47.97]. The lookahead planning capabilities, the sensorimotor generalization capabilities, as well as the abstraction capabilities of these systems still ask for further development. The recent point that **ALCS**s can be very effectively applied

to factored **RL** problems [47.98] should be further pursued. Also, the combination of **ALCS**-based cognitive map or concept learning and **XCS**-based reward learning promises further research advancements.

Even without the addition of hierarchies, network structures, or anticipations, however, **LCS**s can be successfully applied to various domains including reinforcement learning problems, classification and data mining problems, and regression problems. **XCS**, in particular, learns iteratively online, striving for the development of a compact, maximally general, and maximally accurate problem solution. Pitt-style systems typically learn offline and are thus most promising in large-scale data mining tasks in which rather small compact sets of rules are searched for. Seeing that the learning mechanisms of **LCS**s are highly flexible, it is possible to substitute the condition of a classifier with any other form or condition structure, as long as this structure can be mutated and recombined in a way that small structural changes also yield small changes in the defined subspace within which the condition matches. Similarly, the prediction structure can be replaced with any other prediction structure that can be quickly and accurately adapted by suitable learning techniques. Thus, the available **LCS** techniques – such as **GALE** and **GAassist** on the Pitt side and **XCS**, **XCSF**, or **XACS** on the Michigan side – can be further exploited and combined with novel structures and forms of representations. Learning promises to be robust due the combination of a flexible evolutionary component, which searches for optimal rule structures, and the gradient-based fitness estimation, which quickly yields useful prediction and fitness estimations. It seems only a matter of time until **LCS**s gain even more recognition and be successfully applied to even more diverse problem domains and challenging research tasks.

## 47.7 Books and Source Code

Further information about learning classifier systems can be found in the biannually published IWLCS (International Workshop on Learning Classifier Systems) workshop proceedings and yearly workshops on the topic. A book on **LCS**s and the **XCS** classifier system in particular covers **XCS** from a theoretical and application-oriented point of view and also provides a detailed algorithmic description of

the system [47.25]. A more theoretical coverage of the approximation approach in **XCS** can be found in [47.23]. Several books also give further details on theoretical considerations [47.23, 99] as well as on successful applications of **LCS**s [47.100, 101]. The source code can be found online, for example, for **XCS** in C++ [47.102] as well as for **XCSF** in Java [47.103].

# Indicator-Based Selection

Lothar Thiele

The goal of multiobjective evolutionary optimization is to determine a set of solutions that satisfies certain optimality properties. Recently, there is a growing number of very competitive search algorithms that are based on an explicit formulation of the optimization goal as a set property, i. e., they build on the concept of set indicators. These indicators are used to guide the selection process which is usually denoted as indicator-based selection. This major breakthrough leads to several advantages in terms of analysis and algorithm design: Algorithms are conceptually simpler and more robust as they are largely based on a single indicator; certain convergence properties can be proven; the optimization criterion is made explicit; by changing the set indicator, it is possible to explicitly consider preferences of a user. The chapter introduces step-by-step the concept of

set indicators and their use in indicator-based selection.

## 48.1 Motivation

Variation and selection are the main ingredients of evolutionary optimization algorithms. Despite of many variations that have been developed in the past, their basic iterative structure can simply be described by the following three steps:

1. From the current set of solutions (parent set), a subset is determined (mating pool) by mating selection.
2. From the solutions in the mating pool new solutions are generated (offspring set) through variation operators such as mutation and recombination.
3. Environmental selection determines the new parent set as a subset of the joined parent set and offspring set.

As can be seen in the above template, selection denotes the process of forming a subset of a set of solutions. Mating selection determines the set of can-

didate solutions that will be further explored by constructing new solutions, i. e., the offspring set. To this end, promising solutions need to be selected whose offsprings are expected to advance the optimization process most. In contrast, environmental selection combines parent and offspring sets toward the new parent set and thereby, it reduces the number of solutions that are considered in the next iteration. Loosely speaking, mating selection is involved in the exploration phase of the evolutionary optimization whereas environmental selection is central to the decision phase.

Set indicators map sets of solutions to scalar values. They characterize to which degree the set satisfies some desirable property. Therefore, they can be used to guide the selection process which is usually denoted as indicator-based selection. The following chapter concentrates on environmental selection as indicator-based methods have been applied in this context mainly.

The goal of multiobjective evolutionary optimization is to determine a *set* of solutions that satisfies certain optimality properties. The corresponding notion of optimality is partially defined by *solution preference*, i.e., when we consider one single solution to be preferable to another single solution. One common choice of such a solution-oriented preference relation is Pareto-dominance. But there is still a large degree of freedom left in defining what an *optimal set* of solutions is, as there may be many more Pareto-optimal solutions than can be reasonably processed, stored, or presented to the user. Therefore, we need additional information that describes the preference of the user, i.e., what subset of Pareto-optimal solutions he/she is interested in. For example, the user may be interested in a diverse set of solutions or in solutions which cover a certain subspace of interest. Set indicators can now define such a preference relation and influence:

- The result of the population-based optimization and
- The characteristics of the sets of solutions during an optimization run and
- The search efficiency.

Traditionally, multiobjective evolutionary optimization algorithms such as **NSGA-II** (nondominated sorting genetic algorithm II) [48.1] or **SPEA2** (strength

Pareto evolutionary algorithm 2) [48.2] start from solution preference, i.e., the Pareto-dominance relation between the solutions, and then attempt to consider set preferences such as diversity using heuristics. As a downside of this approach, deterioration and cyclic behavior have been reported [48.3], formal convergence results can not be obtained and unsatisfiable optimization results have been shown for high-dimensional objective spaces [48.4].

On the other hand, indicator-based selection treats multiobjective evolutionary optimization as a set-optimization with a *single optimization criterion*, namely the set-preference relation or its defining set indicator. In other words, instead focussing on individual solutions with multiple criteria, set-based methods consider sets of solutions as the object of optimization and a single set criterion, i.e., the set indicator. This is a radical change from the traditional approach. The set indicator directly represents the user preference and the optimization algorithm determines a set of solutions that optimizes this single set indicator. The advantages of this approach are obvious: Formal and unambiguous definition of the optimization goal, possibility to show strong convergence results, and a clear approach to consider user preferences in the search method.

## 48.2 Basic Concepts

Before discussing the role of indicators, selection, and archiving in multiobjective evolutionary algorithms, we will define the notation used in the forthcoming sections. In particular, we will define the underlying class of multiobjective optimization problems.

### 48.2.1 Notation

We will consider the minimization of a vector-valued objective function  $f = (f_1, \dots, f_n) : \mathcal{X} \rightarrow \mathbb{R}$  which maps each point in the decision space  $\mathcal{X}$  to an  $n$ -dimensional vector. The decision space  $\mathcal{X}$  denotes the feasible set of alternatives for the optimization problem and  $n$  denotes the dimension of the minimization problem, i.e., the number of objectives. For simplicity of notation, we suppose in the following that  $\mathcal{X}$  is finite. Often, we call an element of the decision space a *solution* and the corresponding objective value  $z = f(x)$  is denoted as *objective vector*. The image of the decision space  $\mathcal{X}$  under the objective function  $f$  is called

objective space  $Z \subseteq \mathbb{R}^n$  with  $Z = \{f(x) | x \in \mathcal{X}\}$ , i.e., it contains all objective vectors corresponding to solutions in  $\mathcal{X}$ .

In the above formulation, it is not yet clear what we understand as the *minimization* of a vector-valued function. In this chapter, we follow the usual concept of Pareto dominance which defines an order relation between all solutions based on a preference relation, i.e., it defines when we call a solution better than another one.

#### **Definition 48.1**

A solution  $a \in \mathcal{X}$  weakly Pareto dominates a solution  $b \in \mathcal{X}$ , denoted as  $a \leq b$ , if  $f_i(a) \leq f_i(b)$  for all  $1 \leq i \leq n$ . Solution  $a$  strongly Pareto dominates  $b$ , denoted as  $a < b$  if  $(a \leq b) \wedge (b \not\leq a)$ .

We can rewrite the strong domination criterion as  $(a < b) \Leftrightarrow (a \leq b) \wedge (f(a) \neq f(b))$ . We also say that solution  $a$  is *better than* or *weakly preferable to*  $b$  if

$a \prec b$  or  $a \preceq b$ , respectively. Note that the weak Pareto-dominance relation is suitable for optimization as it defines a preorder on the set of solutions  $\mathcal{X}$ . A preorder  $\preceq$  on a given set  $\mathcal{X}$  is reflexive and transitive:  $a \preceq a$  and  $(a \preceq b) \wedge (b \preceq c) \Rightarrow (a \preceq c)$  hold for all  $a, b, c \in \mathcal{X}$ .

In terms of optimization, we say that a solution  $a \in \mathcal{X}$  is Pareto-optimal if there is no better solution in  $\mathcal{X}$ , i.e., if  $b \preceq a$  for some  $b \in \mathcal{X}$  then  $a \preceq b$ . The set of all Pareto-optimal solutions is denoted as the Pareto-optimal set and its image in the objective space as the Pareto-optimal front.

Ideally, a multiobjective optimizer determines the Pareto-optimal set for a given objective function  $f$  and the corresponding decision space  $\mathcal{X}$ . Traditionally, evolutionary multiobjective algorithms attempt to solve this problem by generating a suitable approximation of the Pareto-optimal set. To this end, they maintain and improve sets of solutions, denoted as populations. In this context, the following questions arise:

- If the set of Pareto-optimal solutions is too large to be determined efficiently, how do we select those which will be the result of the optimization process?
- How do we evaluate a set of solutions, i.e., an approximation of the set of Pareto-optimal solutions, in terms of its degree of optimality in order to guide the optimization process?

The chapter describes how indicator-based selection can be used to answer the above questions. Therefore, it touches two core issues for multiobjective evolutionary algorithms: (a) how to formalize the optimization goal in the sense of specifying what type of set is sought; (b) how to efficiently determine a suitable subset to achieve the formalized optimization goal.

The following section introduces the concept of set indicators that can be used to evaluate a set of solutions, i.e., associate a quality indicator which describes its degree of optimality.

### 48.2.2 Set Indicators

Preference relations between sets of solutions are the basis of set-based multiobjective optimization. They provide the information on the basis of which the search is carried out, i.e., for any two Pareto set approximations, they say whether one set is considered to be equal, better, or worse.

A set indicator can now be used to define such a preference relation and therefore to indicate whether one set of solutions is preferable to another one. In addition,

it also contains quantitative information about the degree of preference.

Depending on the particular definition of the preference relation, a set can be considered to be better than another one or even the other way round. With different definitions of such a preference relation, we can expect that the optimal result of a search process will be different as well. Therefore, the definition of an indicator is essential for formally defining the goal of the set-based optimization. In addition, it allows us to adjust the optimization goal according to the preferences of the user, i.e., to provide flexibility with respect to the subset of Pareto-optimal solutions searched for.

But the set indicator and the resulting preference relation can not be chosen arbitrarily as they need to conform to the concept of Pareto dominance. Otherwise, the search process may end up with a set which is weakly preferable to all other sets but does not contain any Pareto-optimal solution.

In order to derive the requirements for a *well-behaved* set indicator, let us first generalize the concept of Pareto dominance of solutions to Pareto dominance of sets.

#### Definition 48.2

A set of solutions  $\mathcal{A} \subseteq \mathcal{X}$  weakly Pareto dominates a set of solutions  $\mathcal{B} \subseteq \mathcal{X}$ , denoted as  $\mathcal{A} \preceq \mathcal{B}$ , if  $(\forall b \in \mathcal{B} : (\exists a \in \mathcal{A} : a \preceq b))$ . Set  $\mathcal{A}$  strongly Pareto-dominates set  $\mathcal{B}$ , denoted as  $\mathcal{A} \prec \mathcal{B}$  if

$$(\mathcal{A} \preceq \mathcal{B}) \wedge (\mathcal{B} \not\preceq \mathcal{A}).$$

In other words, a set of solutions  $\mathcal{A}$  weakly dominates a set of solutions  $\mathcal{B}$  if every solution in  $\mathcal{B}$  is weakly dominated by at least one solution in  $\mathcal{A}$ . Moreover, it can be shown that the set-based dominance relation defines a preorder, i.e., it is suited for optimization purposes.

Now, let us define the concept of a set indicator and its induced preference relation. In the first part of this section, we restrict ourselves to unary indicators. A more detailed discussion on the various aspects of indicators is provided in [48.5].

#### Definition 48.3

A unary indicator maps each set  $\mathcal{A} \subseteq \mathcal{X}$  of the decision space to a real number  $I(\mathcal{A}) \in \mathbb{R}$ . Given an indicator, we can determine the corresponding preference relation  $\preceq_I$  as

$$\mathcal{A} \preceq_I \mathcal{B} := (I(\mathcal{A}) \geq I(\mathcal{B})).$$

In other words, the larger the set indicator of a set of solutions the better we consider the set. It can be shown that the preference relation induced by the indicator defines a total order on the set of solutions  $\mathcal{X}$ .

As discussed above, not all preference relations can be used inside search methods as they at least need to *comply* to the definition of Pareto dominance in Def. 48.2. To this end, the following definition describes the notion of preference refinement:

#### Definition 48.4

A preference relation  $\preceq_{\text{ref}}$  is denoted as a refinement of  $\preceq$  if

$$\mathcal{A} \prec \mathcal{B} \Rightarrow \mathcal{A} \preceq_{\text{ref}} \mathcal{B}.$$

What we need to guarantee can be formulated as follows: If a solution  $\mathcal{A} \subseteq \mathcal{X}$  is strictly better than a solution  $\mathcal{B} \subseteq \mathcal{X}$  in the sense of Pareto dominance, i. e.,  $\mathcal{A} \prec \mathcal{B}$ , then the preference relation used for optimization should say so as well, i. e.,  $\mathcal{A} \preceq_{\text{ref}} \mathcal{B}$ , see also [48.5].

If we use this result for the unary indicator according to Def. 48.3, then we directly get the following condition for a *compliant* indicator, i. e., whose corresponding preference relation is a refinement of  $\preceq$

$$\mathcal{A} \prec \mathcal{B} \Rightarrow (I(\mathcal{A}) > I(\mathcal{B})). \quad (48.1)$$

In other words, if a solution  $\mathcal{A}$  is strictly better than a solution  $\mathcal{B}$ , i. e.,  $\mathcal{A} \prec \mathcal{B}$ , then the indicator should say so as well, i. e.,  $I(\mathcal{A}) > I(\mathcal{B})$ . It has been shown in [48.5] that the Pareto-compliance guarantees that a set with the maximal indicator value is minimal with respect to the Pareto-dominance relation according to Def. 48.2.

Indicators have been introduced to the area of multiobjective evolutionary optimization first as a mean to compare different optimization runs [48.6–9]. The use of indicators to guide multiobjective search methods in general appeared in the year 2003, notably in [48.10] and later in [48.11–13]. In a more restricted setting, indicators have been used for archiving, i. e., maintaining a set of Pareto-approximate solutions [48.3, 14].

In several studies, the properties of set indicators have been investigated in terms of their compliance to the Pareto dominance [48.7, 15]. Whereas many well known and widely applied indicators do not fall into this class, there are various indicators that at least satisfy a weak refinement ( $\mathcal{A} \prec \mathcal{B} \Rightarrow \mathcal{A} \preceq_{\text{ref}} \mathcal{B}$ ), e.g., the unary  $R_2$  and  $R_3$  indicators [48.16] and the multiplicative as well as the unary additive and multiplicative

epsilon indicators [48.3, 15]. The latter two indicators are related to additive or multiplicative approximation [48.17, 18].

Before discussing binary indicators, let us introduce an example of a set indicator that is compliant to Pareto dominance. The hypervolume indicator has been introduced to the field of multiobjective evolutionary optimization in [48.19] for the purpose of performance assessment. It can be defined as

$$I_H(\mathcal{A}, \mathcal{R}) = \int_{z \in H(\mathcal{A}, \mathcal{R})} dz, \quad (48.2)$$

where  $H(\mathcal{A}, \mathcal{R})$  denotes the objective space dominated by  $\mathcal{A}$  and dominating  $\mathcal{R}$

$$H(\mathcal{A}, \mathcal{R}) = \{z \in \mathbb{R}^n \mid \exists a \in \mathcal{A} : \exists r \in \mathcal{R} : f(a) \leq z \leq r\}.$$

In other words, we determine the volume covered by all points  $z \in \mathbb{R}^n$  that are enclosed between the image of the solutions in objective space  $f(\mathcal{A})$  and the reference set  $\mathcal{R}$ , where *enclosed* is interpreted in terms of weak Pareto dominance. Due to its compliance to Pareto dominance it has been used in most of the indicator-based selection schemes to date.

One of the major drawbacks of the hypervolume indicator is the associated computational overhead. Bringmann and Friedrich [48.20] have proven that the problem of computing the hypervolume is  $\#P$ -complete, i. e., there exists no polynomial algorithm unless  $NP = P$ . Several algorithms have been proposed in the past to determine the hypervolume indicator, starting from the hypervolume by slicing objective approach independently proposed by several authors (Knowles and Zitzler) with complexity  $\mathcal{O}(N^{n-1})$  where  $N$  is the number of solutions in the population and  $n$  is the number of objectives. Later on, improved version appeared with complexity  $\mathcal{O}(N^{n-2} \log N)$  [48.21] and finally  $\mathcal{O}(N \log N + N^{n/2} \log N)$  [48.22]. An approximation algorithm with proven bounds is presented in [48.23] which gives an  $\epsilon$ -approximation of the hypervolume with probability  $(1 - \delta)$  in time  $\mathcal{O}(\log(1/\delta) nN/\epsilon^2)$ .

Binary indicators  $I(\mathcal{A}, \mathcal{B})$  can be used to compare two sets  $\mathcal{A}$  and  $\mathcal{B}$  as described in the following Def. 48.5.

#### Definition 48.5

A binary indicator maps an ordered pair of sets  $\mathcal{A}, \mathcal{B} \subseteq \mathcal{X}$  of the decision space to a real number  $I(\mathcal{A}, \mathcal{B}) \in \mathbb{R}$ .

Given a binary indicator, we can determine the corresponding preference relation  $\preceq_I$  as

$$\mathcal{A} \preceq_I \mathcal{B} := (I(\mathcal{A}, \mathcal{B}) \geq I(\mathcal{B}, \mathcal{A})).$$

In a similar way to (48.1), one can derive the condition for an indicator whose corresponding preference relation is a refinement of  $\preceq$ ,

$$\mathcal{A} \prec \mathcal{B} \Rightarrow (I(\mathcal{A}, \mathcal{B}) > I(\mathcal{B}, \mathcal{A})).$$

Two popular examples of a binary indicators that have been successfully used in indicator-based selection [48.11, 24, 25], archiving [48.3] and approximation schemes [48.18] are the additive and multiplicative epsilon indicators. They can be defined as

$$\begin{aligned} I_\epsilon^+(\mathcal{A}, \mathcal{B}) &= \min_{b \in \mathcal{B}} \max_{a \in \mathcal{A}} F_\epsilon^+(a, b), \\ F_\epsilon^+(a, b) &= \min_{1 \leq i \leq n} (f_i(b) - f_i(a)), \end{aligned} \quad (48.3)$$

for the additive version and

$$\begin{aligned} I_\epsilon^*(\mathcal{A}, \mathcal{B}) &= \min_{b \in \mathcal{B}} \max_{a \in \mathcal{A}} F_\epsilon^*(a, b), \\ F_\epsilon^*(a, b) &= \min_{1 \leq i \leq n} \frac{f_i(b)}{f_i(a)}, \end{aligned} \quad (48.4)$$

for the multiplicative one. Formally speaking,  $I_\epsilon^+(\mathcal{A}, \mathcal{B})$  (or  $I_\epsilon^*(\mathcal{A}, \mathcal{B})$ ) denotes the maximum amount one can add to (or multiply to) every objective value  $f_i(a)$  of every solution  $a \in \mathcal{A}$  such that the resulting set still weakly dominates  $\mathcal{B}$ .

Unfortunately, the above binary indicators do not induce a preorder as the resulting preference relation is not transitive in general [48.5]. This negative result needs to be considered when deciding to use it (and similar generalizations of unary indicators) in optimization algorithms.

Next, indicator-based selection and its integration into multiobjective search algorithms will be discussed.

## 48.3 Selection Schemes

### 48.3.1 Basic Search Algorithm

Let us start the discussion of indicator-based selection with a simple template of a multiobjective evolutionary algorithm (**SPAM** – set preference algorithm for multiobjective optimization [48.26]) as shown in Alg. 48.1.

#### Algorithm 48.1 Simple SPAM

- 1: generate initial set of solutions  $\mathcal{P}$  of size  $\mu$
- 2: **while** termination criterion not fulfilled **do**
- 3:   generate  $\lambda$  offspring solutions  $\mathcal{O} \in \mathcal{X}$
- 4:    $S = \text{select}(\mathcal{P} \cup \mathcal{O}, \mu)$
- 5:   **if**  $S \preceq_{\text{ref}} \mathcal{P}$  **then**  $\mathcal{P} \leftarrow S$
- 6: **return**  $\mathcal{P}$

Obviously, the template is still very simplistic but it will help us to understand the integration of the concept of indicators and selection in multiobjective evolutionary algorithms. Line 3 in Alg. 48.1 refers to the variation of solutions that are in population  $\mathcal{P}$ , i. e., starting with mating selection and then applying variation operators such as mutation and recombination. This essential part of any evolutionary algorithm will not be discussed further here. Line 4 is denoted as environ-

mental selection and reduces the union of parent set  $\mathcal{P}$  and offspring set  $\mathcal{O}$  from size  $\mu + \lambda$  to  $\mu$  again, i. e.,  $S \subseteq \mathcal{P} \cup \mathcal{O}$  and  $|S| = \mu$ . Finally, line 5 is responsible for selecting either the old population  $\mathcal{P}$  or the new one  $S$  depending on the chosen preference relation  $\preceq_{\text{ref}}$ .

In the following, we will stepwise refine the selection operator in line 4 and thereby, relate the above template to existing indicator-based selection schemes.

### 48.3.2 Exhaustive Selection

Let us first suppose that the selection operator in line 4 is exhaustive in the following sense: If there exists a subset  $S \subseteq \mathcal{P} \cup \mathcal{O}$  with  $|S| = \mu$  that satisfies  $S \preceq_{\text{ref}} \mathcal{P}$ , then it will generate it with nonzero probability. Under this condition, one can proof an important convergence property of the algorithm that ensures that there is no deterioration behavior as reported for algorithms such as **NSGA-II** and **SPEA2** [48.3]. The line of arguments is just sketched here as it closely follows the investigations in [48.27].

In most general terms, the goal of the optimization is to generate as large as possible subset of the Pareto-optimal solutions. Therefore, what we at least require is that Alg. 48.1 generates such a set provided that it runs

long enough. Indeed, one can show that this is the case if:

- a) The offspring generation in line 3 is exhaustive, i.e., all solutions are generated with nonzero probability,
- b) The selection operator is exhaustive and
- c)  $\preceq_{\text{ref}}$  is a refinement of the Pareto dominance.

Let us suppose for simplicity of arguments, that there are more than  $\mu$  Pareto-optimal solutions in  $X$ . Moreover, suppose that the population at some point in time (still) contains a dominated solution. Then there is a nonzero-probability that in the set  $\mathcal{O}$  of offsprings there is a Pareto-optimal solution not yet in  $\mathcal{P}$ . Replacing the dominated solution with the additional Pareto-optimal solution leads to a preferred set according to  $\preceq_{\text{ref}}$  as it refines the Pareto dominance. Note, however, that the above convergence property does not mean that Alg. 48.1 determines an optimal set w.r.t. to  $\preceq_{\text{ref}}$ , i.e., that the resulting subset of Pareto-optimal solutions actually is minimal in terms of  $\preceq_{\text{ref}}$ .

Exhaustive selection can usually not be implemented efficiently, as all possible subsets must be tested, i.e.,  $\binom{\lambda+\mu}{\mu}$  possible preference relations. The following refinements of the basic algorithm lead to more efficient schemes.

### 48.3.3 Steady State and Greedy Selection

A first possibility has been proposed in the indicator-based selection and archiving schemes described in [48.12, 14]. The size of the offspring set is  $\lambda = 1$  and therefore, at most  $\mu + 1$  preference relations need to be constructed in each iteration. In particular, the hypervolume indicator  $I_H$  [48.9] ( $S$  measure) has been used to define the preference relation, i.e.,  $\preceq_{\text{ref}} := \preceq_H$ . In this case, the selection in line 4 just removes the solution that leads to the least loss in  $I_H$ .

Still, the convergence to a Pareto-optimal subset can be guaranteed if the offspring generation is exhaustive. On the other hand, it cannot be guaranteed that the algorithm determines an optimal set w.r.t.  $\preceq_{\text{ref}}$ , i.e., a set that is not strictly dominated by any other subset of size  $\mu$  w.r.t.  $\preceq_{\text{ref}}$ . First counterexamples for various set indicators that show this property for  $\lambda < \mu$  and especially for  $\lambda = 1$  appeared in [48.5]. A more indepth discussion on this issue for the hypervolume indicator can be found in [48.28].

A second approach allows for general sizes  $\lambda$  of the offspring population  $\mathcal{O}$  and employs a simple greedy

strategy, i.e., solutions are removed one-by-one from the set  $\mathcal{P} \cup \mathcal{O}$  until a set with size  $\mu$  is obtained. The following template in Alg. 48.2 sketches the approach.

---

#### Algorithm 48.2 Greedy Selection

```

1: procedure select( $\mathcal{P} \cup \mathcal{O}, \mu$ )
2:    $S \leftarrow \mathcal{P} \cup \mathcal{O}$ 
3:   while  $|S| > \mu$  do
4:     for all  $a \in S$  do
5:        $\delta_a \leftarrow \text{loss}(S, a)$ 
6:     choose  $p \in S$  with  $\delta_p = \min_{a \in S} \delta_a$ 
7:      $S \leftarrow S \setminus \{p\}$ 
8:   return  $S$ 
```

---

If  $\lambda = 1$ , then this template covers the steady-state selection scheme in [48.12, 14]. The function  $\text{loss}(S, a)$  quantifies the loss in set quality, if solution  $a$  is removed from it. In line 6, the solution with the smallest loss is chosen and removed from the population in line 7. If the preference relation is based on a unary indicator as shown in Def. 48.3, then the loss function can simply be determined as

$$\text{loss}(S, a) = I(S) - I(S \setminus \{a\}).$$

For the more general case of preference relations that are not based on indicators, see also [48.5]. Note that convergence to the set with the maximal indicator value can now not be guaranteed anymore as the greedy selection is a heuristic. For the hypervolume indicator this is shown in [48.29]. On the other hand, we still can guarantee that SPAM with greedy selection generates an as large as possible subset of the Pareto-optimal solutions if the offspring generation in line 3 is exhaustive, i.e. all solutions are generated with nonzero probability, and  $\preceq_{\text{ref}}$  is a refinement of the Pareto dominance.

As shown in Alg. 48.2, we do not need to determine the value of the set indicator but only the least contributor, i.e. the solutions that leads to the minimal loss. Depending on the choice of the indicator, this information may be easier to compute than evaluating the indicator for  $\lambda + \mu$  different sets and comparing the values. In the context of the hypervolume indicator, a more detailed discussion on this issue is provided in [48.30].

As has been mentioned already, the indicator-based selection schemes described here have been applied to the problem of archiving as well. Archiving algorithms attempt to maintain a bounded set of solutions given a sequence of solutions [48.3, 14]. In analogy to the template in Alg. 48.1, the sequence of solutions would be generated by the offspring generation and

the selection process would determine the new population  $\mathcal{P}$ . For archiving purposes, one is usually only interested in maintaining a subset of all nondominated solutions received so far. Dominated solutions in  $\mathcal{P}$  are usually not considered in the underlying set preference relations.

The Pareto-dominance relation on sets is by definition insensitive to dominated solutions. The same holds for set preference relations based on popular indicators such as the hypervolume indicator which reflects the volume dominated by a set of solutions. On the other hand, preferences among dominated solutions may be of importance to guide the search. In particular, all solutions in  $\mathcal{P}$  (dominated and nondominated ones) are candidates for the mating selection and therefore, may be chosen for variation in the generation of offspring solutions. Therefore, useful set preference relations that are refinements of Pareto dominance need to be constructed that allow us to consider preferences on dominated solutions as well.

#### 48.3.4 Hierarchical Set Preferences

Most of the hierarchical indicator-based selection schemes that have been described so far combine set indicators with constructing a sequence of subsets of solutions [48.5, 12, 31]. For example, nondominated sorting [48.32, 33] starts with the whole set as the first element of the sequence, and then removes the nondominated solutions from the previous subset to construct the next subset in the sequence. The following Alg. 48.3 provides a template for a hierarchical selection scheme involving nondominated sorting. Many variants of the above basic scheme could be thought of such as other subset-constructions like dominance ranking [48.34].

#### Algorithm 48.3 Hierarchical Selection

```

1: procedure select  $\mathcal{P} \cup \mathcal{O}, \mu$ 
2:    $S \leftarrow \mathcal{P} \cup \mathcal{O}$ 
3:    $S' \leftarrow \emptyset$ 
4:    $S'' \leftarrow \emptyset$ 
5:   repeat
6:      $S' \leftarrow S' \cup S''$ 
7:      $S'' \leftarrow \{a \in S \mid \nexists b \in S : b \prec a\}$ 
8:      $S \leftarrow S \setminus S''$ 
9:   until  $|S' \cup S''| \geq \mu$ 
10:  while  $|S' \cup S''| > \mu$  do
11:    for all  $a \in S''$  do
12:       $\delta_a \leftarrow loss(S'', a)$ 
13:      choose  $p \in S''$  with  $\delta_p = \min_{a \in S''} \delta_a$ 
14:       $S'' \leftarrow S'' \setminus \{p\}$ 
```

15:   **return**  $S' \cup S''$

The set  $S$  in Alg. 48.3 before the execution of the iteration in lines 5–9 contains the last subset in the sequence of dominating subsets. When leaving the iteration with line 9, we have  $\mathcal{P} \cup \mathcal{O} = S \cup S' \cup S''$  where  $S''$  is the last dominating set that has been peeled off. The iteration in lines 10–14 removes solutions from  $S''$  one-by-one as in Alg. 48.2 until the set  $S' \cup S''$  contains  $\mu$  solutions. In [48.5], a detailed analysis of the optimization and convergence properties of such constructions is provided. In particular, conditions are derived under which the corresponding preference relation is a refinement of Pareto dominance, i. e., can safely be used in an indicator-based selection.

#### 48.3.5 Using Binary Indicators

The previous discussion concentrated on the use of unary indicators in multiobjective evolutionary algorithms. On the other hand, one of the first indicator-based selection schemes used for optimization was based on the concept of binary indicators following Def. 48.5 [48.11]. In particular, the use of a binary variant of the hypervolume indicator, (48.2), as well as the use of the binary additive epsilon indicator, (48.3), have been described.

The structure of **IBEA** (indicator-based evolutionary algorithm) follows directly the greedy selection scheme as described in Alg. 48.2. In the basic scheme of **IBEA**, i. e., without parameter adaptation, the *loss*-function is computed as follows,

$$loss(S, a) = - \sum_{b \in S \setminus \{a\}} e^{I(\{b\}, \{a\})/\kappa}. \quad (48.5)$$

Let us interpret the above loss function by means of the binary additive epsilon indicator, i. e.,  $I(\mathcal{A}, \mathcal{B}) := I_\epsilon^+(\mathcal{A}, \mathcal{B})$ . The solution with the smallest *loss*-function will be selected for removal from the set. This actually is the solution with the *largest* sum  $\sum_{b \in S \setminus \{a\}} e^{I(\{b\}, \{a\})/\kappa}$ . If considering a large scaling factor  $\kappa$ , the sum of exponentials actually acts similar to sorting the indicators and just considers the largest one. If  $\kappa$  is smaller, then not only the largest indicator is taken into account but also smaller ones. As a result, the sum is dominated by the solution  $b$  which leads to the largest value of  $I(\{b\}, \{a\})$ .

Remember that  $I(\{b\}, \{a\}) = \min_{1 \leq i \leq n} (f_i(a) - f_i(b))$  denotes the maximal amount one can add to every objective value  $f_i(b)$  of solution  $b$  such that it

still weakly dominates  $a$ . As a result for large values of  $\kappa$  we can summarize the selection as follows: For each solution  $a$ , we determine the solution  $b$  to which we can add the largest amount such that it still weakly dominates  $a$ . The solution  $a$  is removed for which this amount is largest. In some sense, the first step determines the *closest* solution (or strongest dominator) to  $a$  in the epsilon indicator and the second step then removes the solution which has the closest neighbor (or strongest dominator). If  $\kappa$  is smaller, also the closeness

(or domination) of other solutions  $b$  is taken into account.

Recently, an indicator-based algorithm has been developed [48.25], which uses a similar principle. It uses the binary epsilon indicator as defined in (48.3) and (48.4), but instead of comparing successive populations as in IBEA, it uses a possibly growing archive of the best Pareto-approximations found so far as the reference set. The solution to be removed according to the template in Alg. 48.2 is determined by sorting.

## 48.4 Preference-Based Selection

Recently, there has been increasing interest in constructing evolutionary optimization methods that allow to consider search preferences of the user. In other words, the resulting set of solutions should not contain an arbitrary subset of Pareto-optimal solutions but one that satisfies secondary criteria. For example, it may be desirable to preferably determine solutions that are close to some reference point, that are along a direction in the objective space, or have some other predefined distribution.

The choice of the *right* subset of solutions as a result of an evolutionary multiobjective optimization was of major concern since the beginning. In particular, it was a major goal to design algorithms that lead to well-distributed solutions that are close to the Pareto-optimal front. Various heuristics have been implemented in standard algorithms like SPEA2 [48.2] and NSGA-II [48.1] to achieve such an implicitly defined objective.

The concept of indicator-based selection changed this approach fundamentally. It not only allows to formalize the objective of population-based multiobjective optimization in general but also to design algorithms that optimize a set of solutions toward it. As a result of this achievement, the focus of research moved toward the following questions:

- What kind of user preference is useful in the context of preference-based search?
- How can these preferences be mathematically formulated and incorporated in set indicators?
- How can a preference-based algorithm be integrated into an interactive optimization approach that involves the decision maker?

Including preference information in multiobjective evolutionary methods has been investigated since the beginning [48.37] for a survey. In a very early attempt,

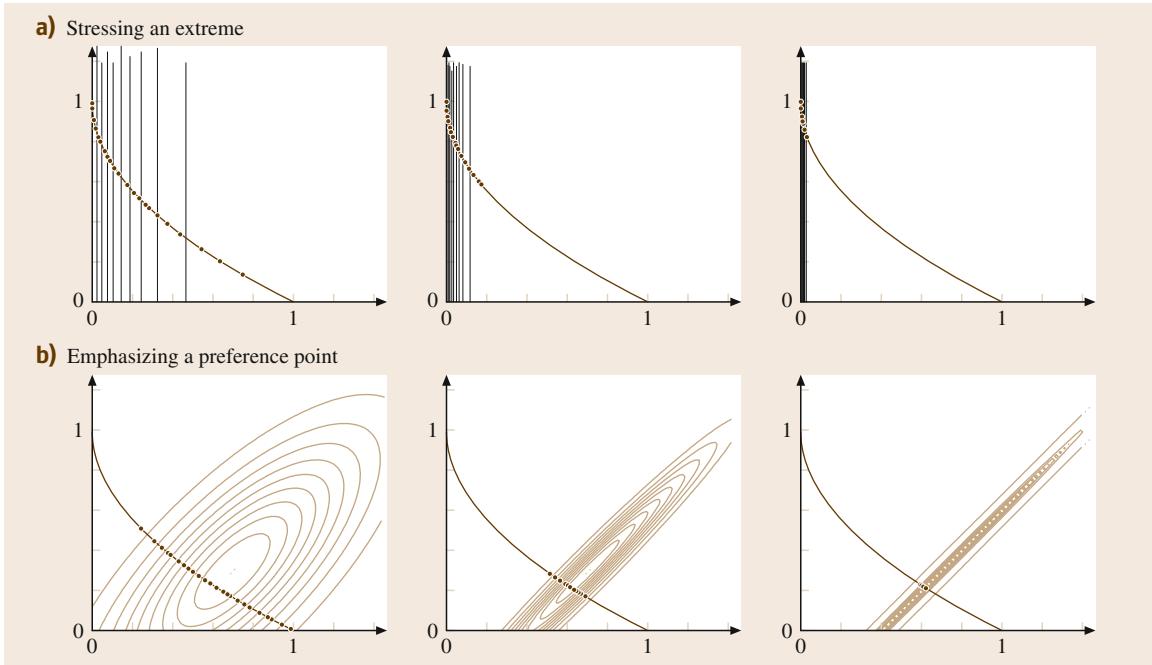

Fonseca and Fleming [48.34] suggested to assign ranks to the members of a population. Much later it was proposed in [48.38] to include preferences through the use of reference points, guided dominance schemes and a biased crowding scheme. Preference-based multiobjective evolutionary methods can be used within a hybrid approach that combine ideas from both, evolutionary and interactive multiobjective optimization [48.24]: In an iterative approach, several consecutive runs of the evolutionary algorithm are performed. The user is asked to give preference information in terms of his reference point consisting of desirable aspiration levels for objective functions. This information is used in a preference-based evolutionary algorithm that generates a new population by combining the fitness function and a so-called achievement scalarizing function containing the reference point.

In the meantime, many other possibilities to formalize user preferences have been investigated [48.35, 39], for example weight functions in the objective space which change the desired (nonuniform) density of solutions, stressing objectives, guiding the search toward preference points, transforming objective functions, weighted Tchebycheff approaches using ideal points, epsilon-constraint methods, and desirability functions, just to name a few.

In the following, two examples for considering preference information in selection schemes will be described in some more detail. In [48.24], the greedy selection scheme according to Alg. 48.2 with a binary indicator according to (48.5) has been used. In particular, a normalization according to

$$I_p(\{b\}, \{a\}) := I(\{b\}, \{a\}) / s^*(g.f(a))$$

is proposed. The normalization function  $s(g.f(x))$  is closely related to the concept of achievement scalariz-

**Fig. 48.1a,b** The figures show the Pareto front approximations (*dots*) found by HypE (after [48.31]) using different weight distribution functions, shown as *contour lines* at intervals of 10% of the maximum weight value. For both rows one parameter of the sampled distribution was modified, i.e., on *top* the rate parameter of the exponential distribution, on the *bottom* the spread of a multivariate normal distribution (after [48.35]). The test problem is ZDT1 (after [48.36]) where the Pareto front is shown as a *solid line*. The graphics appeared in [48.35]

ing functions, first proposed by Wierzbicki [48.40]

$$s(g, f(a)) = \max_{1 \leq i \leq n} (f_i(a) - g_i),$$

where  $g$  denotes the reference point whose components represent the desired values of the objective functions. The function  $s^*$  is obtained from  $s$  by normalization such that only positive values are obtained, i.e.,  $s^*(g, f(a)) > 0$  [48.24].

A second approach uses the the concept of a weighted hypervolume indicator as proposed in [48.41]. In extension to (48.2), we now determine the weighted volume that is covered by all points  $z \in \mathbb{R}^n$  that are enclosed between the image of the solutions in objective space  $f(\mathcal{A})$  and the reference set  $\mathcal{R}$ , where enclosed is interpreted in terms of weak Pareto dominance:

#### Definition 48.6

Given a set of solutions  $\mathcal{A} \subseteq \mathcal{X}$ , a set of reference points  $\mathcal{R} \subset \mathbb{R}^n$  and a positive weight function  $w : \mathcal{R} \rightarrow \mathbb{R}_{\geq 0}$ . Then the weighted hypervolume indica-

tor  $I_H^w(\mathcal{A}, \mathcal{R})$  of  $\mathcal{A}$  with respect to  $\mathcal{R}$  is defined as

$$I_H^w(\mathcal{A}, \mathcal{R}) = \int_{z \in H(\mathcal{A}, \mathcal{R})} w(z) \cdot dz, \quad (48.6)$$

where  $H(\mathcal{A}, \mathcal{R})$  denotes the objective space dominated by  $\mathcal{A}$  and dominating  $\mathcal{R}$

$$H(\mathcal{A}, \mathcal{R}) = \{z \in \mathbb{R}^n \mid \exists a \in \mathcal{A} : \exists r \in \mathcal{R} : f(a) \leq z \leq r\}.$$

The weight function is supposed to be integrable on any bounded set, i.e.,  $\int_{B(0, \gamma)} w(z) dz < \infty$  for any  $\gamma > 0$ , where  $B(0, \gamma)$  is the open ball centered in 0 and of radius  $\gamma$ .

In a similar way to (48.2), the weighted hypervolume indicator is compliant to Pareto dominance and can safely be used in the previously described indicator-based selection schemes.

In later work [48.35, 39], the approach [48.41] has been extended toward more general weight func-

tions, their relation to typical user preference specifications and higher dimensions. Moreover, it is well known that the exact computation of the hypervolume is expensive in the number of objectives, i.e., it is exponential unless  $P = NP$ . To this

end, efficient sampling methods [48.31] have been combined with the general concept of weight functions. Figure 48.1 shows some examples of the effect of weighting the hypervolume indicator, taken from [48.35].

## 48.5 Concluding Remarks

There has been a major shift in our understanding of population-based multiobjective optimization. In a certain sense, the focus of classical algorithms such as NSGA-II or SPEA2 was the Pareto-dominance relation between individual solutions. Properties such as a large diversity of solutions in the final population was achieved through (clever) heuristics and tuning of the selection mechanisms.

The role of set indicators in multiobjective optimization was first limited to the performance assessment. The possibility to assign a single measure to a set was used in elaborated methods that allow us to compare the results of optimization runs and to statistically verify whether one algorithms is preferable to another one. In this context, indicators have been compared in terms of their suitability for performance assessment, e.g., whether they comply to the underlying preference relation between solutions.

Recently, there is a growing number of very competitive search algorithms that are based on an explicit formulation of the optimization goal as a set property, i.e., they build on the concept of set indicators. In simplified terms, they can be regarded as optimization methods that deal with sets of solutions as their optimization object. In contrast, single-objective optimization traditionally works with single solutions. One can simply draw the correspondence between traditional single-objective optimization and population-based multiobjective optimization as follows: single solution versus set of solutions, and single objective function versus single set indicator.

This major breakthrough leads to several advantages in terms of analysis and algorithm design:

- Algorithms are conceptually simpler as they are based on a single indicator and do not rely on heuristics to a large extent. As a result, it can be expected that they are more robust and less parameter tuning is necessary.
- Certain convergence properties can be derived. As a result, the new class of algorithms does not show

deterioration and/or cyclic behavior. It also appears in some of the experiments that have been conducted, that they are more robust toward increasing the number of objectives.

- The optimization criterion is made explicit, i.e., the discussion about convergence versus diversity in the research community can now be based on quantitative measures.
- By changing the set indicator, it is possible to explicitly consider preferences of a user. It will be seen whether this possibility will lead to interactive methods that involve the decision maker in the optimization process.

The purpose of the chapter was to introduce the concept of set indicators and to discuss several ways to use them as essential parts of a set-based multiobjective optimization algorithm. Many other important aspects have not been discussed in detail. In particular, due to its superior properties in terms of:

- a) Compliance to Pareto dominance, and
- b) Sensitivity to changes of single solutions and
- c) Simple interpretation.

The hypervolume indicator has been very popular as a component of set-based optimization methods. Unfortunately, it has some detrimental properties, such as its computation complexity with respect to growing number of objectives. In addition, the complexity to determine a subset of solutions that has the least influence on the hypervolume increases exponentially with the size of the subset.

Finally, it has been shown that removing solutions one-by-one may lead to a major loss in optimization quality. Therefore, its use in indicator-based selection needs to be done with care. As described in this chapter, recent methods overcome some of these difficulties by using advanced methods such as sampling. A more detailed investigation and review of the hypervolume indicator can be found e.g., in [48.31, 35].

# 49. Multi-Objective Evolutionary Algorithms

# Multi-Object

Kalyanmoy Deb

Evolutionary algorithms (EAs) have amply shown their promise in solving various search and optimization problems for the past three decades. One of the hallmarks and niches of EAs is their ability to handle multi-objective optimization problems in their totality, which their classical counterparts lack. Suggested in the beginning of the 1990s, evolutionary multi-objective optimization (EMO) algorithms are now routinely used in solving problems with multiple conflicting objectives in various branches of engineering, science, and commerce. In this chapter, we provide an overview of EMO methodologies by first presenting principles of EMO through an illustration of one specific algorithm and its application to an interesting real-world bi-objective optimization problem. Thereafter, we provide a list of recent research and application developments of EMO to provide a picture of some salient advancements in EMO research. The development and application of EMO to multi-objective optimization problems and their continued extensions to solve other related problems has elevated EMO research to a level which may now undoubtedly be termed as an active field of research with a wide range of theoretical and practical research and application opportunities.

## 49.1 Preamble

Search and optimization problems, particularly involving nonlinear, non-convex and non-differentiable objective and constraint functions, provide a stiff challenge even today. No known mathematical algorithm exists to solve such problems to optimality. In such cases, the use of meta-heuristic optimization methods such as evolutionary algorithms [49.1–3], simulated anneal-

ing [49.4], tabu search [49.5, 6], and other methods motivated by another natural or physical phenomenon have been popularly applied.

EAs were traditionally used for solving problems having a single goal or objective. However, most real-world problems have multiple conflicting goals and theoretically they give rise to a set of trade-off solu-

tions. The classical literature to solve multi-objective optimization problems has been mostly indirect, mainly due to the fact there did not exist any search and optimization methods which could find multiple optimal solutions in a single simulation. While the scientific community was waiting for a suitable algorithm for handling such problems, evolutionary algorithms with their population approach caught the eyes of a number of researchers. This spurred the development of a series of first generation evolutionary multi-objective optimization (**EMO**) algorithms around 1993–1995. A set of three different algorithms (but all motivated by a single idea portrayed by legendary **EA** researcher, Prof. Goldberg [49.1]) showed the world that **EMOs** are viable candidates for multi-objective optimization, and that there are meta-heuristic-based approaches for finding multiple trade-off solutions in a single simulation. **EMO** researchers, and in that spirit the whole **EA** research community, realized the niche of **EAs** in such problem-solving tasks and promoted the developmental and application studies using **EMO**. Subsequently, **EMO** methodologies were made to be better, faster, and more accessible. The algorithms were commercialized by various software companies and they made the field

of **EMO** more popular and applicable to many different problems, which academic researchers alone could not have done.

In this chapter, we provide a brief overview of the **EMO** principle, present one **EMO** algorithm in detail, and emphasize the importance of using **EMO** in practice. Besides this specific algorithm, there exist a number of other equally efficient **EMO** algorithms, which we do not describe here for brevity. Instead, in this chapter, we discuss a number of recent advancements of **EMO** research and applications that are driving researchers and practitioners ahead. Fortunately, researchers have utilized the **EMO** principle of solving multi-objective optimization problems in handling various other problem-solving tasks. The diversity of **EMO**'s research is bringing together researchers and practitioners with different backgrounds, including computer scientists, mathematicians, economists, and engineers. The topics that we discuss here amply demonstrate why and how **EMO** researchers from different backgrounds must and should collaborate on complex problem-solving tasks, which have become the need of the hour in most branches of science, engineering, and commerce today.

## 49.2 Evolutionary Multi-Objective Optimization (**EMO**)

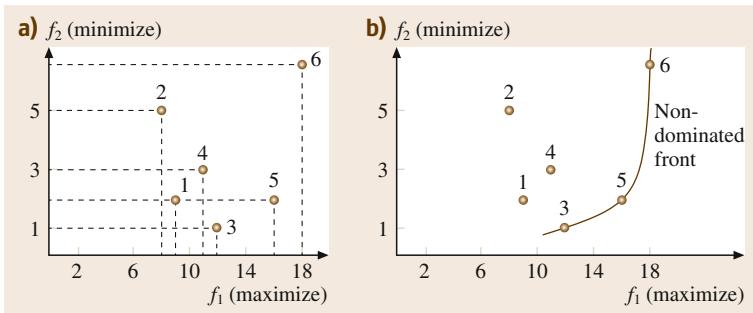

Before we discuss an evolutionary algorithm for multi-objective optimization, we present a generic problem that involves multiple conflicting objectives. A multi-objective optimization problem involves a number of objective functions that are to be either minimized or maximized, subject to a number of constraints and variable bounds

$$\left. \begin{array}{ll} \text{Minimize} & f_m(\mathbf{x}), \quad m = 1, 2, \dots, M; \\ \text{Maximize} & \\ \text{subject to} & g_j(\mathbf{x}) \geq 0, \quad j = 1, 2, \dots, J; \\ & h_k(\mathbf{x}) = 0, \quad k = 1, 2, \dots, K; \\ & x_i^{(L)} \leq x_i \leq x_i^{(U)}, \quad i = 1, 2, \dots, n. \end{array} \right\} \quad (49.1)$$

A solution  $\mathbf{x} \in \mathbf{R}^n$  is a vector of  $n$  decision variables:  $\mathbf{x} = (x_1, x_2, \dots, x_n)^T$ . The solutions satisfying the constraints and variable bounds constitute a feasible set  $S$  in the decision variable space  $\mathbf{R}^n$ .

One of the striking differences between single-objective and multi-objective optimization is that in multi-objective optimization the objective function vectors belong to a multi-dimensional objective space  $\mathbf{R}^M$ . The objective function vectors constitute a feasible set  $Z$  in the objective space. For each solution  $\mathbf{x}$  in  $S$ , there exists a point  $\mathbf{z} \in Z$ , denoted by  $\mathbf{f}(\mathbf{x}) = \mathbf{z} = (z_1, z_2, \dots, z_M)^T$ . To make the descriptions clear, we refer to a decision variable vector as a solution and the corresponding objective vector as a point.

The optimal solutions in multi-objective optimization can be defined from the mathematical concept of *partial ordering* [49.7]. In the parlance of multi-objective optimization, the term *domination* is used for this purpose. In this section, we restrict ourselves to discussing unconstrained (without any equality, inequality or bound constraints) optimization problems. The domination between two solutions is defined as follows [49.8, 9]:

**Fig. 49.1a,b** A set of points and the first non-dominated front are shown

#### Definition 49.1

A solution  $\mathbf{x}^{(1)}$  is said to dominate another solution  $\mathbf{x}^{(2)}$ , if both the following conditions are true.

1. The solution  $\mathbf{x}^{(1)}$  is no worse than  $\mathbf{x}^{(2)}$  in all objectives. Thus, the solutions are compared based on their objective function values (or location of the corresponding points  $(\mathbf{z}^{(1)} \text{ and } \mathbf{z}^{(2)})$  in the objective function set  $Z$ ).
2. The solution  $\mathbf{x}^{(1)}$  is strictly better than  $\mathbf{x}^{(2)}$  in at least one objective.

For a given set of solutions (or corresponding points in the objective function set  $Z$ , for example, those shown in Fig. 49.1a), a pair-wise comparison can be made using the above definition and whether one point dominates another point can be established. All points that are not dominated by any other member of the set are called non-dominated points of class one, or simply non-dominated points. For the set of six points shown in the figure, they are points 3, 5, and 6. One property of any two such points is that a gain in an objective from one point to the other happens only due to a sacrifice in at least one other objective. This *trade-off* property between non-dominated points makes practitioners interested in finding a wide variety of them before making a final choice. These points make up a front when viewed together on the objective space; hence non-dominated points are often visualized to represent a *non-dominated front*. The theoretical computational effort needed to select the points of the non-dominated front from a set of  $N$  points is  $O(N \log N)$  for 2 and 3 objectives, and  $O(N \log^{M-2} N)$  for  $M > 3$  objectives [49.10], but for a moderate number of objectives, the procedure need not be particularly computationally effective in practice.

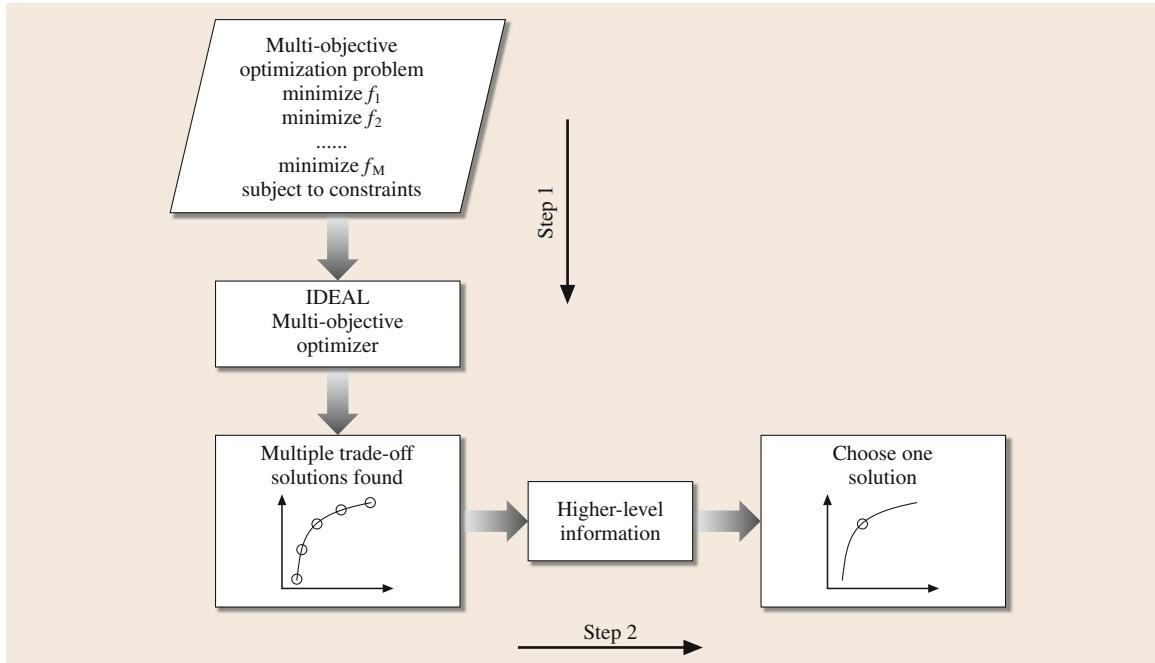

With the above concept, now it is easier to define the *Pareto-optimal solutions* in a multi-objective optimization problem. If the given set of points for the above task contain *all* feasible points in the objective space, the points lying on the first non-domination front, by definition, do not become dominated by any other point in the objective space; hence they are Pareto-optimal points (together they constitute the Pareto-optimal front), and the corresponding pre-images (decision variable vectors) are called Pareto-optimal solutions. However, more mathematically elegant definitions of Pareto-optimality (including the ones for continuous search space problems) exist in the multi-objective optimization literature [49.9, 11]. Some convergence analyses of EMO under certain assumptions can also be found elsewhere [49.12–15].

#### 49.2.1 EMO Principles

In the context of multi-objective optimization, the extremist principle of finding the optimum solution cannot be applied to one objective alone, when the rest of the objectives are also important. This clearly suggests two ideal goals of multi-objective optimization.

- *Convergence*: find a (finite) set of solutions which lies on the Pareto-optimal front.
- *Diversity*: find a set of solutions which is diverse enough to represent the entire range of the Pareto-optimal front.

EMO algorithms attempt to follow both the above principles, similar to the a posteriori multiple criteria decision-making (MCDM) method. Figure 49.2 schematically shows the principles followed in an EMO procedure. Since EMO procedures are heuristic based, they may not guarantee finding exact Pareto-optimal points, as a theoretically provable optimization method

**Fig. 49.2** Schematic of a two-step multi-criteria optimization and decision-making procedure

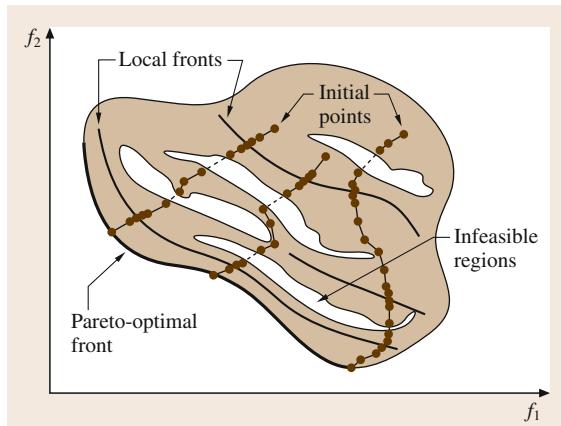

would do for tractable (for example, linear or convex) problems. However, **EMO** procedures have essential operators to constantly improve the evolving non-dominated points (from the point of view of convergence and diversity mentioned above) similar to how most natural and artificial evolving systems continuously improve their solutions. To this effect, a recent study [49.16] demonstrated that a particular **EMO** procedure, starting from random non-optimal solutions, can progress towards theoretical Karush–Kuhn–Tucker (**KKT**) points with iterations in real-valued multi-objective optimization problems. The main difference and advantage of using **EMO** compared to a posteriori **MCDM** procedures is that multiple trade-off solutions can be found in a single run of an **EMO** algorithm, whereas most a posteriori **MCDM** methodologies would require multiple independent runs.

In Step 1 of the **EMO**-based multi-objective optimization and decision-making procedure (the task shown vertically downwards in Fig. 49.2), multiple trade-off, non-dominated points are found. Thereafter, in Step 2 (the task shown horizontally, towards the right), higher-level information is used to choose one of the trade-off points obtained.

#### 49.2.2 A Posteriori **MCDM** Methods and **EMO**

In the a posteriori **MCDM** approaches (also known as *generating MCDM methods*), the task of finding multiple Pareto-optimal solutions is achieved by executing many independent single-objective optimizations, each time finding a single Pareto-optimal solution [49.9]. A parametric scalarizing approach (such as the weighted-sum approach,  $\epsilon$ -constraint approach, and others) can be used to convert multiple objectives into a parametric single-objective objective function. By simply varying the parameters (the weight vector or the  $\epsilon$ -vector) and optimizing the scalarized function, different Pareto-optimal solutions can be found. In contrast, in an **EMO**, multiple Pareto-optimal solutions are attempted to be found in a single run of the algorithm by emphasizing multiple non-dominated and isolated solutions in each iteration of the algorithm and without the use of any scalarization of objectives.

Consider Fig. 49.3, in which we sketch how multiple independent parametric single-objective optimizations (through a posteriori **MCDM** method) may find different Pareto-optimal solutions. It is worth highlighting here that the Pareto-optimal front corresponds to the global optimal solutions of several problems,

**Fig. 49.3** A posteriori MCDM methodology employing independent single-objective optimizations

each formed with a different scalarization of objectives. During the course of an optimization task, algorithms must overcome a number of difficulties, such as infeasible regions, local optimal solutions, flat or non-improving regions of objective landscapes, isolation of optimum, etc., to finally converge to the global optimal solution. Moreover, due to practical limitations, an optimization task must also be completed in a reasonable computational time. All these difficulties in a problem require that an optimization algo-

rithm strikes a good balance between exploring new search directions and exploiting the extent of search in currently-best search direction. When multiple runs of an algorithm need to be performed independently to find a set of Pareto-optimal solutions, the above balancing act must be performed in every single run. Since runs are performed independently from one another, no information about the success or failure of previous runs is utilized to speed up the overall process. In difficult multi-objective optimization problems, such memory-less, *a posteriori* methods may demand a large overall computational overhead to find a set of Pareto-optimal solutions [49.17]. Moreover, despite the issue of global convergence, independent runs may not guarantee achieving a good distribution among obtained points by an easy variation of scalarization parameters.

**EMO**, as was mentioned earlier, constitutes an inherent parallel search. When a particular population member overcomes certain difficulties and makes a progress towards the Pareto-optimal front, its variable values and their combination must reflect this fact. When a recombination takes place between this solution and another population member, such valuable information of variable value combinations is shared through variable exchanges and blending, thereby making the overall task of finding multiple trade-off solutions a parallelly processed task.

## 49.3 A Brief Timeline for the Development of EMO Methodologies

During the seventies and eighties, **EA** researchers realized the need for solving multi-objective optimization problems in practice and mainly resorted to using weighted-sum approaches to convert multiple objectives into a single goal [49.18, 19].

However, the first implementation of a real multi-objective evolutionary algorithm (vector-evaluated **GA** (genetic algorithm) or **VEGA**) was suggested by *Schaffer* in 1984 [49.20]. Schaffer modified the simple three-operator genetic algorithm [49.2] (with selection, crossover, and mutation) by performing independent selection cycles according to each objective. The selection method is repeated for each individual objective to fill up a portion of the mating pool. Then the entire population is thoroughly shuffled to apply crossover and mutation operators. This is performed to achieve the mating of individuals of different subpopulation groups. The algorithm worked efficiently for some generations but in some cases suffered from its bias towards

some individuals or regions (mostly individual objective champions). This does not fulfill the second goal of **EMO**, discussed earlier.

Ironically, no significant study was performed for almost a decade after the pioneering work of Schaffer, until a revolutionary 10-line sketch of a new non-dominated sorting procedure suggested by *Goldberg* in his seminal book on **GAs** [49.1]. Since an **EA** needs a fitness function for reproduction, the trick was to find a single metric from a number of objective functions. Goldberg's suggestion was to use the concept of *domination* to assign more copies to non-dominated individuals in a population. Since diversity is the other concern, he also suggested the use of a *niching* strategy [49.21] among solutions of a non-dominated class. To get this clue, at least three independent groups of researchers developed different versions of multi-objective evolutionary algorithms during 1993–1994 [49.22–24]. These algorithms differ

in the way a fitness assignment scheme is introduced to each individual. Independently, Poloni [49.25] suggested a domination-based **EMO** approach (he called it multi-objective genetic algorithm (**MOGA**)) in which instead of niching, a toroidal grid-based local selection method was used to find multiple trade-off solutions.

These early **EMO** methodologies gave a good head-start to the research and application of **EMO**, but suffered from the fact that they did not use an elite-preservation mechanism in their procedures. Inclusion

of elitists in an **EMO** provides a monotonically non-degrading performance [49.26]. The second generation **EMO** algorithms implemented an elite-preserving operator in different ways and gave birth to elitist **EMO** procedures, such as non-dominated sorting **GA NSGA-II** [49.27], strength Pareto **EA** (**SPEA**) [49.28], Pareto-archived ES (**PAES**) [49.29], and others. Since these **EMO** algorithms are state-of-the-art and commonly-used procedures, we describe one of these algorithms in detail.

## 49.4 Elitist **EMO**: **NSGA-II**

The **NSGA-II** procedure [49.27] is one of the popularly used **EMO** procedures which attempt to find multiple Pareto-optimal solutions in a multi-objective optimization problem and has the following three features:

1. It uses an elitist principle.
2. It uses an explicit diversity preserving mechanism.
3. It emphasizes non-dominated solutions.

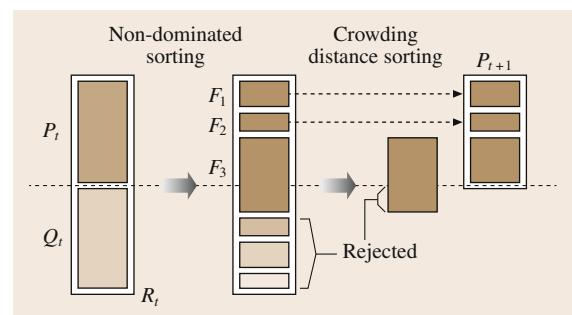

At any generation  $t$ , the offspring population (say,  $Q_t$ ) is first created by using the parent population (say,  $P_t$ ) and the usual genetic operators. Thereafter, the two populations are combined to form a new population (say,  $R_t$ ) of size  $2N$ . Then, the population  $R_t$  is classified into different non-dominated classes. Thereafter, the new population is filled by points of different non-dominated fronts, one at a time. The filling starts with the first non-dominated front (of class 1) and continues with points of the second non-dominated front, and so on. Since the overall population size of  $R_t$  is  $2N$ , not all fronts can be accommodated in the  $N$  slots available for the new population. All fronts that could not be accommodated are deleted. When the last allowed front is being considered, there may exist more points in the front than the slots remaining in the new population. This scenario is illustrated in Fig. 49.4. Instead of arbitrarily discarding some members from the last front, the points that will make the diversity of the selected points the highest are chosen.

The crowded-sorting of the points of the last front which could not be accommodated fully is achieved in the descending order of their *crowding distance* values, and points from the top of the ordered list are chosen. The crowding distance  $d_i$  of point  $i$  is a measure of the objective space around  $i$  which is not occupied by any other solution in the population. Here, we simply calcu-

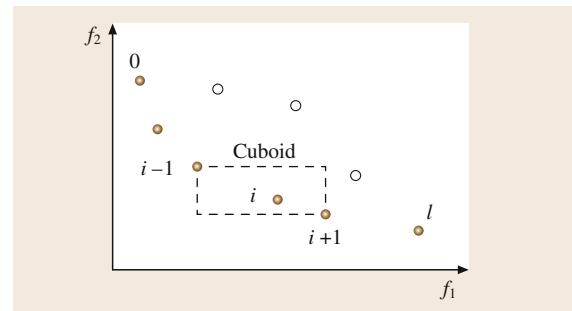

late this quantity  $d_i$  by estimating the perimeter of the cuboid (Fig. 49.5) formed by using the nearest neighbors in the objective space as the vertices (we call this the *crowding distance*).

### 49.4.1 Sample Results

Here, we show results from several runs of the **NSGA-II** algorithm on two test problems. The first problem (**ZDT2** – Zitzler–Deb–Thiele) is a two-objective, 30-

**Fig. 49.4** Schematic of the **NSGA-II** procedure

**Fig. 49.5** The crowding distance calculation

variable problem with a concave Pareto-optimal front

$$\text{ZDT2: } \begin{cases} \text{minimize } f_1(\mathbf{x}) = x_1, \\ \text{minimize } f_2(\mathbf{x}) = s(\mathbf{x})[1 - (f_1(\mathbf{x})/s(\mathbf{x}))^2], \\ \text{where } s(\mathbf{x}) = 1 + \frac{9}{29} \sum_{i=2}^{30} x_i, \\ 0 \leq x_1 \leq 1, \\ -1 \leq x_i \leq 1, \quad i = 2, 3, \dots, 30. \end{cases} \quad (49.2)$$

The second problem (**KUR** – Kurswae), with three variables, has a disconnected Pareto-optimal front

$$\text{KUR: } \begin{cases} \text{minimize } f_1(\mathbf{x}) = \sum_{i=1}^2 \left[ -10 \exp\left(-0.2 \sqrt{x_i^2 + x_{i+1}^2}\right) \right], \\ \text{minimize } f_2(\mathbf{x}) = \sum_{i=1}^3 [|x_i|^{0.8} + 5 \sin(x_i^3)], \\ -5 \leq x_i \leq 5, \quad i = 1, 2, 3. \end{cases} \quad (49.3)$$

**NSGA-II** is run with a population size of 100 and for 250 generations. The variables are used as real numbers and a simulated binary crossover (**SBX**) recombination operator [49.30] with  $p_c = 0.9$ , a distribution index of  $\eta_c = 10$ , and a polynomial mutation operator [49.8] with  $p_m = 1/n$  ( $n$  is the number of variables) and a distribution index of  $\eta_m = 20$  are used. Figures 49.6 and 49.7 show that **NSGA-II** converges to the Pareto-optimal front and maintains a good spread of solutions in both test problems.

There also exist other competent **EMOs**, such as the strength Pareto evolutionary algorithm (**SPEA**) and its improved version SPEA2 [49.31], the Pareto-archived evolution strategy (**PAES**) and its improved versions pareto-envelope based selection algorithm (**PESA**) and PESA2 [49.32], multi-objective messy **GA** (**MOMGA**) [49.33], multi-objective micro-**GA** [49.34], neighborhood constraint **GA** [49.35], adaptive range **MOGA** (**ARMOGA**) [49.36], and others. Moreover, there exist other **EA**-based methodologies, such as particle swarm-based **EMO** [49.37, 38], ant-based **EMO** [49.39, 40], and differential evolution-based **EMO** [49.41]. Simulated annealing method is used to find multiple Pareto-optimal solutions for multi-objective optimization problems [49.42]. The tabu search method is also used for multi-objective optimization [49.43].

## 49.4.2 Constraint Handling in EMO

The constraint handling method modifies the binary tournament selection, where two solutions are picked from the population, and the better solution is chosen. In the presence of constraints, each solution can be either feasible or infeasible. Thus, there may be at most three situations:

- i) Both solutions are feasible.
- ii) One is feasible and other is not.
- iii) Both are infeasible.

We consider each case by simply redefining the domination principle as follows (we call it the

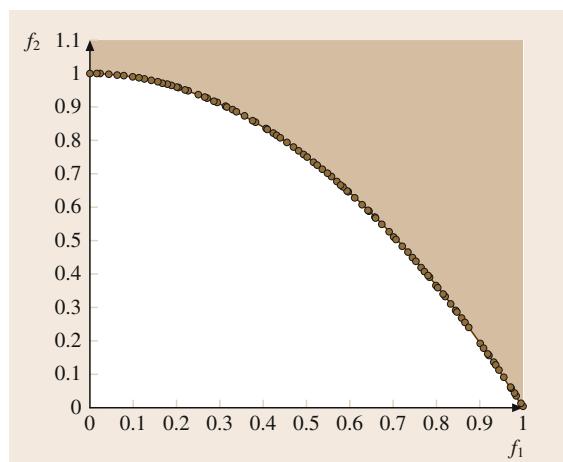

Fig. 49.6 NSGA-II on ZDT2

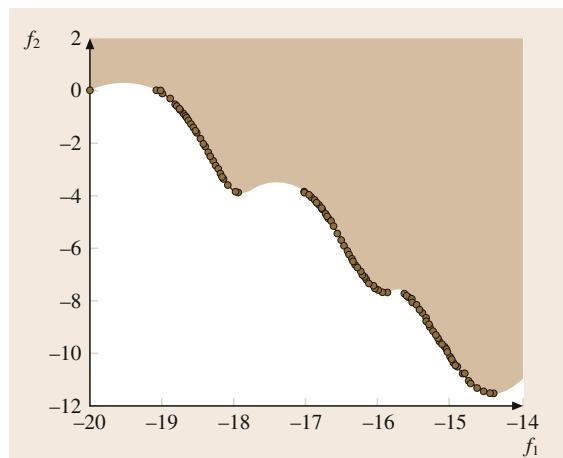

Fig. 49.7 NSGA-II on KUR

*constrained-domination* condition for any two solutions  $\mathbf{x}^{(i)}$  and  $\mathbf{x}^{(j)}$ :

#### Definition 49.2

A solution  $\mathbf{x}^{(i)}$  is said to be a *constrained-dominated* solution  $\mathbf{x}^{(j)}$  (or  $\mathbf{x}^{(i)} \leq_c \mathbf{x}^{(j)}$ ), if any of the following conditions are true:

1. Solution  $\mathbf{x}^{(i)}$  is feasible and solution  $\mathbf{x}^{(j)}$  is not.
2. Solutions  $\mathbf{x}^{(i)}$  and  $\mathbf{x}^{(j)}$  are both infeasible, but solution  $\mathbf{x}^{(i)}$  has a smaller constraint violation, which can be computed by adding the normalized violation of all constraints

$$\text{CV}(\mathbf{x}) = \sum_{j=1}^J \max \left( 0, -\bar{g}_j(\mathbf{x}) \right) + \sum_{k=1}^K \text{abs}(\bar{h}_k(\mathbf{x})) .$$

The normalization is achieved with the population minimum ( $\langle g_j \rangle_{\min}$ ) and maximum ( $\langle g_j \rangle_{\max}$ ) constraint violations

$$\bar{g}_j(\mathbf{x}) = (\langle g_j(\mathbf{x}) \rangle - \langle g_j \rangle_{\min}) / (\langle g_j \rangle_{\max} - \langle g_j \rangle_{\min}) .$$

3. Solutions  $\mathbf{x}^{(i)}$  and  $\mathbf{x}^{(j)}$  are feasible and solution  $\mathbf{x}^{(i)}$  dominates solution  $\mathbf{x}^{(j)}$  in the usual sense (Definition 49.1).

The above change in the definition requires a minimal change in the **NSGA-II** procedure described earlier.

## 49.5 Applications of EMO

Since the early development of **EMO** algorithms in 1993, they have been applied to many challenging real-world optimization problems. Descriptions of some of these studies can be found in books [49.8, 44–47], dedicated conference proceedings [49.48–53], and domain-specific books, journals, and proceedings. A repository of most research and application papers of **EMO** is available [49.54]. In this section, we describe one case study that clearly demonstrates the **EMO** philosophy which we described in Sect. 49.2.1.

### 49.5.1 Spacecraft Trajectory Design

Coverstone-Carroll et al. [49.55] proposed a multi-objective optimization technique using the original non-

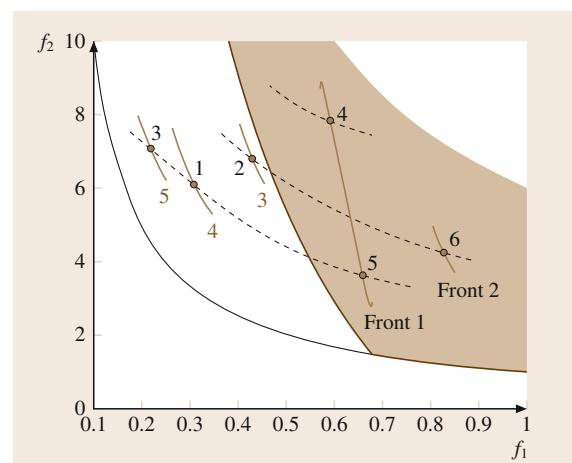

Fig. 49.8 Non-constrained-domination fronts

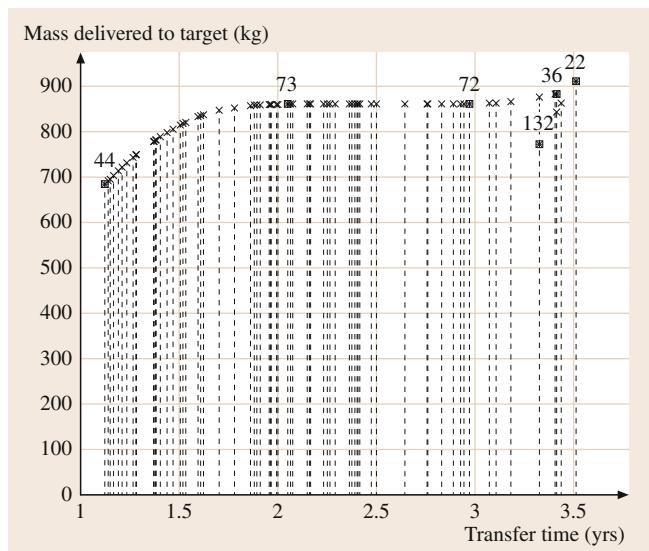

Figure 49.8 shows the non-dominated fronts on a six-member population due to the introduction of two constraints (the minimization problem is described as CONSTR elsewhere [49.8]). In the absence of the constraints, the non-dominated fronts (shown by dashed lines) would have been ((1, 3, 5), (2, 6), (4)), but in their presence, the new fronts are ((4, 5), (6), (2), (1), (3)). The first non-dominated front consists of the *best* (that is, non-dominated and feasible) points from the population and any feasible point lies on a better non-dominated front than an infeasible point.

dominated sorting algorithm (**NSGA**) [49.24] to find multiple trade-off solutions in a spacecraft trajectory optimization problem. To evaluate a solution (trajectory), the SEPTOP (solar electric propulsion trajectory optimization) software [49.56] is called, and the delivered payload mass and the total time of flight are calculated. The multi-objective optimization problem has eight decision variables controlling the trajectory and three objective functions:

- i) Maximize the delivered payload at destination.
- ii) Maximize the negative of the time of flight.
- iii) Maximize the total number of heliocentric revolutions in the trajectory, and three constraints limiting the SEPTOP convergence error and minimum and maximum bounds on heliocentric revolutions.

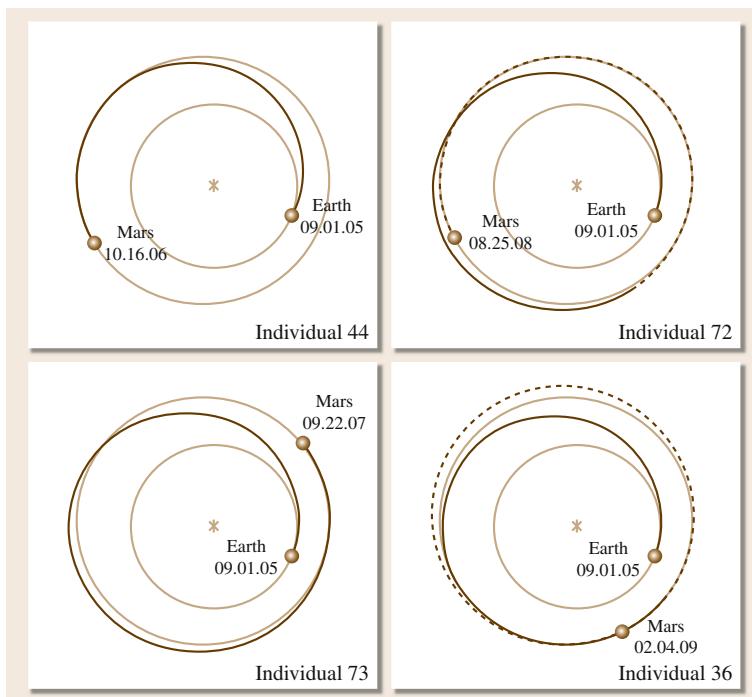

On the Earth–Mars rendezvous mission, the study found interesting trade-off solutions [49.55]. Using a population of size 150, the NSGA was run for 30 generations. The non-dominated solutions obtained are shown in Fig. 49.9 for two of the three objectives, and some selected solutions are shown in Fig. 49.10. It is clear that there exist short-time flights with smaller delivered payloads (solution marked 44 with 1.12 years of flight and delivering 685.28 kg load) and long-time flights with larger delivered payloads (solution marked 36 with close to 3.5 years of flight and delivering about 900 kg load). While solution 44 can deliver a mass of 685.28 kg and requires about 1.12 years, solution 72 can deliver almost 862 kg with a travel time of about 3 years. In these figures, each continuous part of a trajectory represents a *thrusting arc* and each dashed part of a trajectory represents a *coasting arc*. It is interesting to note that only a small improvement in delivered mass occurs in the solutions between 73 and 72 with a sacrifice in flight time of about 1 year.

The multiplicity in trade-off solutions, as depicted in Fig. 49.10, is what we envisaged in discovering in a multi-objective optimization problem by using a posteriori procedure, such as a generating method or using an EMO procedure vis-a-vis an a priori approach in which a single scalarized problem is solved with a single preferred parameter setting to find a single Pareto-optimal solution. This aspect is also shown in Fig. 49.2. Once a set of solutions with a good trade-off among objectives is obtained, one can analyze them to choose a particular solution. For example, in this problem context, it makes sense not to choose a solution between points 73 and 72 due to poor trade-off between the objectives in this range, a matter which is only revealed after a representative set of trade-off solutions are found. On the other hand, choosing a solution within points 44 and 73 is worthwhile, but which particular solution to choose depends on other mission-related issues. However, by first finding a wide range of possible solutions thereby revealing the shape of front in a computationally quicker manner, EMO can help a decision-maker in narrowing down the choices

**Fig. 49.9** Non-dominated solutions obtained using NSGA

and in allowing a better decision to be made. Without the knowledge of such a wide variety of trade-off solutions, proper decision-making may be a difficult task. With the use of an a priori approach to find a single solution using, for example, the  $\epsilon$ -constraint method with a particular  $\epsilon$  vector, the decision-maker will always wonder what solution would have been derived if a different  $\epsilon$  vector had been chosen. For example, if  $\epsilon_1 = 2.5$  years is chosen and the mass delivered to the target is maximized, a solution in between points 73 and 72 will be found. As discussed earlier, this part of the Pareto-optimal front does not provide the best trade-offs between the objectives that this problem can offer. A lack of knowledge of good trade-off regions before a decision is made may allow the decision-maker to settle for a solution which, although optimal, may not be a good compromise solution. The EMO procedure allows a flexible and a pragmatic procedure for finding a well-diversified set of solutions simultaneously so as to enable picking a particular region for further analysis or a particular solution for implementation.

**Fig. 49.10** Four trade-off trajectories (after [49.55])

## 49.6 Recent Developments in EMO

An interesting aspect regarding research and application of **EMO** is that soon after a number of efficient **EMO** methodologies had been suggested and applied in various interesting problem areas, researchers did not waste any time to look for opportunities to make the field broader and more useful by diversifying **EMO** applications to various other problem-solving tasks. In this section, we describe a number of such salient recent developments of **EMO**.

### 49.6.1 Hybrid EMO Algorithms

The search operators used in **EMO** are heuristic based. Thus, these methodologies are not guaranteed to find Pareto-optimal solutions with a finite number of solution evaluations in an arbitrary problem. In single-objective **EA** research, hybridization of **EAs** is common for ensuring convergence to an optimal solution; it is not surprising that studies on developing hybrid **EMOs** are now being pursued to ensure that true Pareto-optimal solutions are found by hybridizing them with mathematically convergent ideas.

**EMO** methodologies provide adequate emphasis on currently non-dominated and isolated solutions so that population members progress towards the Pareto-optimal front iteratively. To make the overall procedure faster and to perform the task with a more theoretical emphasis, **EMO** methodologies are combined with mathematical optimization techniques having local convergence properties. A simple-minded approach would be to start the process with an **EMO** and the solutions obtained from **EMO** could be improved by optimizing a composite objective derived from multiple objectives to ensure a good spread by using a local search technique [49.57]. Another approach would be to use a local search technique as a mutation-like operator in an **EMO**, so that all population members are at least guaranteed to be local optimal solutions [49.57, 58]. To save computational time, instead of performing the local search for every solution in a generation, a mutation can be performed only after a few generations. Some recent studies [49.58–60] have demonstrated the usefulness of such hybrid **EMOs** for a guaranteed convergence.

Although these studies concentrated on ensuring convergence to the Pareto-optimal front, some emphasis should now be placed on providing adequate diversity among the solutions obtained, particularly when a continuous Pareto-optimal front is represented by a finite set of points. Some ideas of maximizing the hypervolume measure [49.61] or the maintenance of a uniform distance between points are proposed for this purpose, but how such diversity-maintenance techniques would be integrated with convergence-ensuring principles in a synergistic way would be interesting and useful future research. Some relevant studies in this direction exist already [49.59, 62–65].

## 49.6.2 Multi-Objectivization

Interestingly, the act of finding multiple trade-off solutions using an **EMO** procedure has found its application outside the realm of solving multi-objective optimization problems. The concept of finding near-optimal trade-off solutions is applied to solve other kinds of optimization problems as well. For example, the **EMO** concept is used to solve constrained single-objective optimization problems by converting the task into a two-objective optimization task of additionally minimizing an aggregate constraint violation [49.66]. This eliminates the need to specify a penalty parameter while using a penalty-based constraint handling procedure. If viewed this way, the usual penalty function approach used in classical optimization studies is a special weighted-sum approach to the bi-objective optimization problem of minimizing the objective function and minimizing the constraint violation, for which the weight vector is a function of the penalty parameter. A well-known difficulty in genetic programming studies, called *bloating*, arises due to the continual increase in the size of *genetic programs* evolved with iteration. The reduction of bloating by minimizing the size of a program as an additional objective has helped find high-performing solutions with a smaller size of the code [49.67, 68]. In clustering algorithms, minimizing the intra-cluster distance and maximizing inter-cluster distance simultaneously in a bi-objective formulation of a clustering problem is found to yield better solutions than the usual single-objective minimization of the ratio of the intra-cluster distance to the inter-cluster distance [49.69]. An **EMO** is found to solve a minimum spanning tree problem better than a single-objective **EA** [49.70]. A recently edited book [49.71] describes many interesting applications in which **EMO** methodologies have helped to solve problems that are oth-

erwise (or traditionally) not treated as multi-objective optimization problems.

## 49.6.3 Uncertainty-Based EMO

A major surge in **EMO** research has taken place in handling uncertainties among decision variables and problem parameters in multi-objective optimization. Practice is full of uncertainties and almost no parameter, dimension, or property can be guaranteed to be fixed at the value it is aimed at. In such scenarios, evaluation of a solution is not precise, and the resulting objective and constraint function values become probabilistic quantities. Optimization algorithms are usually designed to handle such stochasticities by using crude methods, such as Monte Carlo simulation of stochasticities in uncertain variables and parameters and by sophisticated stochastic programming methods involving nested optimization techniques [49.72]. When these effects are taken care of during the optimization process, the resulting solution is usually different from the optimum solution of the problem and is known as a *robust* solution. Such an optimization procedure will then find a solution which may not be the true global optimum solution, but one which is less sensitive to uncertainties in decision variables and problem parameters. In the context of multi-objective optimization, a consideration of uncertainties for multiple objective functions will result in a robust frontier which may be different from the globally Pareto-optimal front. Each and every point on the robust frontier is then guaranteed to be less sensitive to uncertainties in decision variables and problem parameters. Some such studies in **EMO** are [49.73, 74].

When the evaluation of constraints under uncertainties in decision variables and problem parameters is considered, deterministic constraints become stochastic (they are also known as *chance constraints*) and involve a *reliability index* ( $R$ ) to handle the constraints. A constraint  $g(\mathbf{x}) \geq 0$  then becomes  $\text{Prob}(g(\mathbf{x}) \geq 0) \geq R$ . In order to find the left-hand side of the above chance constraint, a separate optimization methodology [49.75] is needed, thereby making the overall algorithm a bi-level optimization procedure. Approximate single-loop algorithms exist [49.76] and recently one such methodology was integrated with an **EMO** [49.72] and shown to find a *reliable* frontier corresponding a specified reliability index, instead of the Pareto-optimal frontier, in problems having uncertainty in decision variables and problem parameters. More such methodologies are needed, as uncertainties are an integral part of practical

problem-solving, and multi-objective optimization researchers must look for better and faster algorithms to handle them.

#### 49.6.4 EMO and Decision-Making

Searching for a set of Pareto-optimal solutions by using an **EMO** fulfills only one aspect of multi-objective optimization, as choosing a particular solution for an implementation is the remaining decision-making task, which is equally important. For many years, **EMO** researchers have postponed the decision-making aspect and concentrated on developing efficient algorithms for finding multiple trade-off solutions. Having pursued that part somewhat, now for the past couple of years or so, **EMO** researchers are putting efforts to design combined algorithms for optimization and decision-making. In the view of the author, the decision-making task can be considered from two main considerations in an **EMO** framework:

1. *Generic consideration*: there are some aspects that most practical users would like to use in narrowing down their choice. Above we discussed the importance of finding robust and reliable solutions in the presence of uncertainties in decision variables and/or problem parameters. In such scenarios, an **EMO** methodology can straightaway find a robust or a reliable frontier [49.72, 73] and no subjective preference from any decision maker may be necessary. Similarly, if a problem resorts to a Pareto-optimal front having *knee* points, such points are often the choice of decision-makers. Knee points demands a large sacrifice in at least one objective to achieve a small gain in another, thereby making it discouraging to move out from a knee point [49.77]. Other such generic choices are related to Pareto-optimal points depicting a certain pre-specified relationship between objectives, Pareto-optimal points having multiplicity (say, at least two or more solutions in the decision variable space mapping to identical objective values), Pareto-optimal solutions which do not lie close to variable boundaries, Pareto-optimal points having certain mathematical properties, such as all Lagrange multipliers with more or less identical magnitudes – a condition often desired to make an equal importance to all constraints, and others. These considerations are motivated from the fundamental and practical aspects of optimization and may be applied to most multi-objective problem-solving tasks, without any

consent of a decision-maker. These considerations may narrow down the set of non-dominated points. A further subjective consideration (which is discussed below) may then be used to pick a preferred solution.

2. *Subjective consideration*: in this category, any problem-specific information can be used to narrow down the choices, and the process may even lead to a single preferred solution at the end. Most decision-making procedures use some preference information (utility functions, reference points [49.78], reference directions [49.79], marginal rate of return, and a host of other considerations [49.9]) to select a subset of Pareto-optimal solutions. A recent book [49.80] is dedicated to the discussion of many such multi-criteria decision analysis (**MCDA**) tools and collaborative suggestions of using **EMO** with such **MCDA** tools. Some hybrid **EMO** and **MCDA** algorithms have been suggested in the recent past [49.81–85].

Many other generic and subjective considerations are needed, and it is interesting that **EMO** and **MCDM** researchers are collaborating on developing such complete algorithms for multi-objective optimization [49.80].

#### 49.6.5 EMO for Handling a Large Number of Objectives: Multi-Objective EMO

Initial studies of **EMO** amply showed that **EMO** algorithms can be used to find a wide spread of trade-off solutions on two and three-objective optimization problems. However, their performance on four or more objective problems have not been studied enough. Recently, such studies have become important and are known as many-objective optimization studies in the **EMO** literature.

A detailed study [49.86] made on eight-objective problems revealed somewhat negative results about the existing **EMO** methodologies. However, in his book [49.8] and recent other studies [49.87–90] the author has clearly explained the reasons for this behavior of **EMO** algorithms. **EMO** methodologies work by emphasizing non-dominated solutions in a population. Unfortunately, as the number of objectives increases, most population members in a randomly created population tend to become non-dominated to each other. For example, in a three-objective scenario, about 10% of the members in a population of the size 200 are non-dominated, whereas in a 10-objective problem sce-

nario, as much as 90% of the members in a population of size of 200 are non-dominated. Thus, in a large-objective problem, an **EMO** algorithm runs out of room to introduce new population members into a generation, thereby causing a stagnation in the performance of an **EMO** algorithm. It has been argued that to make **EMO** procedures efficient, an exponentially large population size (with respect to the number of objectives) is needed. This makes the **EMO** procedure slow and computationally less attractive.

However, recent techniques use a fixed set of reference points [49.91–93] or reference directions [49.94] and are promising, as they are shown to find a widely distributed set of solutions in 3 to 15-objective test and real-world problems.

However, practically speaking, even if an algorithm can find tens of thousands of Pareto-optimal solutions for a multi-objective optimization problem, besides simply getting an idea of the nature and shape of the front, they are simply too many to be conceivable for any decision-making purposes. Keeping these views in mind, **EMO** researchers have taken two different approaches in dealing with many-objective problems.

### Finding a Partial Set

Instead of finding the complete Pareto-optimal front in a problem having many objectives, **EMO** procedures can be used to find only a preferred part of the Pareto-optimal front. This can be achieved by indicating preference information by various means. Ideas such as reference point-based **EMO** [49.81, 85], *light beam search* [49.82], biased sharing approaches [49.95], cone-dominance [49.96], etc. have been suggested for this purpose. Each of these studies has shown that for up to 10 and 20-objective problems, although finding the complete frontier is a difficulty, finding a partial frontier corresponding to certain preference information is not that difficult a proposition.

The use of a parallel or a distributed computing platform can be used with the above idea, and the complete Pareto-optimal front can be obtained by a distributed computing procedure [49.96]. In the study, each processor in a distributed computing environment receives a unique cone defining domination. The cones are designed carefully so that at the end of such a distributed computing **EMO** procedure, solutions are found to exist in various parts of the complete Pareto-optimal front. A collection of these solutions is then able to provide a good representation of the entire original Pareto-optimal front.

### Identifying and Eliminating Redundant Objectives

Many practical optimization problems can easily list a large of number of objectives (often more than 10), as many different criteria or goals are often of interest to practitioners. In most instances, it is not entirely sure whether or not the chosen objectives are all in conflict with each other. For example, the minimization of weight and the minimization of cost of a component or a system are often mistaken to have an identical optimal solution, but may lead to a range of trade-off optimal solutions. Practitioners do not take any chances and tend to include all (or as many as possible) objectives into the optimization problem formulation. There is another fact which is more worrisome. Two apparently conflicting objectives may show a good trade-off when evaluated with respect to some randomly created solutions. However, if these two objectives are evaluated for solutions close to their optima, they tend to show a good correlation. That is, although objectives can exhibit conflicting behavior for random solutions, near their Pareto-optimal front, the conflict vanishes and the optimum of one becomes close to the optimum of the other.

Thinking of the existence of such problems in practice, certain researchers [49.90, 97, 98] performed linear and non-linear principal component analysis (**PCA**) to a set of **EMO**-produced solutions. Objectives causing a positively correlated relationship between the the obtained **NSGA-II** solutions were identified and declared as redundant. The **EMO** procedure is then restarted with non-redundant objectives. This combined **EMO-PCA** procedure is continued until no further reduction in the number of objectives is possible. The procedure has handled practical problems involving five and more objectives and has shown to reduce the choice of real conflicting objectives to a few. On test problems, the proposed approach has been shown to reduce an initial 50-objective problem to the correct three-objective Pareto-optimal front by eliminating 47 redundant objectives. Another study [49.99] used an exact and a heuristic-based conflict identification approach on a given set of Pareto-optimal solutions. For a given error measure, an effort is made to identify a minimal subset of objectives that does not alter the original dominance structure on a set of Pareto-optimal solutions. This idea was recently introduced within an **EMO** [49.100], but a continual reduction of objectives through a successive application of the above procedure would be interesting.

This is a promising area of **EMO** research and more computationally faster objective-reduction techniques are definitely needed for the purpose. A recent approach uses previously-fixed multiple directional searches to find a widely distributed set of Pareto-optimal points [49,94]. In this direction, the use of alternative definitions of domination may be beneficial. One such idea redefined the definition of domination: a solution is said to dominate another solution, if the former solution is better than the latter one in more objectives. This certainly excludes finding the entire Pareto-optimal front and helps an **EMO** to converge near the intermediate and central part of the Pareto-optimal front. Another **EMO** study used a fuzzy dominance [49,101] relation (instead of Pareto-dominance), in which superiority of one solution over another in any objective is defined in a fuzzy manner. Many other such definitions are possible and can be implemented based on the problem context.

#### 49.6.6 Knowledge Extraction Through **EMO**

One striking difference between single-objective optimization and multi-objective optimization is the cardinality of the solution set. In the latter, multiple solutions are the outcome and each solution is theoretically an optimal solution corresponding to a particular trade-off among the objectives. Thus, if an **EMO** procedure can find solutions close to the true Pareto-optimal set, what we have in our hands is a number of high-performing solutions trading-off the conflicting objectives considered in the study. Since these solutions are all near optimal, they can be analyzed for finding properties which are common to them. Such a procedure can then become a systematic approach in deciphering the important and hidden properties that optimal and high-performing solutions must have for that problem. In a number of practical problem-solving tasks, the so-called *innovation* procedure is shown to find important knowledge about high-performing solutions [49,102]. Such useful properties are expected to exist in practical problems, as they follow certain scientific and engineering principles at the core, but in the past not much attention had been paid to finding them through a systematic scientific procedure. The principle of first searching for multiple trade-off and high-performing solutions using a multi-objective optimization procedure and then analyzing them to discover useful knowledge certainly remains a viable way forward. The current efforts [49,103,104] to automate the knowledge extraction procedure through a sophisticated

data-mining task should make the overall approach more appealing and useful in practice.

#### 49.6.7 Dynamic **EMO**

Dynamic optimization involves objectives, constraints, or problem parameters that change over time. This means that as an algorithm approaches the optimum of the current problem, the problem definition changes and now the algorithm must solve a new problem. This is not equivalent to another optimization task in which a new and different optimization problem must be solved afresh. Often, in such dynamic optimization problems, an algorithm is usually not expected to find the optimum, instead it is best expected to track the optimum changing with the iteration. The performance of a dynamic optimizer then depends on how close it is able to track the true optimum (which changes with iteration or time). Thus, practically speaking, it may be hoped that optimization algorithms can handle problems that do not change significantly with time. With respect to the algorithm, since here the problem is not expected to change too much from one time instance to another and some good solutions to the current problem are already at hand in a population, researchers fancied solving such dynamic optimization problems using evolutionary algorithms [49,105].

A recent study [49,106] proposed the following procedure for dynamic optimization involving single or multiple objectives. Let  $\mathcal{P}(t)$  be a problem that changes with time  $t$  (from  $t = 0$  to  $t = T$ ). Despite the continual change in the problem, we assume that the problem is fixed for a time period  $\tau$ , which is not known a priori, and the aim of the (offline) dynamic optimization study is to identify a suitable value of  $\tau$  for an accurate as well as a computationally faster approach. For this purpose, an optimization algorithm with  $\tau$  as a fixed time period is run from  $t = 0$  to  $t = T$  with the problem assumed fixed for every  $\tau$  time period. A measure  $\Gamma(\tau)$  determines the performance of the algorithm and is compared with a pre-specified and expected value  $\Gamma_L$ . If  $\Gamma(\tau) \geq \Gamma_L$ , for the entire time domain of the execution of the procedure, we declare  $\tau$  to be a permissible length of stasis. Then, we try with a reduced value of  $\tau$  and check if a smaller length of stasis is also acceptable. If not, we increase  $\tau$  to allow the optimization problem to remain static for a longer time so that the chosen algorithm can now have more iterations (time) to perform better. Such a procedure will eventually come up with a time period  $\tau^*$ , which would be the smallest time of stasis allowed for the optimiza-

tion algorithm to work based on chosen performance requirement. Based on this study, a number of test problems and a hydro-thermal power dispatch problem were tackled recently [49.106].

In the case of dynamic multi-objective problem-solving tasks, there is an additional difficulty which is worth mentioning here. Not only does an **EMO** algorithm need to find or track the changing Pareto-optimal fronts, in a real-world implementation, it must also make an immediate decision about which solution to implement from the current front before the problem changes to a new one. Decision-making analysis is considered to be time-consuming, involving execution of analysis tools, higher-level considerations, and sometimes group discussions. If dynamic **EMO** is to be applied in practice, *automated* procedures for making decisions must be developed. Although it is not clear how to generalize such an automated decision-making procedure in different problems, problem-specific tools are certainly possible and a worthwhile and fertile area for research.

#### 49.6.8 Quality Estimates for **EMO**

When algorithms are developed and test problems with known Pareto-optimal fronts are available [49.107–110], an important task is to have performance measures with which the **EMO** algorithms can be evaluated. Thus, a major focus of **EMO** research has been used to develop different performance measures. Since the focus in an **EMO** task is multi-faceted – convergence to the Pareto-optimal front and diversity of solutions along the entire front, it is also expected that one performance measure to evaluate **EMO** algorithms will be unsatisfactory. In the early years of **EMO** research, three different sets of performance measures were used:

1. Metrics evaluating convergence to the known Pareto-optimal front (such as error ratio, distance from reference set, etc.)
2. Metrics evaluating spread of solutions on the known Pareto-optimal front (such as spread, spacing, etc.).
3. Metrics evaluating certain combinations of convergence and spread of solutions (such as hypervolume, coverage, R-metric, etc.).

Some of these metrics are described in texts [49.8, 44]. A detailed study [49.111] comparing most existing performance metrics based on out-performance relations recommended the use of the S-metric (or the hypervolume metric) and the R-metric suggested

by [49.112]. A recent study argued that a single unary performance measure or any finite combination of them (for example, any of the first two metrics described above in the enumerated list or both together) cannot adequately determine whether one set is better than another [49.113]. That study also concluded that binary performance metrics (indicating usually two different values when a set of solutions  $A$  is compared against  $B$  and  $B$  is compared against  $A$ ), such as an epsilon-indicator, a binary hypervolume indicator, utility indicators R1 to R3, etc., are better measures for multi-objective optimization. The flip side is that the chosen binary metric must be computed  $K(K-1)$  times when comparing  $K$  different sets to make a fair comparison, thereby making the use of binary metrics computationally expensive in practice. Importantly, these performance measures have allowed researchers to use them directly as fitness measures within indicator-based **EAs (IBEAs)** [49.114]. In addition, the attainment indicators of [49.115, 116] provide further information about location and inter-dependencies among the solutions obtained.

The hypervolume metric is a popular metric used in **EMO** studies. However, the computation of the hypervolume metric for more than three-objective problems becomes a computationally challenging task. Recent studies on computationally fast estimation methods of the hypervolume metric have gained popularity among theoretical minds [49.62, 63, 117, 118]. These methods compute the proportion of randomly generated objective points that are dominated by the current set of non-dominated points to estimate the hypervolume metric. A reliable computation method of these studies will facilitate the use of the hypervolume metric in designing efficient **EMO** algorithms.

#### 49.6.9 Exact **EMO** with Run-Time Analysis

Since they were first suggested, efficient **EMO** algorithms have been increasingly applied in a wide variety of problem domains to obtain trade-off frontiers. Simultaneously, some researchers have also devoted their efforts to developing exact **EMO** algorithms with a theoretical complexity estimate in solving certain discrete multi-objective optimization problems. The first such study [49.119] suggested a pseudo-Boolean multi-objective optimization problem – a two-objective **LOTZ** (leading ones trailing zeroes) – and a couple of **EMO** methodologies – a simple evolutionary multi-objective optimizer (**SEMO**) and an improved version fair evolutionary multi-objective optimizer (**FEMO**).

The study then estimated the worst-case computational effort needed to find all Pareto-optimal solutions of the **LOTZ** problem. This study spurred a number of improved **EMO** algorithms with run-time estimates and resulted in many other interesting test problems [49, 120–123]. Although these test problems may not resemble common practical problems, the working principles of suggested **EMO** algorithms to handle specific problem structures bring in a plethora of insights about the working of multi-objective optimization, particularly in comprehensively finding all (not just one or a few) Pareto-optimal solutions.

#### 49.6.10 **EMO** with Meta-Models

The practice of optimization algorithms is often limited by the computational overheads associated with evaluating solutions. Certain problems involve expensive computations, such as numerical solution of partial differential equations describing the physics of the problem, finite difference computations involving an analysis of a solution, computational fluid dynamics simulation to study the performance of a solution over a changing environment, etc. In some such problems, evaluation of each solution to compute constraints and objective functions may take a few hours to a complete day or two. In such scenarios, even if an optimization algorithm needs one hundred solutions to get anywhere close to a good and feasible solution, the application needs an easy 3 to 6 months of continuous computational time. In most practical

purposes, this is considered a *luxury* in an industrial set-up. Optimization researchers are constantly on their toes in coming up with approximate, yet faster algorithms.

A little thought brings out an interesting fact about how optimization algorithms work. The initial iterations deal with solutions which may not be close to optimal solutions. Therefore, these solutions need not be evaluated with high precision. Meta-models for objective functions and constraints have been developed for this purpose. Mostly two different approaches are followed. In one approach, a sample of solutions is used to generate a meta-model (an approximate model of the original objectives and constraints), and then efforts are made to find the optimum of the meta-model, assuming that the optimal solutions of both the meta-model and the original problem are similar to each other [49, 124, 125]. In another method, a successive meta-modeling approach is used in which the algorithm starts to solve the first meta-model obtained from a sample of the entire search space [49, 126–128]. As the solutions start to focus near the optimum region of the meta-model, a new and more accurate meta-model is generated in the region dictated by the solutions of the previous optimization. A coarse-to-fine-grained meta-modeling technique based on artificial neural networks is shown to reduce the computational effort by about 30 to 80% on different problems [49, 126]. Other successful meta-modeling implementations for multi-objective optimization are based on Kriging and response surface methodologies exist [49, 128, 129].

## 49.7 Conclusions

The research and application in evolutionary multi-objective optimization (**EMO**) over the past 15 years have resulted in a number of efficient algorithms for finding a set of well-diversified, near Pareto-optimal solutions. **EMO** algorithms are now regularly being applied to different problems in most areas of science, engineering, and commerce. This chapter has discussed the principles of **EMO** and illustrated the principle by depicting one efficient and popularly used **EMO** algorithm. Results from an inter-planetary spacecraft trajectory optimization problem reveal the importance of the principles followed in **EMO** algorithms. Thereafter, a specific constraint handling procedure used in **EMO** studies was briefly described.

The main highlight of this chapter has been the description of some of the current research and appli-

cation activities in **EMO**. One critical area of current research lies in collaborative **EMO-MCDM** algorithms for achieving a complete multi-objective optimization task of finding a set of trade-off solutions and finally arriving at a single preferred solution. Another direction taken by researchers is to address guaranteed convergence and diversity of **EMO** algorithms through hybridizing them with mathematical and numerical optimization techniques as local search algorithms. Interestingly, **EMO** researchers have discovered its potential in solving traditionally hard optimization problems, but not necessarily multi-objective ones in nature, in a convenient manner using **EMO** algorithms. So-called multi-objectivization studies are attracting researchers from various fields to develop and apply **EMO** algorithms in many innovative ways. Considerable interest

in research and application has also been shown in addressing practical aspects in existing **EMO** algorithms. In this direction, handling uncertainty in decision variables and parameters, meeting an overall desired system reliability in obtained solutions, handling dynamically changing problems (on-line optimization), and handling a large number of objectives have been discussed in this chapter. Besides the practical aspects, **EMO** has also attracted mathematically-oriented theoreticians to develop **EMO** algorithms and design suitable problems for coming up with a computational complexity analysis. There are many other research directions which could not even mention due to space restrictions.

In the short span of about 15 years, it has become clear that the field of **EMO** research and application now has efficient algorithms and numerous interesting

and useful applications, and has been able to attract theoretically and practically-oriented researchers to come together and collaborate. The practical importance of **EMO**'s working principle, the flexibility of evolutionary optimization, which lies at the core of **EMO** algorithms, and the demonstrated diversification of **EMO**'s principle to a wide variety of different problem-solving tasks are the main cornerstones for their success so far. The scope of research and application in **EMO** and using **EMO** are enormous and open-ended. This chapter remains an open invitation to everyone who is interested in any type of problem-solving tasks to take a look at what has been done in **EMO** and to explore how one can contribute to collaborating with **EMO** to address problem-solving tasks that are still in need of a better solution procedure.

# 50. Parallel Multiobjective Evolutionary Algorithms

# Parallel Multiobjective Evolutionary Algorithms

Francisco Luna, Enrique Alba

The use of evolutionary algorithms (EAs) for solving multiobjective optimization problems has been very active in the last few years. The main reasons for this popularity are their ease of use with respect to classical mathematical programming techniques, their scalability, and their suitability for finding trade-off solutions in a single run. However, these algorithms may be computationally expensive because (1) many real-world optimization problems typically involve tasks demanding high computational resources and (2) they are aimed at finding a whole front of optimal solutions instead of searching for a single optimum. Parallelizing EAs emerges as a possible way of reducing the CPU time down to affordable values, but it also allows researchers to use an advanced search engine – the parallel model – that provides the algorithms with an improved population diversity and enable them to cooperate with other (eventually nonevolutionary) techniques. The goal of this chapter is to provide the reader with an up-

to-date review of the recent literature on parallel EAs for multiobjective optimization.

## 50.1 Multiobjective Optimization and Parallelism

Multiobjective optimization arises in many real-world applications, especially in engineering, in which several performance criteria conflict with each other. These conflicting objectives make the optimization results in that no single solution can usually optimize them all simultaneously. Indeed, the aim of multiobjective optimization is to find a set of compromise solutions with different tradeoffs among criteria, also known as the *Pareto optimal set*. When this set is plotted in the objective space it is called the *Pareto front* [50.1, 2].

Many different techniques have been proposed in the multiobjective research community to address multiobjective optimization problems (MOPs). Unlike classical mathematical programming approaches, meta-

heuristics in general, and EAs (multiobjective evolutionary algorithms or MOEAs) in particular, have attracted growing attention over the last decade because of two main facts. On the one hand, EAs have the ability to generate several members of the Pareto optimal set in one single run, as opposed to classical multicriteria decision-making techniques. They are also less sensitive to the shape of the Pareto front so therefore can deal with a large variety of MOPs. On the other hand, as randomized black-box algorithms, EAs can address optimization problems with nonlinear, nondifferentiable, or noisy objective functions.

In spite of these advantages, these algorithms might be computationally expensive because, on the one hand,

they need to explore larger portions of the search space since they seek the entire Pareto front, which usually results in more function evaluations being performed; on the other hand, and even more importantly, many real-world multiobjective problems typically use computationally expensive methods for computing the objective functions and constraints.

These issues are usually addressed in two different ways. First, one can use surrogate models of the fitness functions instead of true fitness function evaluations [50.3–5]. The second more important line lies in using parallel computing platforms to speed up the EA search [50.6]. This is the mainstream of this chapter.

Due to their population-based approach, EAs are very suitable for parallelization because their main operations (i.e., crossover, mutation, and in particular function evaluation) can be carried out independently on different individuals. There is a vast amount of literature on how to parallelize EAs; the reader is referred to [50.7–10] for surveys on this topic. However, parallelism here is not only a way for solving problems more rapidly, but also for developing new and more efficient search models: a parallel EA can be more effective than a sequential one, even when executed on a single processor. The advantages that parallelism offer to single-objective optimization also hold in multiobjective optimization. Of particular interest for parallel

MOEAs is the improvement in population diversity that shall help to fully approximate the entire Pareto front of the given optimization problems.

The contribution of this chapter is to provide the reader with a recent review of publications related to parallel MOEAs, showing the latest advances in the field. Given the shear volume of papers, we have been forced to restrict ourselves to only those works which have been published since 2008/09, the years to which the two best known surveys date back [50.11, 12]. The structure of this chapter distinguishes between the numerical model of the parallel MOEA and its physical parallelization. In seminal papers in the fields [50.13], it was assumed that the model maps directly onto the parallel computing platform, but this is no longer true and any (MO)EA can be deployed in parallel, but not always resulting in a high performance. The next section is therefore devoted to presenting the classical models for parallel EAs and a recent proposal that not only considers EAs, but metaheuristics and exact algorithms in general. Section 50.3 dives into the details of more than 80 publications, analyzing particular features of MOEAs (fitness assignment, diversity preservation) as well as on their parallelization (model, topology, parallel platform). Finally, the last section presents the main conclusions and the trends for future research on parallel MOEAs.

## 50.2 Parallel Models for Evolutionary Multi-Objective Algorithms

Parallelism arises naturally when dealing with populations of individuals, since each individual is an independent unit. As a consequence, the performance of population-based algorithms is particularly improved when run in parallel. The main models for parallel MOEAs have been proposed within two clear scopes: especially EA-targeted models coming from the EA community [50.7, 14, 15] and those proposed for parallel metaheuristics in general (of which EAs are a subclass) [50.12, 16]. They are briefly presented in the following subsections.

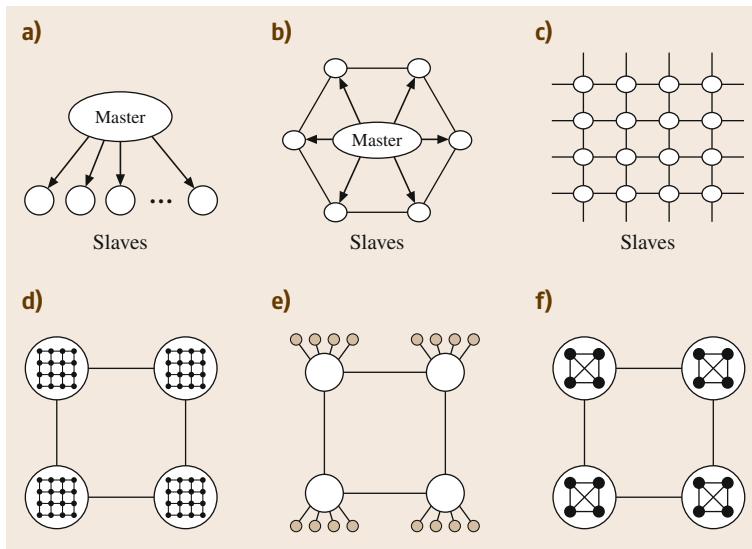

### 50.2.1 Specialized Models for Parallel EAs

The most well-known models for parallel MOEAs have been inherited directly from the single-objective parallel EA community, in which two parallelizing strategies are defined for population-based algorithms: (1) parallelization of computation, in which the operations

commonly applied to each individual are performed in parallel, and (2) parallelization of population, in which the population is split into different parts, each one evolving in semi-isolation (individuals can be exchanged between subpopulations).

The simplest parallelization scheme of EAs is the well-known *master-slave* or *global parallelization* method (Fig. 50.1a). In this scheme, a central processor performs the selection operations while the associated slave processors perform the recombination, mutation, and/or the evaluation of the fitness function. This algorithm is the same as the traditional (one population, panmictic), although it is faster, especially for time-consuming objective functions. Its simplicity has made it the most popular among practitioners.

However, other models for parallel EAs utilize some kind of spatial disposition of the individuals (it is said that the population is then *structured*), and afterward parallelize the resulting chunks in a pool of proces-

**Fig. 50.1a-f** Different models of parallel EAs: (a) global parallelization, (b) coarse grain, and (c) fine grain. Many hybrids have been defined by combining parallel EAs at two levels: (d) coarse and fine grain, (e) coarse grain and global parallelization, and (f) coarse grain at the two levels

sors. Among the most widely known types of structured EAs, the *distributed* (**dEA**) (or coarse-grain) and *cellular* (**CEA**) (fine-grain or diffusion) algorithms are very popular optimization procedures [50.7]. In the case of distributed EAs (Fig. 50.1b), the population is partitioned into a set of islands in which isolated EAs run in parallel. Sparse individual exchanges are performed among these islands, with the goal of inserting some diversity into the subpopulations, thus avoiding them getting stuck in local optima. Islands may apply the same (homogeneous) or different (heterogeneous) EAs [50.17]. In the case of a cellular EA (Fig. 50.1c), subpopulations are typically composed of one individual, which may only interact with its nearest neighbors in the breeding loop, i.e., the concept of *neighborhood* is introduced. These neighborhoods are overlapped, which implicitly defines a migration mechanism and allows a smooth diffusion of the best solutions throughout the population. This parallel scheme was targeted to massively parallel computers but nowadays it can be used sequentially on a regular computer or in parallel on graphic processing units (**GPUs**). Also, hybrid models have been proposed (Fig. 50.1d-f) in which a two-level approach of parallelization is undertaken. In these models, the higher level for parallelization uses to be a coarse-grain implementation and the basic island performs a **CEA**, a master–slave method, or even another distributed one.

This taxonomy holds as well for parallel MOEAs [50.15], so we can consider master–slave MOEAs (**msMOEAs**), distributed MOEAs (**dMOEAs**),

and cellular MOEAs (**cMOEAs**). Nevertheless, these two decentralized population approaches need a further particularization for MOPs [50.14]. As we stated before, the main goal of any multiobjective optimization algorithm is to find the optimal Pareto front for a given MOP. It is clear that in **msMOEAs** the management of this Pareto front is carried out by the master processor. But, when the search process is distributed among different subalgorithms, as happens in **dMOEAs** and **cMOEAs**, the management of the nondominated set of solutions during the optimization procedure becomes a capital issue. Hence, it can be distinguished when the Pareto front is distributed and locally managed by each sub-EA during the computation, or it is a centralized element of the algorithm. They have been called *centralized Pareto front (CPF)* structured MOEAs and *Distributed Pareto Front (DPF)* structured MOEAs, respectively [50.16].

For distributed MOEAs, very specialized models have been proposed in the literature which are aimed at capturing the different approaches for partitioning the search of each island so as to avoid them overlapping their exploration [50.18]. On the one hand, each island may consider a different subset of the objectives and then either aggregate them into a single-objective problem [50.19] or use a coevolutionary approach [50.20]. On the other hand, the search space (either the decision space or the objective space) can be explicitly partitioned and assigned to different islands. As stated in [50.11], in a general multiobjective problem it is difficult to design an a priori distribution so that it:

1. Covers the entire search space,
2. Assigns regions of equal size, and
3. Aggregates a minimum complexity to constraint demes to their assigned region.

### 50.2.2 General Models for Parallel Metaheuristics

Several models have been proposed for parallelizing metaheuristics [50.21, 22] in which **EAs**, as a type of metaheuristic, perfectly fit. For parallel **MOEAs**, two main approaches have been proposed in the literature. In [50.16], the authors distinguish between single-walk and multiple-walk parallelizations. The former is aimed at speeding up the computations by parallelizing the evaluation of the objective functions or the search operators. In the latter, several search threads (**EAs** or any other search method) cooperate to better explore the search space (not only accelerating the execution). The same issue with the Pareto front as in the parallel **MOEA** models emerges here, so the authors also subdivide into centralized and distributed Pareto front models (**CPF** and **DPF**, respectively).

On the other hand, *Talbi et al.* [50.12] categorize parallel metaheuristics in three major hierarchical models. The *self-contained parallel cooperation* is targeted to parallel computing platforms with limited communication. The search is performed by several subalgorithms in parallel, which might cooperate by exchanging some kind of information. It embraces the island model or **dMOEAs** explained before. Two main groups are distinguished: cooperating subpopulations, which are based on partitioning the objective/search space; and the multistart approach, in which several optimization algorithms run separately in parallel. In the former, subpopulations can be homogeneous or heterogeneous, explore separate regions of the search space, etc. The latter lies in running several local search algorithms in parallel. On a second and third level of the hierarchy, the authors consider those models aimed merely at speeding up the computations: *problem independent parallelization*, which mainly comprises the master-slave approach of parallel fitness evaluation, and *problem dependent parallelization*, which focuses on subdividing single evaluations into parallel tasks that speed up the evaluation step.

## 50.3 An Updated Review of the Literature

This section is devoted to presenting and analyzing the most recent contributions in the literature to the parallel evolutionary multiobjective optimization field. We have structured the published material according to the classical parallel **EA** models, i. e., master/slave, distributed, cellular, and hybrid models (Sect. 50.2.1) because this chapter is targeted precisely to **EAs** and, as a consequence, this classification better captures the design principles of the different contributions. Table 50.1 includes, ordered by the year of publication, an updated review of the field. Also, in order to help the reader with the terminology of this table, Table 50.2 displays the symbols used and their definitions. Then, for each row of Table 50.1, the following information is shown:

- **FA-DP** (Fitness assignment and diversity preservation): As two of the most important design issues in **EMO** algorithms, the fitness assignment and diversity preservation mechanisms allow, respectively, to better guide the search toward Pareto optimal solutions and to spread out these Pareto optimal solutions along the entire Pareto front. They are frequently merged into one single measure that translates the vector of objective functions value

of a multiobjective problem into one single scalar value which is used to rank solutions properly (from a Pareto optimality point of view, nondominated solutions are noncomparable).

- **PM** (Parallel model): It can take the values **MS** (Master/slave), **Dis** (distributed model), **Cell** (cellular model) or **Hyb** (hybrid), according to the classical parallel **EA** categorization.
- **PFC** (Pareto front computation): This column distinguishes between the **CPF** and **DPF** strategies defined before.
- **PP** (parallel platform): When applicable, this column indicates the kind of parallel computing platform in which the given algorithm is executed (**GPUs**, multicore, cluster, grid, etc.).
- Topology: Communication topology of the parallel **MOEA** (Star, Hybrid, all-to-all [A2A], etc.).
- Programming: When publicly reported, the programming language used to implement the parallel **MOEA** is included in this column.
- Description: The main features of the parallel **MOEA** in a few words.
- Application domain: The area in which the parallel **MOEA** has been applied.

**Table 50.1** Parallel MOEAs since 2008

Table 50.2 includes a list of the symbols used here and their definitions.

### 50.3.1 Analysis by Year

The first point of analysis of the published material is done with respect to the number of publications over the years considered in this chapter, i.e., the period between 2008 and 2011. Figure 50.2 displays this information not only for the period analyzed in this chapter,

**Table 50.2** List of symbols used in Table 50.1

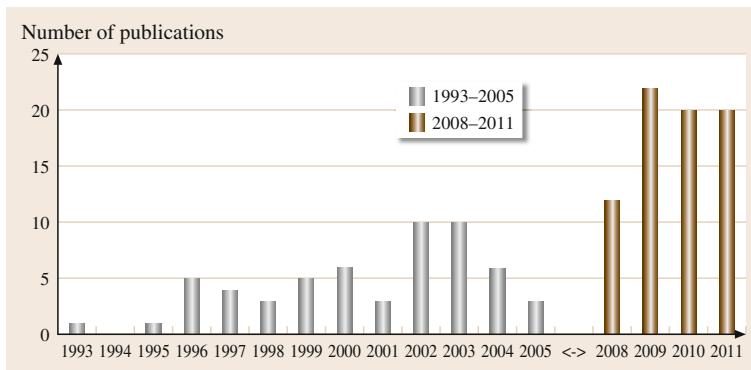

| Column      | Symbol     | Definition                               |
|-------------|------------|------------------------------------------|

but also for the period 1993–2005 presented in [50.14]. The trend is fairly clear: this research topic has been active during the last few years. Indeed, if one compares this evolution with that presented in [50.14] by 2006, where the highest number of works per year was 10, it can be seen that the published material is doubled (more than 20 publications/year in 2009, 2010, and 2011). Despite the relative lack of novel, attractive approaches in the field, parallelism remains as a powerful tool in the **EMO** community because of one major factor: the optimization problems addressed require to reduce the execution times to affordable values. This is emphasized with the current availability of cheap parallel computing platforms such as multicore processors and, lately, **GPUs**. Indeed, the keyword *multicore* in column **PP** in Table 50.1 is the second that appears the most.

### 50.3.2 Analysis of the Parallel Models

In this section, the different contributions are analyzed from the point of view of the characteristics of the parallel model. We will pay particular attention to the columns **FA-DP**, **PM**, **PFC**, and **Topology**.

The fitness assignment and diversity preservation is a major issue in parallel **MOEAs** because, in many cases, the Pareto front is spread between different sub-algorithms (especially in the distributed models). The management of optimal solutions (via fitness assignment) and how they are distributed along the Pareto front (diversity) deserves a brief review. The **FA-DP** column shows that the Ranking and Crowding mechanisms inherited from the most widely used algorithm in the area, namely **NSGA-II** [50.95], are also the most present in the literature as long as **NSGA-II** is the base algorithm for many of these parallel **MOEAs**. In the case of the distributed and cellular models, it is worth mentioning that Crowding is applied locally, i.e., diversity is kept within the same subalgorithm. If no advanced mechanism is devised to partition the search space (such as in [50.96, 97]), the algorithm will be accepting/discardng solutions that should probably be in the same region as those computed by the other subalgorithm components. The same happens with classical **FA-DP** methods such as the strength raw fitness (**SRF**) or the indicator-based (**IB**) in column **FA-DP**, respectively). As a final note, we strongly believe that these algorithms based on decomposition such as **MOEA/D** [50.98] are especially well suited to profit from parallel platforms. Indeed, they are based on decomposing the multiobjective problems into a num-

**Fig. 50.2** Number of publications on parallel MOEAs grouped by the year of publication in the periods 1993–2005 (after [50.14]) and 2008–2011 (this chapter)

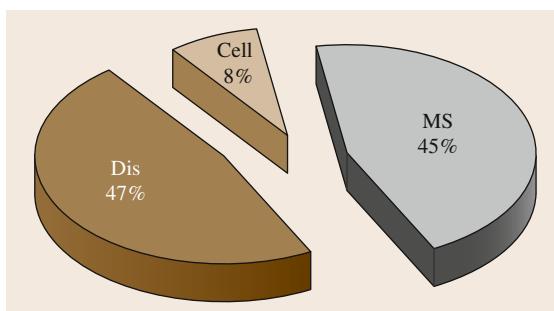

ber of scalar subproblems that are distributed along the Pareto front. Therefore, the partition of the search space is implicitly done and they take full advantage of multicore processors. The texts [50.80, 81] follow this line of research.

If one analyzes the usage of the different parallel models in the revised publications (Fig. 50.3), i.e., **MS**, distributed (Dis), and cellular (Cell), several clear conclusions can be drawn. First, despite the simplicity of the **MS** model, it appears in almost half of the related literature (45%). Multiobjective optimization problems are becoming more and more complex and demand high-end computational resources, what makes this approach very suitable in this context. Indeed, the underlying search model remains unchanged (entirely located at the master process), because authors are usually only interested at speeding up the computations. Second, the distributed models are still receiving much attention from the multiobjective community (47% of the analyzed publications use this model) in the quest for engineering an improved algorithm that reaches the Pareto fronts in a more effective way (not only reducing execution times). The promising results published with

their single objective counterparts [50.7] have pushed forward the research on this area. The major issue with distributed models arises with the difficult management of the Pareto front, as stated in Sect. 50.2.1 and as will be discussed below. Finally, a special comment about the cellular model: even though it is to be exploited in future literature, its percentage of use has doubled since the previous literature review in 2006 [50.14]. The point is that these algorithms are usually executed sequentially, with no parallelism at all, because they were originally targeted to massively parallel machines, and these kind of machines fell into disuse. There are, of course, some exceptions such as [50.46], where a cellular-like **MOEA** for aerodynamic optimization is deployed on a cluster of computers.

The **PFC** column is a hot topic in parallel **MOEAs**. Handling the nondominated solutions found during the search, when the search is distributed in probably separate processors, has promoted and is still promoting fundamental research within the community. The most widely used strategy, however, is to keep a central pool of nondominated solutions (**CPF**), that is, there is one single front. This approach appears in 55% of the analyzed publications and totally matches both the master/slave and the cellular parallel models. This design option is straightforward and makes common sense.

Almost the same happens with the **DPF** strategy (45% of the papers), which is mostly used with the distributed model of parallel **MOEAs**: the Pareto front is approximated separately for each of the subalgorithmic components during the search, only merged into one single front at the end of the exploration. In general, all **DPF** strategies are complemented with eventual **CPF** phases, which allows the search of the different subalgorithms to get overlapped [50.11]. A couple of exceptions are to be found among the revised literature, in which a distributed computation of the Pareto

**Fig. 50.3** Percentage of use of the different parallel **MOEA** models in the revised literature

front is endowed with a fully centralized Pareto front. In [50.50], a distributed MOEA has one single Pareto front that is computed with several isolated islands. Each island uses a weighted sum approach (with different weights) and is targeted to one region of the search space. The second exception appears in [50.80, 81], in which a multithreaded parallelization of MOEA/D is presented. The Pareto front is stored in global memory and the different threads are in charge of separate groups of weight combinations.

The final aspect under analysis in this section is the interconnection topology of the different components of the parallel algorithms. The Star topologies are widely used in two scenarios: (i) master/slave models and (ii) in distributed models with periodic gathering operations required to generate a single Pareto front. A star topology is able to capture the idea of topologies with a central master that delivers tasks to a set of worker nodes and this is why it is so popular in these two previous cases. The column *Topology* in Table 50.1 also reveals that All-to-All (A2A) and Random topologies also exist in the literature. The former enables the different components of the parallel algorithm to be tightly coupled, thus quickly spreading the nondominated solutions found for a faster convergence toward the optimal Pareto front. The later implies that the genetic material may take longer to reach all the algorithmic components, thus promoting diversity.

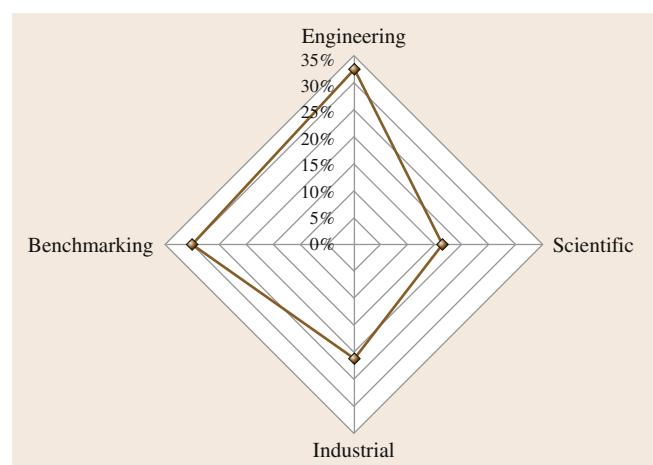

### 50.3.3 Review of the Software Implementations

This section is mainly targeted to summarize the contents of the column *Programming* in Table 50.1, in which a note on the implementation of the algorithms is given. A quick look at the items of the column clearly states that the combination of C/C++ as the programming language and MPI (Message Passing Interface) [50.99] as the technology for enabling the parallel communication between the different components of the parallel algorithms are the preferred options. This can be explained by the strong engineering background of most of the MOPs addressed (and researchers), a field in which C/C++ has had a dominant position for many years. Indeed, C/C++ allows researchers to include very low level routines (even assembler code) that enable full control of all parts of their applications. MPI, in turn, is a standard (not just a library) for which many implementations exist (MPICH, LAM, etc.), so its use always guarantee correctness and efficiency.

Despite this clear fact, only two novels, relevant trends on this topic that are worth mentioning in detail can be found. On the one hand, even though clusters of computers are able to provide researchers with a large computational power, there are MOPs that require still more additional resources. These resources can only be supplied by grid computing platforms [50.100]. This has promoted the parallelization of EMO algorithms with grid-enabled technologies such as MPICH-G2 [50.40] or MatGrid [50.34]. On the other hand, there already are several seminal works on the parallelization of multiobjective optimizers in GPUs, as stated in Sect. 50.3.1. To the best of our knowledge, only implementations with C and CUDA (compute unified device architecture) [50.101] have been proposed in [50.66, 93], but nowadays other opportunities have also emerged such as, for example, OpenCL [50.102].

### 50.3.4 Main Application Domains

One of the main reasons, if not the main one for the popularity of MOEAs, is their success in solving real-world problems. Parallel EMO algorithms are no exception. As a consequence, the variability in the application domains is very large, which makes the task of classification rather difficult. By partially following the categorization proposed in [50.18], three main areas of application are distinguished: *engineering*, *industrial*, and *scientific*. Figure 50.4 summarizes the percentage of revised publications that fall into each area. Besides these three categories, we have also displayed in this figure a fourth item devoted to bench-

**Fig. 50.4** Application domains

marking. This latter is not an *application* but it appears a lot in the revised literature. There are well-established testbeds such as Zitzler–Deb–Thiele (**ZDT**) [50.103], Deb–Thiele–Laumanns–Zitzler (**DTLZ**) [50.104], or the walking fish group (**WFG**) [50.105], that have been widely used as a comparison basis for introducing new algorithmic proposals.

Among the real-world applications, engineering applications are, by far, the most popular domain within the parallel **EMO** literature (also in the entire **EMO** field), principally because they usually have suitable mathematical models for this kind of algorithms. Indeed, Fig. 50.4 shows that almost 35% of the papers analyzed address an optimization problem from the engineering domain. Several relevant works among those analyzed are devoted to aerodynamic shape optimization [50.27, 30, 46], reconfiguration of operational satellite constellations [50.41], or the combustion control for different types of vehicles [50.85, 91].

The second place in terms of popularity is occupied by the industrial applications, that appear in 21% of the papers reviewed. These applications are related to the fields of manufacturing, scheduling, and management.

Very interesting problems have been addressed in this industrial domain, such as the optimization of sonic crystal attenuation properties [50.52], the Camembert cheese ripening process [50.78], and evaluation of the input tax to regulate pollution from agricultural production [50.65].

Scientific applications, the third category of real-world applications analyzed (16% of the papers), is intended to group optimization problems in bioinformatics, chemistry, and computer science. The most successful applications here are devoted to the bioinformatic and chemistry fields, in problems on molecular docking [50.33], protein design [50.40], drug design [50.56], and phylogenetic inference [50.69, 70]. In our view, the reason these applications (either engineering, industrial or scientific) have been tackled with parallel **MOEAs** is precisely the tasks involved to compute their objective functions. When a new enhanced parallel search model is sought, then authors usually rely on benchmarking functions. Indeed, as stated above, 30% of the revised papers (Fig. 50.4) use these testbeds either exclusively [50.61, 68, 82, 94] or prior to solving a real-world application [50.5, 20, 51].

## 50.4 Conclusions and Future Works

### 50.4.1 Summary

In this chapter, we have carried out a comprehensive survey of the literature concerning parallel **MOEAs** since 2008/2009, the year when two of the most well-known comprehensive surveys were published. We have first described the existing parallel models for **MOEAs**, distinguishing between those specifically targeted at **EAs** and those aimed at capturing the essence of parallel metaheuristics in general. Based on the former model (as long as we are interested in surveying parallel **MOEAs**), more than 80 relevant papers have been carefully analyzed (many dozens more studied but left out because of little relevance to this survey). Fundamental aspects such as the fitness assignment and the diversity preservation, the parallel model used, the management of the approximated Pareto front, the underlying parallel platform used (if any), and the communication topology of the algorithms have been revised. Their main application domains have been gathered and structured into engineering, industrial, and scientific real-world multiobjective problems.

Despite the lack of new, attractive ideas in the area, this survey has revealed that the research on parallel **MOEAs** is still moving forward for two main reasons. On the one hand, researchers think of parallelism as a way to not only speed up computations, but also as a strategy to enhance the search engines of the algorithms. On the other hand, the computational demands of many multiobjective problems (dimensionality, uncertainty, simulations, etc.) means that the parallelism is the only suitable option to address them.

In the following section, some topics for future research for engineers interested in parallel **MOEAs** are outlined. In the authors' opinion, these topics merit particular attention so that the current state-of-the-art can be improved.

### 50.4.2 Future Trends

We have structured the future trends section as a bottom-up approach, proposing research lines for parallel **MOEAs** that range from low-level algorithmic details to more complex enhanced strategies at a higher level. We will also suggest that different studies that are

missing in the literature need to be carried out and, in our opinion, once completed, might have a great impact within the community.

Let us start with one of the main issues of parallel **MOEAs** which is such that, in the end, the algorithms have to compute one single approximation to the Pareto front, namely, they have an inherent centralized structure. When several subalgorithms cooperate to approximate such a Pareto front (i.e., the distributed models), they may coordinate themselves somehow in order to effectively sample different regions of the front in order to avoid overlaps. These overlaps are the main reason for the distributed algorithms being outperformed by centralized approaches (such as the master/slave). This issue has been partially addressed in the literature [50.96, 97] with some degree of success. However, these cited results have not been widely used yet and new advances are needed.

We propose here two lines of research that might help the distributed models of parallel **MOEAs** to overcome this issue. The first one is based on designing a fully distributed diversity preservation method (e.g., a distributed crowding). The research question here is whether it is possible to devise a density estimator that considers both local and global information from the other components of the distributed **MOEA**. We think so. Instead of trying to allocate a given portion of the Pareto front to each island, these islands should periodically broadcast a list with the objective values of their local solutions (but not the decision variables). Then, when checking whether a solution is to be stored in its local Pareto front, the island has to consider both the local information and the global information received from the other islands. To the best of our knowledge, such a mechanism does not exist in the literature. The second proposal is to use rough set theory [50.106] to effectively partition the search space and allocate different portions to different components of the parallel **MOEA**. There does exist a preliminary work [50.107] that uses a multiobjective simulated annealing, and

these ideas will have a great impact on the design of parallel **MOEAs**.

On a higher algorithmic level, this survey has also revealed that, despite their advanced search model and accurate results on many benchmarking functions [50.108], cellular models of parallel **MOEAs** have been marginally used in most of the application domains. We strongly believe that these algorithms might improve the state-of-the-art in many of these unexplored research areas. On a related matter, designing heterogeneous algorithms [50.17] is also a line of research with a high potential. Indeed, few contributions in the literature have considered parallel heterogeneous algorithms for multiobjective optimization [50.59]. To the best of our knowledge, there is no published analysis on the impact of heterogeneity (i.e., several different subalgorithms cooperating, namely, **NSGA-II**, **SPEA2**, **PAES**, **MOEA/D**, etc.) while approximating Pareto fronts. Our experience with these totally different algorithms is that each one is usually better suited to explore given regions of the search space, so their collaboration may result in a newly improved algorithm.

Finally, the last group of open research lines are devoted to well-grounded studies on the behavior of parallel **MOEAs** concerning their scalability with respect to the number of decision variables or their convergence speed toward the optimal Pareto front, as done for sequential **MOEAs** in [50.109, 110], respectively. Again, the influence of heterogeneity on these two search capabilities of parallel **MOEAs** is of interest.

Last but not least, there is a distinct lack of theoretical work in this area. For example, to the best of our knowledge, there is no analysis of the takeover time [50.111] in the multiobjective context, and we believe that characterizing parallel **MOEAs** based on this metric may help researchers in future developments. The difficulty of the landscapes in **MOPs** and the relative theoretical advantages for different types of problems are open research lines.

# 51. Many-Objective Problems: Challenges and Methods

Antonio López Jaimes, Carlos A. Coello Coello

This chapter presents a short review of the state-of-the-art efforts for understanding and solving problems with a large number of objectives (usually known as many-objective optimization problems, MOPs). The first part of the chapter presents the current studies aimed at discovering the sources that make a multiobjective optimization problem (MOP) harder when more objectives are added, degrading in this way, the performance of a multiobjective evolutionary algorithm (MOEA). Next, some of the most relevant techniques designed to deal with MOPs are presented and categorized.

## 51.1 Background

Since the first implementation of an MOEA in the mid-1980s [51.1], a wide variety of new MOEAs have been proposed, gradually improving in both their effectiveness and efficiency to solve MOPs [51.2]. However, most of these algorithms have been evaluated and applied to problems with only two or three objectives, in spite of the fact that many real-world problems have more than three objectives [51.3–6].

Recent experimental [51.7–9] and analytical [51.10, 11] studies have shown that MOEAs based on Pareto optimality [51.12] scale poorly in MOPs with a high number of objectives (4 or more). These MOPs are usually known in the community as MOPs. Although those scalability issues seem mainly to affect Pareto-based MOEAs, as we will see later in this chapter, optimization problems with a large number of objec-

tives introduce some difficulties common to any other multiobjective optimizer.

The goal of this chapter is to present a general view of the difficulties posed by many-objective problems for Pareto-based MOEAs. Specifically, we present a review of the potential sources of difficulty currently found in the specialized literature. Likewise, we present a brief review of the current proposals to deal with these sources of difficulty. These proposals are classified into five classes. Among the most common approaches to deal with MOPs, we can find the use of preference relations to further rank nondominated solutions, the removal of redundant objectives during or after the search, and the incorporation of preference information. Finally, at the end of the chapter some future research paths are outlined.

## 51.2 Basic Concepts and Notation

In this section, we will introduce the concepts and notation that will be used throughout the rest of the paper. Since some of these proposals are based on conflict information among the objectives, some definitions of conflict are also provided.

### 51.2.1 Multiobjective Optimization Problems

**Definition 51.1 Multiobjective optimization problem**

An **MOP** is defined as

$$\begin{aligned} \text{Minimize } f(\mathbf{x}) &= [f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_k(\mathbf{x})]^T, \\ \text{subject to } \mathbf{x} &\in \mathcal{X}. \end{aligned} \quad (51.1)$$

The vector  $\mathbf{x} \in \mathbb{R}^n$  is formed by  $n$  *decision variables* representing the quantities for which values are to be chosen in the optimization problem. The *feasible set*  $\mathcal{X} \subseteq \mathbb{R}^n$  is implicitly determined by a set of equality and inequality constraints. The vector function  $f : \mathcal{X} \rightarrow \mathbb{R}^k$  is composed of  $k \geq 2$  scalar *objective functions*  $f_i : \mathcal{X} \rightarrow \mathbb{R}$  ( $i = 1, \dots, k$ ). In multiobjective optimization, the sets  $\mathbb{R}^n$  and  $\mathbb{R}^k$  are known as the *decision variable space* and *objective function space*, respectively. The image of  $\mathcal{X}$  under the function  $f$  is a subset of the objective function space denoted by  $\mathcal{Z} = f(\mathcal{X})$  and referred to as the *feasible set in the objective function space*.

In order to define precisely the multiobjective optimization problem stated in Definition 51.1, we have to establish the meaning of minimization in  $\mathbb{R}^k$ . That is to say, we need to define how vectors  $\mathbf{z} = f(\mathbf{x}) \in \mathbb{R}^k$  have to be compared for different solutions  $\mathbf{x} \in \mathbb{R}^n$ . In single-objective optimization the relation *less than or equal* ( $\leq$ ) is used to compare the scalar objective values. By using this relation there may be many different optimal solutions  $\mathbf{x} \in \mathcal{X}$ , but only one optimal value  $f^{\min} = \min\{f(\mathbf{x}) \mid \mathbf{x} \in \mathcal{X}\}$  since the relation  $\leq$  induces a total order in  $\mathbb{R}$  (i.e., every pair of solutions is comparable, and thus, we can sort solutions from the best to the worst one). In contrast, in multiobjective optimization problems, there is no canonical order of  $\mathbb{R}^k$ , and thus, we need weaker definitions of order to compare vectors in  $\mathbb{R}^k$ .

In multiobjective optimization, the *Pareto dominance relation* is usually adopted. This relation was originally proposed by *Edgeworth* in 1881 [51.13], but generalized by the French-Italian economist *Pareto* in 1896 [51.12].

**Definition 51.2 Pareto dominance relation**

We say that a vector  $\mathbf{z}^1$  dominates vector  $\mathbf{z}^2$ , denoted by  $\mathbf{z}^1 \prec \mathbf{z}^2$ , if and only if

$$\forall i \in \{1, \dots, k\} : z_i^1 \leq z_i^2 \quad (51.2)$$

and

$$\exists i \in \{1, \dots, k\} : z_i^1 < z_i^2. \quad (51.3)$$

If  $\mathbf{z}^1 = \mathbf{z}^2$  or  $z_i^1 > z_i^2$  for some  $i$ , then we say that  $\mathbf{z}^1$  does not dominate  $\mathbf{z}^2$  (denoted by  $\mathbf{z}^1 \not\prec \mathbf{z}^2$ ). Thus, to solve an **MOP**, we have to find those solutions  $\mathbf{x} \in \mathcal{X}$  whose images,  $\mathbf{z} = f(\mathbf{x})$ , are not dominated by any other vector in the feasible space. It is said that two vectors,  $\mathbf{z}^1$  and  $\mathbf{z}^2$ , are *mutually nondominated vectors* if  $\mathbf{z}^1 \not\prec \mathbf{z}^2$  and  $\mathbf{z}^2 \not\prec \mathbf{z}^1$ .

**Definition 51.3 Pareto optimality**

A solution  $\mathbf{x}^* \in \mathcal{X}$  is Pareto optimal if there does not exist another solution  $\mathbf{x} \in \mathcal{X}$  such that  $f(\mathbf{x}) \prec f(\mathbf{x}^*)$ .

**Definition 51.4 Pareto optimal set**

The Pareto optimal set,  $P_{\text{opt}}$ , is defined as

$$P_{\text{opt}} = \{\mathbf{x} \in \mathcal{X} \mid \nexists \mathbf{y} \in \mathcal{X} : f(\mathbf{y}) \prec f(\mathbf{x})\}. \quad (51.4)$$

**Definition 51.5 Pareto front**

For a Pareto optimal set  $P_{\text{opt}}$ , the Pareto front  $PF_{\text{opt}}$  is defined as

$$PF_{\text{opt}} = \{\mathbf{z} = (f_1(\mathbf{x}), \dots, f_k(\mathbf{x})) \mid \mathbf{x} \in P_{\text{opt}}\}. \quad (51.5)$$

In decision variable space, these vectors are referred to as decision vectors of the Pareto optimal set, while in objective space, they are called objective vectors of the Pareto optimal set. In practice, the goal of **MOEAs** is to find the *best approximation set* of the Pareto optimal front. An approximation set is a finite subset of  $\mathcal{Z}$  composed of mutually nondominated vectors and is denoted by  $PF_{\text{approx}}$ . Currently, it is well accepted that the best approximation set is determined by the closeness to the Pareto optimal front, and the spread over the entire Pareto optimal front [51.2, 14, 15].

A common approach to deal with multiobjective optimization problems is formulating it as a single optimization problem by means of a kind of function called scalarizing function.

#### Definition 51.6 Scalarizing function

A scalarizing function is a parameterized function  $s : \mathbb{R}^k \rightarrow \mathbb{R}$ . Thus, the multiobjective problem is transformed into the following scalar problem:

$$\begin{aligned} & \text{Minimize } s(z), \\ & \text{subject to } z \in \mathcal{Z}. \end{aligned} \quad (51.6)$$

It is worth noting, however, that scalarizing functions generate one point at a time (instead of several, as happens when using the definition of Pareto optimality). A common scalarizing function is based on the Chebyshev distance ( $L_\infty$  metric) [51.16, 17].

#### Definition 51.7 Weighted Chebyshev scalarizing function

The weighted Chebyshev scalarizing function (or Chebyshev function for short) is defined by

$$s_\infty(z, z^{\text{ref}}) = \max_{i=1, \dots, k} \{\lambda_i(z_i - z_i^{\text{ref}})\}, \quad (51.7)$$

where  $z^{\text{ref}}$  is a reference point,  $\lambda = [\lambda_1, \dots, \lambda_k]$  is a vector of weights such that  $\forall i \lambda_i \geq 0$  and, for at least one  $i$ ,  $\lambda_i > 0$ .

### 51.2.2 Notions of Conflict Among Objectives

One important condition of a multiobjective problem is the conflict among their objectives. If the objectives have no conflict among them, then we could solve the problem optimizing each objective function independently. Nonetheless, it has been found that in some problems, although a conflict exists elsewhere, some objectives behave in a nonconflicting manner. Although different authors have proposed definitions for conflict (nonconflict) among objectives [51.18–21], in this chapter we only present conflict (nonconflict) definitions relevant to this document.

#### Definition 51.8

Let  $S_X$  be a subset of  $\mathcal{X}$ , then, according to Carlsson and Fullér, two objectives can be related in the following ways (assuming minimization):

- $f_i$  is in conflict with  $f_j$  on  $S_X$  if  $f_i(\mathbf{x}^1) \leq f_i(\mathbf{x}^2)$  implies  $f_j(\mathbf{x}^1) \geq f_j(\mathbf{x}^2)$  for all  $\mathbf{x}^1, \mathbf{x}^2 \in S_X$ .

- $f_i$  supports  $f_j$  on  $S_X$  if  $f_i(\mathbf{x}^1) \geq f_i(\mathbf{x}^2)$  implies  $f_j(\mathbf{x}^1) \geq f_j(\mathbf{x}^2)$  for all  $\mathbf{x}^1, \mathbf{x}^2 \in S_X$ .
- $f_i$  and  $f_j$  are independent on  $S_X$ , otherwise.

In the cases 2 and 3, those objectives are also called nonconflicting objectives. When  $S_X = \mathcal{X}$ , it is said that  $f_i$  is in conflict with (or supports)  $f_j$  globally. However, in many MOPs the relation among the objectives changes when comparing different subsets of  $\mathcal{X}$ . Figure 51.1 shows an example in which two functions are in conflict in some subsets of  $\mathcal{X}$ , while in others, they support each other.

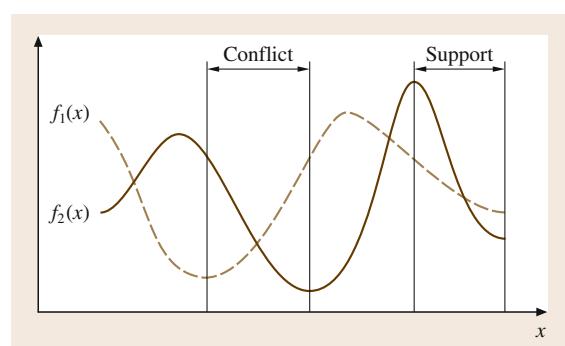

Nonconflicting objectives are also known as nonessential or redundant objectives because, as pointed out by Gal and Hanne [51.22], when a nonconflicting objective is removed from the original set of objectives, the resulting Pareto front does not change. Based on the notion of nonessential objectives, Brockhoff and Zitzler [51.21] proposed a conflict definition that verifies whether the Pareto dominance relation changes when some objectives are removed, or not. The Pareto dominance relation induced by a given set of objectives,  $F \subseteq \{f_1, f_2, \dots, f_k\}$ , is defined as

$$\preceq_F = \{(x, y) \mid x, y \in \mathcal{X} \text{ and } \forall f_i \in F : f_i(x) \leq f_i(y)\}.$$

#### Definition 51.9

Let  $F_1, F_2 \subseteq \Phi$  be two subsets of objectives, where  $\Phi$  is the entire set of objectives  $\Phi = \{f_1, f_2, \dots, f_k\}$ . Then, we call  $F_1$  nonconflicting with  $F_2$  iff  $(\preceq_{F_1} \subseteq \preceq_{F_2}) \wedge (\preceq_{F_2} \subseteq \preceq_{F_1})$ .

In other words,  $F_1$  and  $F_2$  are called nonconflicting if and only if the corresponding relations  $\preceq_{F_1}$  and  $\preceq_{F_2}$

**Fig. 51.1** Two objective functions can be in conflict in some subsets of the feasible space, and can be supportive in other subsets

are identical, but not necessarily  $F_1 = F_2$ . The nonconflicting definition is useful since if  $F$  and  $F' \subset F$  are nonconflicting, then we can replace  $F$  with  $F'$  and obtain the same Pareto optimal front. The objectives in  $F'$  are then called essential objectives, whereas the objectives in  $F \setminus F'$  are known as nonessential or redundant objectives.

In practice, however, it is useful to allow a certain extent of change on the Pareto front when an objective is omitted in order to define degrees of nonconflict among objectives. In this direction, Brockhoff and Zitzler proposed to use the additive  $\epsilon$ -dominance indicator to measure the change between two dominance rela-

tions. The  $\epsilon$ -dominance relation induced by a set  $F$  is defined by  $\preceq_F^\epsilon = \{(x, y) \mid x, y \in X \text{ and } \forall f_i \in F : f_i(x) - \epsilon \leq f_i(y)\}$ .

#### Definition 51.10

Let  $F_1, F_2 \subseteq F$  be two subsets of objectives, where  $F$  is the entire set of objectives. Then, we call  $F_1$   $\delta$ -nonconflicting with  $F_2$  iff  $(\preceq_{F_1} \subseteq \preceq_{F_2}^\delta) \wedge (\preceq_{F_2} \subseteq \preceq_{F_1}^\delta)$ .

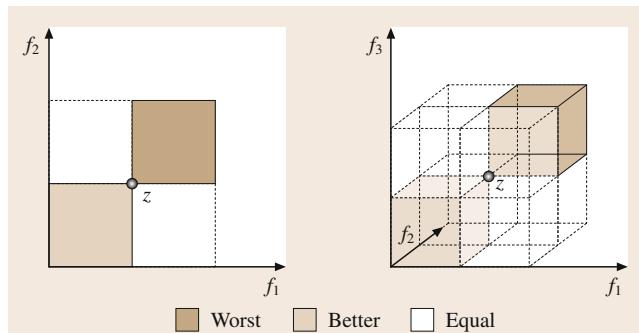

In this case, if an objective subset  $F' \subset F$  is  $\delta$ -nonconflicting with  $F$ , then we can omit all objectives in  $F \setminus F'$  without causing a larger error than  $\delta$  in the omitted objectives.

## 51.3 Sources of Difficulty to Solve Many-Objective Optimization Problems

### 51.3.1 Deterioration of the Search Ability

A widespread explanation for this problem is based on the fact that the proportion of nondominated solutions (i.e., equally good solutions according to Pareto dominance) in a population increases rapidly with the number of objectives [51.23, 24]. In order to illustrate this condition, Fig. 51.2 shows the nondominated regions with respect to a given solution  $z$ .

In general, as presented by Farina and Amato [51.23], the expression to compute the proportion,  $e$ , of mutually nondominated regions and the whole search space is given by  $e = (2^k - 2)/2^k$ , where  $k$  is the number of objectives. This proportion goes to infinity when the number of objectives approaches infinity.

**Fig. 51.2** Example of the increasing proportion of nondominated solutions: for 2 objectives 1/2 of the search space is composed of nondominated regions, whereas for 3 objectives 3/4 of the search space consists of nondominated regions. In general, for  $k$  objectives,  $(2^k - 2)/2^k$  of the objective space comprises nondominated regions

Therefore, since in MOPs with a high number of objectives almost all solutions are equivalent, many researchers have suggested [51.11, 23, 25–28] that in such problems, the selection of the appropriate individuals for steering the population toward the Pareto optimal set gets more difficult. As a result, an MOP gets harder to solve as more objectives are added.

However, as pointed out by Schütze et al. [51.29], the increase of the number of nondominated individuals is not a sufficient condition for an increase of the hardness of a problem. Specifically, they conclude that in a class of uni-modal problems, their difficulty is marginally increased when more objectives are added despite the exponential growth of the proportion of nondominated solutions with  $k$ . Nonetheless, they suggest that the hardness increase observed in experimental studies might be the result of the addition of local optima to the problem as more objectives are aggregated.

Therefore, although the rise of the proportion of incomparable solutions does not significantly determine the difficulty of an MOP per se, it seems that the addition of objectives aggravates some particular difficulties observed in the context of 2 or 3 objectives. This is the case of the so-called dominance resistant solutions (DRSs) or outliers [51.14, 30–32]. DRSs are solutions with a poor value in at least one of the objectives, but with near optimal values in the others. In other words, those are nondominated solutions, but far from the Pareto optimal front. Figure 51.3 shows an example of DRSs in the well-known test problem DTLZ2 [51.14]. These kinds of solutions represent potential difficulty since, as many

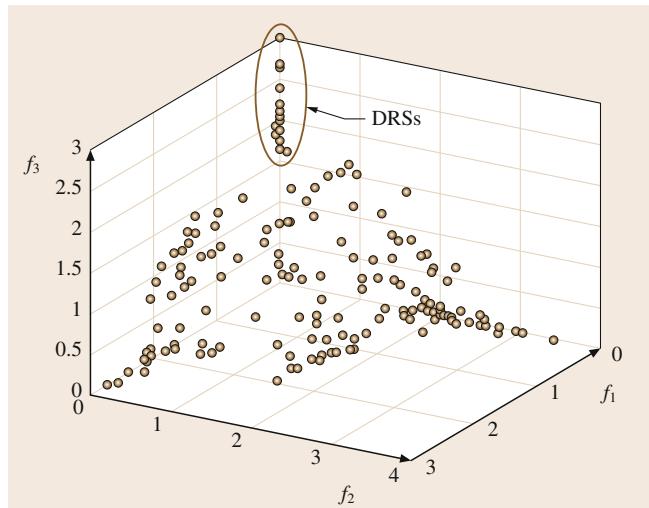

researchers have pointed out [51.14, 30–32], the number of DRSs grows as the number of objectives is increased.

### 51.3.2 Effectiveness of Crossover Operators

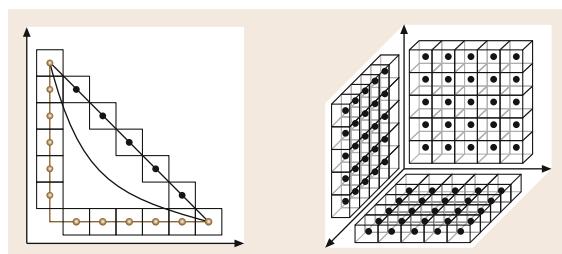

In a combinatorial class of MOPs, Sato et al. [51.33] performed a series of experiments that revealed that solutions in the variable space become more distant (in terms of the Hamming distance between binary encoded solutions.) from each other as more objectives are added to the problem. In this scenario, the recombination of two parents close to the Pareto front might generate an offspring far from the Pareto front since a conventional crossover operator might be too disruptive.

### 51.3.3 Dimensionality of the Pareto Front

Due to the *curse of dimensionality*, the number of points required to represent accurately a Pareto front increases exponentially with the number of objectives. Formally, the number of points necessary to represent a Pareto front with  $k$  objectives and resolution  $r$  is bounded by  $O(kr^{k-1})$  [51.34]. This expression is derived assuming that each solution is contained inside a hypercube to preserve an even distribution. As can be seen in Fig. 51.4, the number of hypercubes determines the resolution of the Pareto front, i.e.,  $r$  is the number of hypercubes per dimension. An example of the shortest connected and nondegenerated 2-objective Pareto front (a straight line) is shown on the left side of Fig. 51.4. The figure also shows a bound for the largest Pareto front for 2 and 3 objectives. In general, the bounding Pareto front is formed by  $k$  hyperplanes containing  $r^{k-1}$  hypercubes each (see, for example, the 3-objective case shown on the right side of Fig. 51.4). This way, the maximum number of points of a 2-objective Pareto front with resolution  $r = 6$  is  $2 \times 6^{2-1} = 12$ , whereas for 3 objectives and  $r = 5$  is  $3 \times 5^{3-1} = 75$ . Table 51.1 shows the maximum number of points required to represent a Pareto front for different numbers of objectives using a resolution of  $r = 25$ , which is a conservative number considering that a resolution of  $r = 50$  is usually used in several studies to obtain 100 solutions in 2-objective problems. Notwithstanding, for 5 objectives, we would require approximately 2 million points to represent a Pareto front with resolution  $r = 25$ . There are other formulations leading to a similar exponential expression with respect to  $k$ . For example, using the concept of  $\epsilon$ -dominance, Laumanns et al. [51.35]

**Fig. 51.3** Illustration of some DRSs in problem DTLZ2: although solutions marked as DRSs seem to be dominated by some solution in the lower part of the circled solutions, they achieve marginal improvements in objectives  $f_1$  or  $f_2$ , and therefore, they are nondominated solutions, but having poor values in objective  $f_3$ , though

**Fig. 51.4** Number of points required to represent a Pareto front with a resolution  $r$ , i.e., the number of hypercubes per dimension

**Table 51.1** Bound for the number of points required to represent a Pareto front with resolution  $r = 25$

| $k$ | Points        |
|-----|---------------|
| 2   | 50            |
| 4   | 62 500        |
| 5   | 1 953 125     |
| 7   | 1 708 984 375 |

and Schütze et al. [51.36] give a similar exponential bound for the size of an approximation of a Pareto front.

This poses some difficulties to solve MOPs. The most important one is the number of function eval-

uations required to deal with a large number of solutions. This is a serious issue since plenty of real-world problems (e.g., [51.37–43]), due to time constraint reasons, have a small budget of function evaluations. In fact, there is an important research effort toward designing **MOEAs** that generate good approximations of the Pareto front using less than 1000 function evaluations (e.g., [51.44–47]). Other challenges are related to the design of both data structures to efficiently manage that number of points, and density estimators to achieve an even distribution of the solutions along the Pareto front. Unfortunately, even if we could efficiently obtain an accurate approximation of the Pareto front, the selection of one solution among such a huge number of solutions

would be a very difficult task for a decision maker (**DM**).

### 51.3.4 Visualization of the Pareto Front

Clearly, with more than three objectives it is not possible to plot the Pareto front as usual. This is a serious problem since visualization plays a key role for a proper decision-making process. Parallel coordinates [51.48] and self-organizing maps [51.49] are some of the methods proposed to ease decision making in high dimensional problems. The reader is referred to Chapters 8 and 9 of [51.50] for a good review of various visualization techniques. Nevertheless, more research in the many-objective optimization context is still required.

## 51.4 Current Approaches to Deal with Many-Objective Problems

Besides studies about the scalability of Pareto-based **MOEAs**, in the current literature we can find several proposals to overcome those scalability issues. The most common approaches can be categorized as follows:

1. Adopt or propose a preference relation that yields a finer solution ordering than the one yielded by Pareto optimality. In other words, these relations are able to further rank nondominated solutions. In addition, most of these preference relations share the property that their optimal set of solutions is a subset of the Pareto optimal set. Therefore, these techniques can also be used as a remedy to cope with the dimensionality of Pareto fronts in MOPs.
2. Reduce the number of objectives of the problem during the search process or, *a posteriori*, once an approximation of the Pareto front has been found [51.21, 26, 51]. The main goal of these kinds of reduction techniques is to identify the nonconflicting objectives (at least to a certain extent) in order to discard them.
3. Scalarizing decomposition of an **MOP**. As described in the previous section, the degradation observed on **MOEAs** when dealing with many-objective problems is mainly attributed to the inefficiency of the Pareto relation in high-dimensional spaces. Therefore, methods that do not rely on Pareto dominance, like scalarizing decomposition methods, have been suggested as an alternative to

deal with many-objective problems. The underlying idea of these types of methods is to perform a number of single-objective searches along different search vectors evenly distributed over the objective space. Each single-objective search is formulated by means of a scalarizing function. This way, the approximation of the Pareto front is composed of the optima found by every single-objective search.

4. Incorporation of preference information interactively throughout the course of the optimization process. By incorporating preferences we can cope with MOPs in two aspects. First, the search can be focused on the decision maker's region of interest, avoiding this way, the evaluation of a huge number of solutions. Second, the preference relations usually used in interactive methods help to deal with a large number of objectives since they are able to rank incomparable nondominated solutions.
5. Use of specialized recombination operators or strategies to control the mating among parents. The first approach tries to diminish the disruptive effect of recombination operators by regulating the proportion in which the traits of each parent contribute to create the offspring. The second approach restricts which individuals can be paired for recombination, for instance, using the similarity as mating criteria or the location in the objective space.

In the remainder of this section, some of the most relevant approaches to deal with many-objective problems are presented.

### 51.4.1 Preference Relations to Deal with Many-Objective Problems

Bentley and Wakefield [51.52] proposed the average ranking (**AR**) and the maximum ranking (**MR**) preference relations. The **AR** relation computes, for each solution, a different rank considering each objective independently. The final rank is obtained by summing up the ranks on each objective. In turn, the **MR** relation takes the best rank as the global rank. Clearly, this method favors extreme solutions, i.e., solutions with high performance in some of the objectives, although with poor overall performance. Although it is less evident, the average ranking relation also favors extreme solutions.

In the *favor relation*, proposed by Drechsler et al. [51.53], a vector  $z^1$  is preferred to vector  $z^2$  with respect to the favor relation ( $z^1 \prec_{\text{favor}} z^2$ ), if and only if

$$\begin{aligned} & \#\{i : z_i^1 < z_i^2, 1 \leq i \leq k\} \\ & > \#\{j : z_j^1 > z_j^2, 1 \leq j \leq k\}. \end{aligned}$$

In other words, the favored vector is that which outperforms the other one in more objectives. Unfortunately, this relation emphasizes extreme solutions.

The preference order relation (**POR**), developed by di Pierro [51.54], is based on the concept of *efficiency of order* proposed by Das [51.55], which states that: A vector  $z^*$  is efficient of the order  $q$  if it is not dominated by any other vector in all the  $\binom{k}{q}$  objective subsets of size  $q$ .

Based on that definition, it is said that the vector  $z^1$  is preferred to the vector  $z^2$  ( $z^1 \prec_{\text{POR}} z^2$ ), if and only if, for some integer  $q$  and  $\forall I \subseteq \{1, 2, \dots, k\}$  such that  $|I| = q$

$$z_i^1 \leq z_i^2 \quad \forall i \in I, \quad \text{and} \quad \exists i \in I : z_i^1 < z_i^2.$$

In other words, if  $z^1$  and  $z^2$  do not dominate each other, then the solutions are compared in a lower dimensional space in order to break the tie.

Sato et al. [51.56] proposed a preference relation to control the dominance area of solutions. This method controls the degree of expansion or contraction of the dominance area by modifying each objective vector  $z$  with the expression

$$z'_i = \frac{r \cdot \sin(\omega_i + s_i \cdot \pi)}{\sin(s_i \cdot \pi)} \quad \forall i = 1, 2, \dots, k,$$

where  $s \in \mathbb{R}^k$  is a user-defined vector,  $r = ||z||$ , and  $\omega_i$  is the declination angle between  $z$  and the axis of  $f_i$ .

If the user adopts values  $s_i < 0.5$  ( $\forall i = 1, 2, \dots, k$ ), the dominance area is expanded and produces a more fine-grained ranking of solutions which would strengthen the selection process. Thus, we can say that vector  $z$  is preferred to vector  $y$  with respect to the *expansion relation* ( $z \prec_{\text{expansion}} y$ ), if and only if  $z' \prec y'$ .

Farina and Amato [51.57] proposed an alternative relation which takes into account the number of improved objectives between two solutions. This relation employs three quantities,  $n_b(x_1, x_2)$ ,  $n_e(x_1, x_2)$  and  $n_w(x_1, x_2)$ , which denote the objectives where  $x_1$  is better, equal or worse than  $x_2$ , respectively. Using these quantities, the concepts of  $(1-k)$ -dominance and  $k$ -optimality are defined. A solution  $x_1$  ( $1-k$ ) dominates  $x_2$  if and only if

$$\begin{cases} n_e(x_1, x_2) < M \\ n_b(x_1, x_2) \geq \frac{M - n_e}{k+1}. \end{cases}$$

In a similar way to Pareto optimality, a solution  $x^*$  is a *k-optimum* if and only if there is no  $x$  in the decision variable space such that  $x$   $k$ -dominates  $x^*$ .

An important remark that we have to keep in mind with respect to a new preference relation is that in spite of the fact that some preference relations contribute to converge faster to the Pareto front than the Pareto dominance relation, they also stress the generation of solutions far from the knee region (usually the middle region of the Pareto front). This condition limits the applicability of these relations since, in the general case, it is commonly assumed that the **DM** prefers solutions from the knee region [51.58–61].

### 51.4.2 Objective Reduction Approaches

Deb and Saxena [51.26] proposed a method for reducing the number of objectives based on principal component analysis. The main assumption is that if two objectives are negatively correlated (taking the generated Pareto front as the data set), then these objectives are in conflict with each other. To determine the most conflicting objectives (i.e., the most essential), the authors analyze in turn the eigenvectors (i.e., the principal components) of the correlation matrix. That is, by picking the most negative and the most positive elements from the first eigenvector, we can identify the two most important conflicting objectives. To aggregate more objectives to the set of essential objectives, the remainder of the eigenvectors are analyzed in a similar way

until the cumulative contribution of the eigenvalues exceeds a threshold cut ( $TC$ ). This method is incorporated into an iterative scheme which uses a multiobjective optimizer (the actual implementation uses the nondominated sorting genetic algorithm II (**NSGA-II**) [51.62]) to obtain a reduced objective set containing only the nonredundant objectives according to the analysis of the eigenvectors. In this scheme, the evolutionary multiobjective optimizer is first run and then, the correlation analysis is carried out to obtain a reduced set of objectives. This process is repeated using the new reduced set of objectives. The process stops when the current subset is equal to the subset generated in the previous iteration.

*Brockhoff and Zitzler* [51.21] defined two kinds of objective reduction problems and two corresponding algorithms to solve them. The problems proposed are the following:

1. *The  $\delta$ -MOSS problem.* Given an **MOP**, the  $\delta$ -minimum objective subset problem is defined as follows.
  - *Input:* A Pareto front approximation of the **MOP** and a  $\delta \in \mathbb{R}$ .
  - *Task:* Compute the minimum objective subset  $F' \subseteq F$  such that  $F'$  is  $\delta$ -nonconflicting with  $F$ .
2. *The  $\mathcal{K}$ -EMOSS problem.* Given an **MOP**, the problem of finding the minimum objective subset of size  $\mathcal{K}$  with minimum error is defined as follows.
  - *Input:* A Pareto front approximation of the **MOP** and a  $\mathcal{K} \in \mathbb{N}$ .
  - *Task:* Compute an objective subset  $F' \subseteq F$  with size  $|F'| \leq \mathcal{K}$ , such that  $F'$  is  $\delta$ -nonconflicting with  $F$  with the minimum possible  $\delta$ .

Since both problems are  $\mathcal{NP}$ -hard, the authors proposed both an exact and a greedy algorithm for each of them. The exact algorithms for both problems have time complexity  $O(m^2 k \cdot 2^k)$ , where  $m$  is the size of the given nondominated set and  $k$  is the number of objectives. On the other hand, the greedy algorithm for the  $\delta$ -MOSS problem has time complexity  $O(\min\{m^2 k^3, m^4 k^2\})$ , while the greedy algorithm for the  $\mathcal{K}$ -EMOSS problem has time complexity  $O(m^2 k^3)$ .

A similar approach was proposed by *López Jaimes et al.* [51.51]. They proposed two different objective reduction algorithms:

1. An algorithm that finds a minimum subset of nonredundant objectives with the minimum error possible.

2. An algorithm that finds a  $\mathcal{K}$ -size subset of nonredundant objectives, yielding the minimum error possible.

Both algorithms are based on an unsupervised feature selection technique proposed by *Mitra et al.* [51.63], in which the correlation coefficient is used to estimate the conflict among objectives. Specifically, a negative correlation between a pair of objectives means that one objective increases, while the other decreases and vice versa (see, for example, the functions in Fig. 51.1). On the other hand, if the correlation is positive, then both objectives increase or decrease at the same time. This way, we could interpret that the more negative the correlation between two objectives, the more the conflict between them.

These two algorithms were designed to be used after an approximation of the Pareto front has been found. From a general point of view, the removal of the nonconflicting objectives can help to the problem designer or the decision maker to gain knowledge about the relation and importance of the objectives according to the conflict. With regard to the decision-making process, the removal of the nonconflicting objectives eases the visualization of the approximation of the Pareto front. In cases with a moderate number of objectives (i. e., 4–7), the reduced objective set might be visualized using the traditional 3D plots.

However, an objective reduction technique can also be used in the course of the search. In [51.64], for instance, the authors proposed the incorporation of an objective reduction technique into a Pareto-based **MOEA** in order to cope with many-objective problems during the search. One possible approach is gradually reducing the number of objectives throughout different stages of the search until a target objective subset size has been reached. In each reduction stage, an objective reduction method is applied on the current Pareto front approximation. Toward the end of the search, the original objective set is used again to approximate the entire Pareto front. This kind of approach can be advantageous for solving real-world problems with expensive objective functions since only a small subset of the objective functions is evaluated. Additionally, the use of a small set of objectives throughout the course of the search makes possible the adoption of expensive ranking schemes (e.g., those based on the hypervolume indicator) in problems with a high number of objectives [51.65].

A further approach, presented in [51.66], consists in partitioning the objective set into several subsets so

that a different portion of the population focuses the search on a different subspace. The partitioning of the set of objectives is based on the analysis of the conflict information obtained from the current Pareto front approximation.

### 51.4.3 Preference Incorporation Approaches

Like the alternative preference relations reviewed in Sect. 51.4.1, the integration of DM's preferences provides a finer rank of the solutions. However, unlike preference relation approaches, in an interactive approach, the region of interest can be changed during the search according to the requirements of the decision maker.

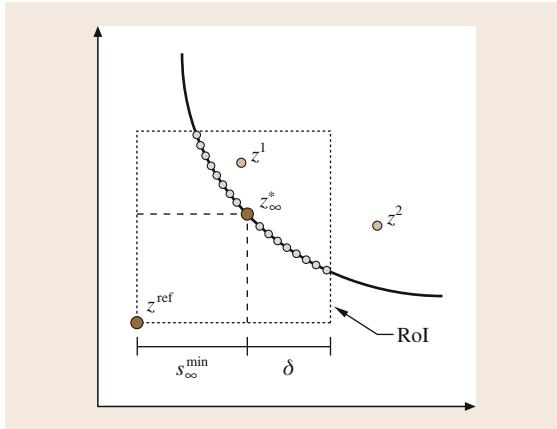

Among the earliest attempts to incorporate preferences in an MOEA, we can find *Fonseca* and *Fleming*'s proposal [51.67, 68]. This proposal consisted of extending the ranking mechanism of multiobjective genetic algorithm (MOGA) [51.69] using the so-called *preferability relation*. This relation accommodates goal information (equivalent to a reference point in other methods) and priorities in a single preference relation. The DM should define goal values and group objectives according to its priority. Using the preferability relation, two solutions are first compared in terms of the group of objectives with the highest priority. If the objectives of both solutions meet all their goal values or, contrarily, violate some or all of their goal values in a similar way, the next priority objective group is considered. This process continues until reaching the lowest priority group, where solutions are compared using the Pareto dominance relation. By setting particular goals and priorities the authors derived the following special cases: the usual Pareto relation, lexicographic relation, constrained optimization, and goal programming. One disadvantage of this relation is that it is affected by the feasibility of the goal provided by the decision maker. If the given goal is far away from the feasible region, then the solutions will be mainly compared in terms of the objective priorities, reducing the relation to the lexicographic relation. In addition, if two solutions either do or do not meet their goals, the relation does not take into account the degree of under- or over-attainment.

*Deb* [51.70] proposed a technique to transform goal programming problems into multiobjective optimization problems which are then solved using an MOEA. In goal programming, the DM has to assign goals that wishes to achieve for each objective, and these values are incorporated into the problem as additional

constraints. The objective function then attempts to minimize the absolute deviations from the goals to the objectives. Unfortunately, as the previous method, this approach is sensitive to the feasibility of the goal values. If the goal is contained in the feasible space, it could prevent the generation of a better solution. On the other hand, if the goal is located far away from the feasible space, the effect of the method is practically nonexistent.

More recently, *Deb* and *Sundar* [51.71] incorporated a reference point approach into the NSGA-II [51.72]. They introduced a modification in the crowding distance operator in order to select from the last nondominated front the solutions that would take part of the new population. They used the Euclidean distance to sort and rank the population accordingly (the solution closest to the reference point receives the best rank). This method was designed to take into account a set of reference points. The drawback of this scheme is that it only guarantees weak Pareto optimality. That is to say, besides Pareto optimal solutions, the method might generate some weakly Pareto optimal solutions, particularly in MOPs with disconnected Pareto fronts. A similar approach was also proposed by *Deb* and *Kumar* [51.73], in which the light beam search procedure [51.74] was incorporated into the NSGA-II. Similar to the previous approach, they modified the crowding operator to incorporate DM's preferences. They used a weighted achievement function to assign a crowding distance to each solution in each front. Thus, the solution with the least distance will have the best crowding rank. Like in the previous approach, this algorithm finds a subset of solutions around the optimum of the achievement function adopting the usual outranking relation. A vector  $z^1$  outranks vector  $z^2$  if  $z^1$  is considered to be at least as good as  $z^2$ . In [51.74], three kinds of thresholds are defined to determine if one solution outranks another one, namely, indifference, preference, and veto threshold. However, in [51.73] the veto threshold is the only one used. This relation depends on the crowding comparison operator. In contrast, the new preference relation presented in this work does not depend on external methods, and, therefore, it can be used in every Pareto-based MOEA.

Recently, *Thiele* et al. [51.75] proposed a variant of the indicator-based evolutionary algorithm (IBEA) [51.76], in which preference information is incorporated by means of an achievement scalarization function. The basic idea is to divide the original indicator value (which is to be maximized) by the

**Fig. 51.5** Nondominated solutions with respect to the Chebyshev relation

achievement value (which is to be minimized). Thus, solutions with a smaller achievement value will be preferred since the modified indicator value is larger. In a further paper, the new **IBEA** of Thiele et al. was used in [51.77] in order to approximate the entire Pareto front by defining several reference points.

A recent interactive optimization method was proposed by *López Jaimes* et al. [51.78] to deal with

MOPs. This method is based on a Chebyshev achievement function. The basic idea of the Chebyshev preference relation is to combine the Pareto dominance relation and the achievement function to compare solutions in objective function space. The Chebyshev preference relation is defined as follows.

#### Definition 51.11

A solution  $z^1$  is preferred to solution  $z^2$  with respect to the Chebyshev relation ( $z^1 \prec_{\text{cheby}} z^2$ ), if and only if:

1.  $s_\infty(z^1, z^{\text{ref}}) < s_\infty(z^2, z^{\text{ref}}) \wedge \{z^1 \notin R(z^{\text{ref}}, \delta) \vee z^2 \notin R(z^{\text{ref}}, \delta)\}$ , or,
2.  $z^1 \prec z^2 \wedge \{z^1, z^2 \in R(z^{\text{ref}}, \delta)\}$ ,

where

$$R(z^{\text{ref}}, \delta) = \{z \mid s_\infty(z, z^{\text{ref}}) \leq s^{\text{min}} + \delta\}$$

is the region of interest (ROI) with respect to the vector of aspiration levels  $z^{\text{ref}}$ .

As an illustration of the preference relation, consider solutions  $z^1$  and  $z^2$  presented in Fig. 51.5. Since  $z^2 \notin R(z^{\text{ref}}, \delta)$  and  $s_\infty(z^1, z^{\text{ref}}) < s_\infty(z^2, z^{\text{ref}})$ , then  $z^1 \prec_{\text{cheby}} z^2$ .

## 51.5 Recombination Operators and Mating Restrictions

The idea of restricted mating is not new in the field of evolutionary optimization. For instance, in 1989 *Deb* and *Goldberg* [51.79] suggested the use of restrictive mating with respect to the phenotypic (i.e., using the decoded values of the variables) distance using some metric. A different approach consisted in distributing solutions on a logical topology. For example, *Baita* et al. [51.80] placed solutions on a grid and restricted the area within which each solution could mate. For more examples of restricted mating, the reader is referred to [51.2].

Recently, specific mating techniques to deal with many-objective problems have been proposed. *Sato* et al. [51.81] described a local recombination scheme that recombines individuals if they have similar search directions in the objective space. The search direction is defined by the polar coordinates of each solution, i.e., its norm and declination angles to the axis associated with the first  $k - 1$  objectives.

In order to control the disruptive effect of recombination, in [51.33], a crossover operator for binary representation was proposed, namely the controlling crossed genes (**CCG**) operator. This technique was applied into the two-point and uniform-crossover operators. In two-point crossover, from the three binary segments in which two parents are divided, the middle segment is exchanged between the parents to produce two children. Thus, in the **CCG** operator for two-point crossover, the length of the middle segment is regulated by a user parameter. This way, as the middle segment gets shorter, the generated children become more similar to each parent.

Regarding uniform crossover, the number of exchanged bits between parents is regulated with the probability of writing a 1 or a 0 in the bit mask string that determines which parent bit will be copied into the produced offspring.

## 51.6 Scalarization Methods

Most of the scalarization methods have in common the following mechanisms (although they differ in the way in which they are implemented):

- A class of scalarizing function to evaluate solutions.
- A mechanism to generate a uniform distribution of search direction vectors.
- A mechanism to obtain an overall ranking of the solutions derived from the evaluation of each scalarizing function.

*Hughes* [51.82] proposed a method in which the weighted Chebyshev function and the vector angle distance scaling are used as scalarizing functions. The method to generate the search direction is formulated as the problem of maximizing the angle between each

pair of neighboring search vectors. The fitness of each solution in the current population is based on the best result obtained over all the scalarizing function, i. e., the search direction in which the solution performs better.

Another algorithm that has been recently tested in many-objective problems is the multiobjective evolutionary algorithm based on decomposition (**MOEA/D**) [51.83]. In [51.84], the performance of **MOEA/D** using either a weighted sum function or a Chebyshev function was studied using several instances of a knapsack problem. The results showed that the weighted sum function provided better results than the Chebyshev function, while in nonconvex problems, the Chebyshev function helped to achieve a better performance of **MOEA/D**.

## 51.7 Conclusions and Research Paths

This chapter presented a short review of the current advances to cope with optimization problems with a high number of objectives MOPs using **MOEA**. We covered results aimed at discovering and studying the causes that make an **MOP** more difficult as more objectives are aggregated. We also described and classified some of the current techniques to deal with MOPs.

Regarding the sources of difficulty of many-objective optimization problems, we can realize that most of the initial works are based on experimental analysis, and only a few studies are focused on investigating the nature of the problem using theoretical considerations. When the interest on many-objective optimization problems begun, some hypotheses about the causes of the poor performance of **MOEA** on MOPs were suggested. Although some of them were considered highly probable and may turn out to be true, further investigation is still needed to confirm or refute these hypotheses. This was the case of the proportion of nondominated solutions, which was often taken as a sufficient condition to increase the difficulty of an **MOP**. However, recent studies have shown that there exists some problems, in which this proportion rises exponentially, while the hardness of the problem only

increases marginally. In this sense, future research paths must be channeled to investigate other sources of difficulty. Some promising areas of future research are, for example, the following:

- Since **DRS** are not present in every **MOP**, a characterization of the problems that promote the creation of **DRS**s is required.
- Investigate if recombination operators in continuous spaces also represent an issue as observed in discrete spaces.

Regarding the methods to solve MOPs, many proposals have been designed to improve the search ability of **MOEAs** in high-dimensional scenarios. However, a few efforts are perceived for developing visualization methods specialized for MOPs. Similarly, more proposals for coping with the dimensionality of the Pareto front are needed. For instance, diversity mechanisms that are effective in large spaces or data structures to efficiently manage a large number of solutions. With respect to the assessment of a new **MOEA** in many-objective scenarios, our recommendation is adopting a diverse set of **MOPs**, taking instances from different families of test suites.

# 52. Memetic and Hybrid Evolutionary Algorithms

# Memetic and

Jhon Edgar Amaya, Carlos Cotta Porras, Antonio J. Fernández Leiva

This chapter presents an overview of hybridization mechanisms in evolutionary algorithms. Such mechanisms are aimed to introducing problem knowledge in the optimization technique by means of the synergistic combination of general-purpose methods and problemspecific add-ons. This combination is presented in this work from two wide perspectives: memetic algorithms and cooperative optimization models. Memetic algorithms are based on the smart orchestration of global (population-based) and local (trajectorybased) techniques, using an algorithmic scheme in which the latter are often subordinated to the former. As to cooperative models, they are based on the collaboration of different optimization techniques that exchange information in order to boost their respective performances. Both approaches, memetic algorithms and cooperative

models, provide a framework to achieve synergistic algorithmic combinations for the resolution of large-scale combinatorial problems.

## 52.1 Overview

Heuristic methods are aimed to efficiently produce near-optimal solutions for hard problems (optimization problems in particular). We are here specifically concerned with those methods used to solve an optimization problem by means of an intelligent exploration of the search space and the fruitful exploitation of knowledge about the problem structure. This is admittedly a very broad class of methods that comprise – among others – classical artificial intelligence tools such as the A\* algorithm as well as modern optimization techniques such as metaheuristics [52.1]. The latter are general-purpose techniques for optimization that guide some underlying basic heuristics for intelligently exploring the search space of the problem under consideration.

There exists a plethora of metaheuristic methods, each of them with its own distinctive features and governing parameters, typically (yet not always) based

on some analogy of a real-world phenomenon (be it in the area of biology, zoology, physics, etc.) Indeed, there have been several attempts in the literature to classify these techniques according to different criteria, e.g. whether they are inspired by nature or not, use of memory, neighborhood structure, use of single solutions or populations thereof, etc. Blum and Roli [52.1] proposed a classification in which a distinction was firstly made between trajectory-based (or single-point search) and population-based techniques (see also Fig. 52.1). The former can be depicted as following a particular trajectory (sequence of points) in the search space by the smart exploration of the neighborhood of a single solution (this is to some extent an oversimplification, since trajectory-based techniques are often endowed with intensification/diversification mechanisms that may turn this trajectory into complex branching paths; nevertheless, it serves as an initial

analogy). The latter are, however, better imagined as a cloud of points moving through the search space, expanding and contracting according to some internal dynamics.

Despite what the above depiction may suggest in terms of the superiority or adequateness of methods falling within some particular class, it is not possible to state that any method is better than any other one, at least not in a general sense. This is a somewhat counterintuitive result that was formally derived by *Wolpert and Macready* [52.2] in the so-called “no free lunch theorem” (NFL). This theorem can be formulated as

$$\sum_f P(x_m | f, A, e) = \sum_f P(x_m | f, B, e), \quad (52.1)$$

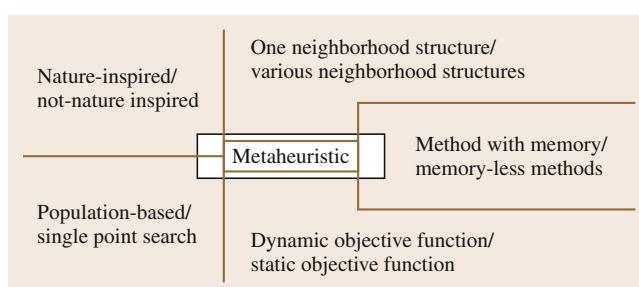

where  $P(x_m | f, A, e)$  is the probability that algorithm  $A$  detects the optimal solution for a generic objective function  $f$  using computational effort  $e$  (i.e., generating  $e$  different solutions) and  $P(x_m | f, B, e)$  is the analogous probability for algorithm  $B$ . In other words, the average performance of any pair of algorithms across all possible problems defined on particular domains and co-domains is identical. Hence, whenever an algorithm performs well on a certain problem or class of problems, it follows that it will exhibit degraded performance on the set of all remaining problems. While the initial assumptions from which the NFL theorem is derived are questionable (most importantly, the consideration of all possible problems include many functions that are random or incompressible in an algorithmic information-complexity sense, and hence cannot be efficiently calculated, thus rendering them irrelevant from an optimization point of view), the concept that there is no universal optimizer had a significant impact on the scientific community and provides a safe ground onto which particular optimization procedures can be

built. To be precise, the NFL theorem highlights the limitations of black-box optimization procedures, i.e., techniques whose search strategy is independent or unaware of the internal working of the objective function that is being optimized, and emphasizes the need for trying to exploit domain knowledge within the search algorithm in order to tailor the optimization process to the problem under consideration.

The argument above is commonly used to support the development and utilization of hybrid metaheuristics, where the term *hybrid* is used to denote in a broad sense the exploitation of problem-dependent knowledge (typically attained via the sensible combination of general-purpose and problem-specific mechanisms). Indeed, these hybrid methods can be shown to provide an efficient behavior and notable flexibility for dealing with real-world problems. The general idea here is achieving a synergetic combination of complementary techniques in order to enhance their strengths and having their weaknesses alleviated. Roughly speaking, such hybrid approaches can be attained via two different (and complementary) approaches: cooperation (the techniques involved exchange information in order to boost their respective performances) and integration (one of the techniques is subordinated to the other one, which uses the former as a tool to achieve some internal goal) [52.3].

Arguably, one of the advantages (if not from the performance point of view at least from the design point of view) of population-based methods over trajectory-based methods is their greater flexibility when it comes to integrating different metaheuristics. For example, cooperative methods can often be defined as a population of (possibly heterogenous) search agents exchanging information according to some underlying connection topology. Different architectures for such cooperative methods have been defined, e.g. MAGMA [52.4] or COSEARCH [52.5], depending on the communication strategy and the intervening methods. We can also cite hyper-heuristics [52.6, 7] in this regard, i.e., the use of a high-level heuristic to control the application of a population of low-level heuristics.

The above ideas fit nicely with the notion of memetic algorithm (MA). MAs are a family of metaheuristics that try to blend several concepts from population-based and trajectory-based techniques. The term *memetic* comes from *meme*, a word coined by *Dawkins* [52.8] as an analogy to the *gene* in the context of cultural evolution. In this sense, there is, indeed, a connection between cultural evolution and memetic

**Fig. 52.1** Classification of metaheuristics according to *Blum* and *Roli* (after [52.1])

algorithms, in the sense that memes are much more plastic and flexible than genes – and hence evolve faster – and can be subject to lifetime learning, thus leading to the transmission of acquired traits (much unlike biological evolution). Due to the way in which this can be implemented, **MAs** are often termed hybrid **EAs** or Lamarckian **EAs**, among other fancy terms. From a general perspective, we can say that an **MA** is a search strategy in which a population of optimizing agents – explicitly concerned with using knowledge from the problem being solved – synergistically cooperate and compete [52.9].

Focusing on combinatorial optimization problems, that is, problems whose solution space is composed of combinatorial structures such as graphs, trees, sets, lists, permutations, etc., built on a discrete collection of variables, **MAs** and hybrid metaheuristics are very well suited to their resolution. On the one hand, the solutions to these problems are information-rich structures that the algorithmic designer can analyze in order to extract problem information to be later used in the optimizer (some attempts have been made to automatically extract this information in combina-

torial contexts as well [52.10]). This contrasts with most continuous optimization problems in which the high-dimensionality and highly non-linear coupling of variables makes them much more opaque in general (not to mention that black-box scenarios are more frequent in this continuous domain, e.g., optimization of physical or industrial processes via simulations of the system). On the other hand, it is very often the case that the objective function for combinatorial problems is decomposable or at least incrementally computable, meaning that after a small perturbation has been introduced in a solution the latter does not need to be fully evaluated from scratch (only an incremental term dependent on the modification done must be computed). This makes the use of local search strategies much more computationally amenable than in most continuous domains. Before describing **MAs** in more detail, let us first overview some generic ideas about evolutionary algorithms (**EAs**) and hybrid metaheuristics. Throughout the discussion we will focus on combinatorial problems and provide illustrative examples on the instantiation of these techniques for discrete optimization.

## 52.2 A Bird's View of Evolutionary Algorithms

An **EA** is a stochastic iterative procedure for generating candidate solutions for a certain problem. The algorithm manipulates a pool *pop* of individuals (the so-called population), each of them carrying one or more chromosomes. Chromosomes are, in turn, composed of smaller pieces called genes, each of them taking a value from a certain domain (the allele set). Chromosomes represent a solution for the problem at hand via an encoding/decoding process. More precisely, **EAs** assume the existence of a phenotype space comprising the solutions for the problem under consideration and a genotype space, comprising all possible chromosomes. It is between these two sets that the growth (or expression) function is defined so as to have the mapping between chromosomes and solutions. While in some cases these two spaces may be identical, this does not generally happen. In this general situation, the growth function is merely required to be surjective.

The pool of solutions is initialized either at random or by means of some heuristic seeding procedure. Each individual then receives a fitness value quantifying how good the solution it carries is. This value will be used by the **EA** for guiding the search. The ini-

tial population is actually the playground on which the **EA** will subsequently work, iteratively applying some evolutionary operators to modify its contents. More precisely, the process comprises two major stages: selection (promising solutions are selected for breeding and survival), and reproduction (new solutions are created by modifying selected solutions using some reproductive operators). Selection is further decomposed into two sub-stages: the first one is selection for reproduction (often simply called *selection*) in which solutions from the population are picked and fed to the reproduction stage; the second one is selection for survival (commonly called *replacement*) in which the new solutions obtained in the reproduction stage are inserted in the population at the expense of removing some older solutions. Both selection sub-stages are present in **EAs** (although in some cases one of these sub-stages may take a very simplistic form; e.g., random selection for reproduction is sometimes used in evolution strategies). This selection–production cycle is repeated until a certain termination criterion (usually reaching a maximum number of fitness computations; some more complex criteria based on stagnation detection are also possi-

ble [52.11]) is fulfilled. Each iteration of this process is commonly termed a generation. The whole process is illustrated in Algorithm 52.1. Every possible instantiation of this algorithmic template leads to a different EA.

#### Algorithm 52.1 A Basic Evolutionary Algorithm

```

1: function BasicEA (in  $P$ : Problem, in  $par$ : Parameters): Solution;
2: begin
```

```

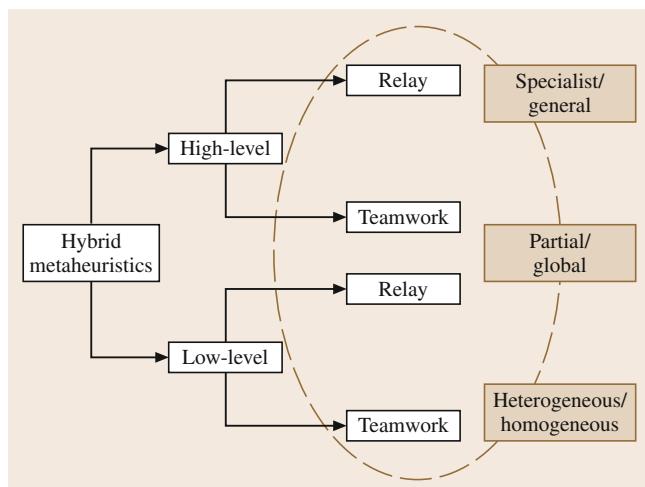

3:    $pop \leftarrow \text{INITIALIZE}(par, P)$  ;
4:   repeat
5:      $newpop_1 \leftarrow \text{SELECT}(pop, par, P)$  ;
6:      $newpop_2 \leftarrow \text{REPRODUCE}(newpop_1, par, P)$  ;
7:      $pop \leftarrow \text{REPLACE}(pop, newpop_2)$  ;
8:   until  $\text{TERMINATIONCRITERION}(par)$ ;
9:   return  $\text{GETBEST}(pop)$  ;
10:  end
```

## 52.3 From Hybrid Metaheuristics to Hybrid EAs

As was mentioned before, hybrid metaheuristics (and in particular hybrid EAs) are developed aiming to attain a synergistic combination of several techniques, exploiting their strengths and mitigating their weaknesses [52.12]. Besides the theoretical justifications for hybrid metaheuristics (arising, for example, from the NFL theorem sketched before), these techniques have been repeatedly vindicated by their practical success. Before getting to hybrid EAs, let us first focus on how hybridization can be approached.

### 52.3.1 Hybridization Mechanisms

As was already mentioned in Sect. 52.1, attempts to classify hybrid metaheuristics are manifold [52.13–17]. We will focus in the following on two of these, namely the classification of *Talbi* [52.13] and that of *Raidl* [52.16].

**Fig. 52.2** Classification of hybrid metaheuristics by *Talbi* (after [52.13])

*Talbi* proposed a hierarchical taxonomy based on two design issues: functionality and algorithmic architecture. According to this, we can distinguish between high/low-level hybrids and relay/team-work hybrids. Low-level hybridization addresses the functional composition of a single optimization method in which a certain function of a metaheuristic is replaced by another metaheuristic. On the contrary, in high-level hybrids, the internals of different metaheuristics are non-intersecting. As for relay hybridization, it comprises models in which a set of metaheuristics are sequentially applied, each using the output of the previous as its input. On the other hand, teamwork hybridization represents cooperative optimization models. These two distinctions (low versus high, relay versus teamwork) are orthogonal, and hence lead to four different combinations. These four classes can, in turn, be refined using three additional dichotomies, namely homogeneous versus heterogeneous (referring to the type of metaheuristics involved in the hybrid), global versus partial (referring to whether or not each technique explores the whole search space) and specialist versus general (referring to whether or not all algorithms solve the same optimization problem). Figure 52.2 shows this taxonomy.

*Raidl* [52.16], in turn, proposed a hybrid metaheuristic classification centered around four elements: type of hybridization, level/strength of hybridization, control strategy, and execution order. Regarding the type of hybridization, we can distinguish between:

- 1) Combinations of different metaheuristics
- 2) Combination of metaheuristics and problem-specific algorithms
- 3) Combinations of metaheuristics with general operational research (OR), artificial intelligence (AI), or constraint programming (CP) techniques.

Regarding the hybridization strength, we can distinguish high-level/weakly-coupled hybrids and low-level/strongly-coupled hybrids. As to the control strategy, there are two possibilities: integrative (a technique takes a subordinate role) and collaborative (exchange of information without subordination). Finally, the order of execution captures the temporal aspect of the interaction among techniques. Thus, we can have sequential execution (a technique takes as input the output of another technique), intertwined execution (both techniques alternate parts of their execution at a computational or algorithmic level), and parallel execution (the techniques run in parallel). Figure 52.3 shows this classification.

### 52.3.2 Hybrid EAs

One of the most classical hybridization approaches for EAs is defined in the context of knowledge-augmented representations, particularly in the case that the solutions sought have an extremely complex structure for which a direct search does not seem adequate, or with problems that exhibit constraints. In the latter case, these can be handled in three ways:

- By using penalty functions that guide the search to feasible solutions
- By using repairing mechanisms that turn infeasible solutions into feasible ones

- By defining reproductive operators that always remain in the feasible region.

While the complexity of the representation and the operators can be kept low in the first two cases (i.e., the complexity is moved to the fitness function and the repairing function, respectively), the third case requires either a careful representation safeguarding feasibility, or complex operators intelligently handling the constraints of the problem. Focusing on representations, decoders [52.18] are commonly used. These provide a complex genotype-to-phenotype mapping that may not just produce feasible solutions, but can also provide better quality solutions. Consider, for example, the knapsack problem: solutions are sets of objects in this case, but clearly a random set may be infeasible due to the knapsack capacity constraint. This could be handled with a penalty term to account for this capacity violation or by adding/removing some objects to turn the solution into a feasible one [52.19]. A decoder approach could, however, encode solutions as permutations, indicating the order in which objects are to be considered for inclusion in the knapsack. Since any object violating the capacity constraint would be skipped, a feasible solution would be always obtained. Problem-space search [52.20] – the use of a construction heuristic that is guided through problem-space – also falls within this class of low-level/strong hybrids. Following with the knapsack problem, solutions could in this case be represented as

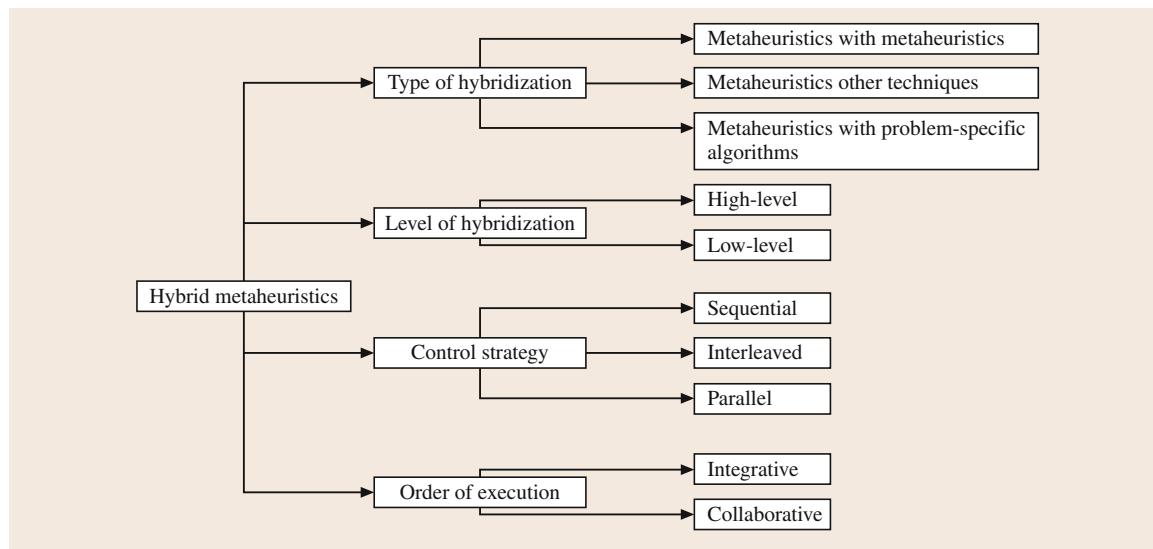

Fig. 52.3 Classification of hybrid metaheuristics by Raidl (after [52.16])

perturbations of the value of objects. Each of these solutions would be evaluated by constructing the so-modified problem instance, solving it with a greedy heuristic and using the original instance to evaluate the quality of the solution obtained. This strategy is very competitive for this problem, as is shown in [52.21].

On the other hand, high-level/weak hybrid evolutionary algorithms are most typically obtained either by integrating within the EA a local-search (single-point or trajectory-based) method, or other techniques from the realm of OR/AI/CP/..., etc. Regarding the former approach, the underlying idea is to boost the intensification capabilities of the algorithm by improving the solutions generated by the population-based search engine. This kind of combination dates back to the late 1980s, when it used to take the form of a genetic algorithm hybridized with simulated annealing (SA), [52.22]. A particularly interesting hybrid EA along this line is the parallel recombinative simulated annealing algorithm [52.23], in which a pool of SA algorithms cooperate/compete in a genetic algorithm framework. Tabu search (TS) is another popular local search metaheuristic to be hybridized with EAs (see [52.24–29], to mention just a few).

Other EA techniques such as estimation of distribution algorithms (EDAs) have also been hybridized with local search approaches, e.g., Campelo et al. [52.30] for the design of electromagnetic devices and Laguna et al. [52.31] for maximum cut. It is also worth mentioning the work by Santana et al. [52.32] on the combination of variable neighborhood search [52.33] (VNS) with EDAs for protein structure prediction. This is done in different ways, most notably either integrating VNS within the EDA or alternating the two algorithms. Zhang et al. [52.34] propose an analogous approach for quadratic programming based on the hybridization

of EDAs and 2-opt hill climbing. A very interesting approach was also proposed by Peña et al. [52.35], who hybridized a steady-state genetic algorithm and an EDA; each of these algorithms is responsible for generating a part of the population. On the other hand, Zhou et al. [52.36] and Ahn et al. [52.37] propose the hybridization of an EDA with particle swarm optimization (PSO) where the latter is used for intensification purposes.

As for hybridization with techniques from the realms of AI/OR or constraint programming, examples date back to the mid 1990s. Particularly interesting is the combination of EAs with exact techniques and derivatives thereof. For example, branch and bound (BnB) can be integrated within an EA as a recombination operator [52.38, 39] or in the decoding process [52.40]. Conversely, an EA can be used for the strategic guidance of BnB [52.41]. As for collaborative combinations, intertwined approaches were considered in [52.42] by combining EAs and BnB within a parallel multiagent system, and in [52.38, 43] by defining a model in which the exact technique provided partial promising solutions, and the EA returned improved bounds. A related multilevel approach involving beam search and an EA hybridized with local-search algorithm can be found in [52.44–46]. For further details on this kind of exact/metaheuristic hybridization we refer the reader to [52.3].

Most of the above hybrid EAs can be safely described as memetic algorithms, if only under the broad interpretation of MASs emanating from seminal and early works on the topic [52.9, 47]. Indeed, the algorithmic hybridizations mentioned above can be seen as combinations of global and local search, probably the most widely recognized feature of MASs. The next section provides a more detailed overview of MASs.

## 52.4 Memetic Algorithms

MASs are population-based metaheuristics and as such they keep a population of candidate solutions for the problem under consideration. While these solutions were called individuals in EA jargon, in the context of MASs it is sometimes more appropriate to think of them as agents, thus highlighting their more active nature (i.e., behavior purposefully directed at optimizing some problem) in contrast to the passive nature of EA individuals (which are mere information placeholders

subject to evolutionary operations). The particular way in which this active behavior can be captured will be discussed later on. Algorithm 52.2 shows the general pseudocode of a simple MA.

---

**Algorithm 52.2 Pseudocode of a basic MA based on a local search LS**

1: **function** Basic MA (**in**  $P$ : Problem, **in**  $par$ : Parameters): Solution;

```

2: for  $i \in \mathbb{N}_\mu$  do
3:    $pop[i] \leftarrow \text{GENERATE-SOLUTION}(P)$ ;
4:    $pop[i] \leftarrow \text{LOCAL-IMPROVEMENT } (pop[i], P,$ 
    $par)$ ;
5: end for
6:  $i \leftarrow 0$ ;
7: while  $i < MaxEvals$  do
8:    $auxpop[0] \leftarrow \text{SELECT } (pop)$ ;
9:   for  $j \leftarrow 1$  to  $\#op$  do
10:     $auxpop[j] \leftarrow \text{APPLY}(op[j], auxpop[j - 1], P,$ 
      $par)$ ;
11:   end for
12:    $newpop \leftarrow \text{LOCAL-IMPROVEMENT}$ 
      $(auxpop[\#op], P, par)$ ;
13:    $pop \leftarrow \text{REPLACE}(pop, newpop)$ ;
14:   if DEGENERATED( $pop$ ) then
15:     RESTART( $pop, P$ );
16:   end if
17: end while
18: return GetBest( $pop$ );

```

First of all, the population must be initialized. Problem knowledge can be introduced in this stage by using constructive heuristics. For example, greedy strategies based in the nearest neighbor heuristic [52.48] could be used to generate solutions for the traveling salesman problem (**TSP**) – see also [52.49–51] for other examples in the context of scheduling and timetabling. Then, the population of agents is subject to processes of competition and mutual cooperation much like in **EAs**. Competition (i.e., selection and replacement) can be done in general using any of the well-known strategies used in **EAs**, e.g., tournament, ranking, or fitness-proportionate selection, and/or comma replacement, etc. As for cooperation, it is accomplished by using a number of reproductive operators. Many different such operators can be used in an **MA**, as illustrated in the general pseudocode shown in Algorithm 52.2: an array  $op$  of operators is sequentially applied to the population in a pipeline fashion. Note also how these operators receive as input not just the solutions they act on but also problem data, thus emphasizing the usage of problem knowledge. While it is possible to consider local improvement as one of these operators, it plays such a distinctive role in most **MAs** that it is independently depicted in the pseudocode.

Recombination is the algorithmic component that best captures cooperation among two (or more [52.52]) agents in **MAs**. By using this operation, the relevant information contained in the parents is combined to

produce new solutions. Relevance here amounts to be significant when it comes to evaluating the quality of solutions. As an example, consider again the **TSP**. While solutions can be encoded as permutations, a standard permutational recombination operator will not perform adequately in general. The reason is that permutations are information-rich structures carrying positional, precedence, and adjacency information [52.53]. Clearly, the latter is the really relevant piece of information when the **TSP** is involved. Hence, an edge-manipulation operator such as edge recombination [52.54] (**ER**) will perform better than position-based operators such as partially-mapped crossover [52.55] (**PMX**) or uniform cycle crossover [52.56] (**UCX**). There are several principled approaches to define measures capturing the goodness of different representations (that is, the way a particular encoding is interpreted) among which we can cite epistasis (non-additive influence on the fitness function of combining several information units) [52.57, 58], fitness variance of formae (variance of the fitness values of a representative subset of solutions carrying a particular information unit) [52.59], and fitness correlation (correlation in the fitness values of parents and offspring) [52.60, 61].

Mutation is the other classical reproductive operator. Its role is that of injecting new material in the population (at a low rate to prevent the search degrading to a random walk in the solution space). This view of mutation as an important operator but it is, nevertheless, secondary to recombination and departs from the interpretation of the search process made in, e.g. evolutionary programming [52.62]. In either case, mutation plays an important role in **EAs** since it favors the effectiveness of recombination (particularly in some unstructured landscapes). Furthermore, if the problem exhibits constraints it is commonly much easier to handle these in a local way and maintain/achieve feasibility by introducing small perturbations in a solution than via recombination (e.g., consider a university timetabling problem [52.63]: given a feasible solution, it is easier to exchange a couple of slots, and keep them feasible, than to produce a new feasible solution that comes from the combination of two feasible assignments). However, it must be noted that unlike classical **EAs**, in which recombination is a mere random shuffler of information (and hence can be arguably cast as a macro-mutational process), **MAs** usually utilize intelligent problem-aware mechanisms for recombination, and thus play a crucial role in the search. Broadly speaking, this inclusion of problem knowledge during recombination can be projected on two aspects of the process, namely the se-

lection of the pieces of information from the parents that will be transmitted to the offspring, and the selection of the external information that will be added to it. Regarding the former issue, it is commonly assumed that transmission of common features is beneficial for some problems [52.54, 64]. Further completion of the descendant can be done in several ways. *Radcliffe* and *Surry* [52.59] proposed the use of local improvers or implicit enumeration schemes. *Cotta* and *Troya* suggested the use of exact techniques to find the best way of combining the information present in the parents [52.39]. *Ibaraki* [52.65] and *Gallardo* et al. [52.66] used dynamic programming for this purpose.

The use of local search (**LS**) is one of the most distinctive components of **MAs**, to the extent that **MAs** are often equated to **EAs** endowed with **LS**. While this is certainly a very popular implementation of **MAs**, several authors [52.47, 67, 68] advocate a broader interpretation of the paradigm in which an explicit local search algorithm need not be present (e.g., local improvement can take place during recombination as in the edge assembly crossover defined in [52.69] for the **TSP**). In its simplest incarnation, these local improvers can be hill climbers, exploring the neighborhood of the current solution and performing uphill moves in the corresponding fitness landscape [52.70] until a local optimum is found or the computational budget assigned to this operator is exhausted. Obviously, much more complex mechanisms can be defined for this purpose, such as the use of fully-fledged metaheuristics, such as, for example, **TS**, **SA**, or **VNS**, just to mention a few. It must be also noted that it is mainly because of the use of this mechanism for improving solutions on a local (and even autonomous) basis that the term *agent* is deserved. Under this interpretation, the **MA** can be viewed as a collection of agents that autonomously explore the search space, cooperate via recombination, and compete for computational resources via selection and replacement. This also provides an interesting link to cooperative models for optimization and to memetic computing in general [52.71, 72].

One of the crucial elements governing the successful application of local search within an **MA** is achieving a good balance between global and local search. This amounts to determining when to apply local search (how often and on which solutions) and how intense this local search has to be. This parameterization problem is very hard and constitutes an active area of research [52.73]. An additional issue is the selection of a particular local search scheme within the **MA**. This has actually led to a very fruitful line of research in

so-called multimemetic algorithms (**MMA**s). Therein, a meme is interpreted as a lifetime learning procedure capable of improving individual solutions [52.74–79]. Each solution in a **MMA** carries a gene indicating the particular **LS** operator that has to be applied on it (a pointer to an existing operator, or the parameterization of a generic local search template). Thus, they constitute a generalization of meta-lamarckian **EAs** [52.80] (in which the selection of the **LS** operator – from a pre-fixed set – is made using some rules that are hard-wired into the **MA**) and an intermediate step in the direction of co-evolving **MAs** [52.75] (in which a population of **LS** operators co-evolve along with a population of solutions). Finally, it is essential from a purely computational perspective to be able to apply **LS** in an efficient way. As was mentioned in Sect. 52.1 this is normally attained in combinatorial problems by incrementally evaluating solutions belonging to the neighborhood area. For example, consider the 2-opt neighborhood in the **TSP** [52.48]: each neighbor of a given solution is obtained by a 2-opt move that removes two edges and adds two new edges; the fitness of such a neighbor can thus be computed by taking the fitness of the initial solution and adding a term accounting for the difference between added edges and removed edges.

Another interesting element of **MAs** is the restarting process invoked whenever the population is deemed degenerate due to a lack of diversity or any other factor impairing the subsequent performance of the algorithm. This restarting process can be done in numerous ways (for example, triggering hypermutation [52.81] or introducing random solutions in the population [52.82]) and can be often found in plain **EAs** as well (indeed the use of restarting procedures in **EAs** can be traced back to the CHC algorithm [52.83] in the early 1990s). This said, it constitutes a generic element to be routinely included in **MAs**. Indeed, scatter search [52.84] (a technique that can reasonably be termed memetic, despite having an independent origin from **MAs** and its fair share of distinctive features such as the emphasis on using deterministic strategies) has a restart as a crucial element in its algorithmic cycle. Note also that it is not unusual to have **MAs** without mutation, given the fact that new information can also be injected in the population via local search, and the availability of restarting mechanisms. Indeed, in some applications, it may be better to converge quickly and then restart, rather than continuously diversifying the search. This is not the general norm at any rate. As a matter of fact, one can easily find **MAs** that use sev-

eral mutation operators, either by considering different basic neighborhoods [52.27, 85] or by defining *light* and *heavy* mutations that introduce different amounts of new information [52.86, 87] – cf. hypermutation. Needless to say, the use of restarting strategies is a corrective measure that is taken once a diversity problem is encountered and can be complemented with preventive measures aimed to hinder (or even avoid) this problem taking place for the first time. For example, structured populations [52.88] could be used to cause

a slowdown in the propagation of information across the population, hence hindering the apparition of *super agents* that might quickly take the population over and destroy diversity. Also, population management strategies based on the use of distance measures have been utilized with notable success in combinatorial problems [52.89]. More traditional strategies for maintaining diversity during selection and replacement, such as crowding [52.90] or sharing [52.91], can be used as well.

## 52.5 Cooperative Optimization Models

As stated in previous section, the interpretation of **MAs** as a collection of interacting agents that autonomously explore the search space while cooperating/competing with each other seamlessly integrates with the more general notion of memetic computing and cooperative optimization models. According to the definition in [52.92], memetic computing is:

*a paradigm that uses the notion of meme(s) as units of information encoded in computational representations for the purpose of problem solving,*

where *meme* should be interpreted as local-search operator as mentioned before. This orchestration of different **LS** operators naturally links with cooperative models dating back to the late 1990s [52.93]. These attempts to attain an effective mechanism for exploring the search space try to escape from local optima by combining search agents that have diverse intensification/diversification characteristics and that start from different points in the search space [52.94]. According to [52.95], the distinctive features of this kind of models are (1) a collection of autonomous algorithms (agents), each of them supporting a different optimization method, and (2) a cooperative scheme for combining these autonomous elements into an unified problem-solving strategy.

Early cooperative models involve an algorithmically homogenous collection of algorithms exchanging information. For example, *Toulouse* et al. [52.93] considered a collection of **TS** algorithms exchanging tabu attributes (notice the relation of this model with the parallel recombinative **SA** algorithm mentioned in Sect. 52.3.2) and later proposed a hierarchical decomposition approach [52.96]. A related model was also proposed by *Crainic* and *Gendreau* [52.97]. *Crainic*

et al. [52.98] put forward an asynchronous cooperative search procedure on the basis of **VNS**. A different approach based on the used of a central manager was proposed by *Pelta* et al. [52.99]. This central manager gathers information about the performance of the different agents and acts on them, altering their behavior – see also [52.100]. Other centralized approaches were defined by *LeBouthillier* and *Crainic* [52.101] by means of maintaining a *solution warehouse* upon which individual heuristics act. More recently, *Barbucha* [52.102] explored synchronous and asynchronous versions of an analogous memory-centralized approach in the context of vehicle routing problems. *Leung* et al. [52.103] proposed, in turn, a cooperative/competitive scheme in which the problem space is partitioned and a pool of agents is structured into several subgroups which repel each other, thus contributing to keeping diversity.

Multi-level models have also received a lot of attention in the last years. These models consist of layered algorithmic approaches and are not to be confused with multilevel partitioning strategies proposed for combinatorial optimization [52.104, 105], in which the resolution of the problem is attained via its incremental reduction and further reconstruction, using some solver at each level and the solution obtained therein as seeds for solving the next higher level. *Hulianytskyi* and *Sirenko* [52.106] presented a two-level cooperative approach: the lower level corresponds to basic algorithms, whereas the upper level combines the information found by these and broadcasts a refined version back to the basic algorithms. *Milano* and *Roli* [52.4] developed a multiagent system called MAGMA (multiagent metaheuristic architecture) allowing the use of metaheuristics at different levels (generating solutions, improving them, defining search strategies, and co-ordinating lower-level agents). Each level (or layer)

provides a different abstraction level and can contain several agents loaded with a particular search algorithm. The lowest layer (level 0) generates solutions to be fed to level 1. The latter provides local improvement of these solutions. Level 2 has a global view of the search space and provides the means for escaping from local optima. The upmost level (level 3) coordinates the functioning of the underlying agents, rewarding

those which perform well or adapting and improving their functioning. They specifically adapt this framework for deployment of **MA**s within it. Finally, Amaya et al. [52.107] defined a multilevel model in which heterogeneous *simple MA*s (i. e., **MA**s obtained from the hybridization of an **EA** and a local search method) are combined in a cooperative model, and exchange information following an underlying arbitrary topology.

## 52.6 Conclusions

Memetic algorithms in particular, and memetic computing in general, constitute a flexible and powerful optimization approach. Rather than being competitors for existing methods and/or paradigms, they are a very suitable framework for integrating such existing techniques in order to attain synergistic combinations or being able to deal with the curse of dimensionality in large-scale optimization settings. They are also a very active research area in which, in addition to a steadily growing number of application works, new fundamental issues are attracting the interest of the research community. Among these we

can cite the theoretical study of their self-adaptation capabilities and their deployment on the emerging computational platforms that are available nowadays. We refer to [52.72, 108, 109] for recent reviews of the field. For an overview of the literature dealing with the application of these techniques to combinatorial optimization problems we refer the reader to [52.67, 108] for a general perspective and to [52.63] for a review of scheduling and timetabling applications. Finally, we refer the reader to [52.110, 111] for further information on the deployment of **MA**s on combinatorial optimization problems.

# 53. Design of Representations and Search Operators

Franz Rothlauf

Successful and efficient use of evolutionary algorithms depends on the choice of genotypes and the representation – that is, the mapping from genotype to phenotype – and on the choice of search operators that are applied to the genotypes. These choices cannot be made independently of each other. This chapter gives recommendations on the design of representations and corresponding search operators and discusses how to consider problem-specific knowledge. For most problems in the real world, similar solutions have similar fitness values. This fact can be exploited by evolutionary algorithms if they ensure that the representations and search operators used are defined in such a way that similarities between phenotypes correspond to similarities between genotypes. Furthermore, the performance of evolutionary algorithms can be increased by problem-specific knowledge. We discuss how properties of high-quality solutions can be exploited by biasing representations and search operators.

## 53.1 Representations

Successful and efficient use of evolutionary algorithms ([EA](#)) and other types of modern heuristics [53.1, 2] depends on the choice of genotypes and the representation – that is, the mapping from genotype to phenotype – and on the choice of search operators that are applied to the genotypes. These choices cannot be made independently of each other [53.2]. The question whether a certain representation leads to a better performing [EA](#) than an alternative representation can only be answered when the operators applied are taken into account. The reverse is also true: deciding between alternative operators is only meaningful for a given representation.

In practice, one can distinguish two complementary approaches to the design of representations and

search operators [53.3]. The first approach defines *representations* (also known as *decoders* or *indirect representations*) where a solution is encoded in a standard data structure, such as strings or vectors, and applies standard off-the-shelf search operators to these genotypes. To evaluate a solution, the genotype needs to be mapped to the phenotype space. The proper choice of this genotype–phenotype mapping is important for the performance of the search process. The second approach encodes solutions to the problem in its most *natural* problem space and designs search operators to operate on this search space. In this case, often no additional mapping between genotypes and phenotypes is necessary, but domain-specific search operators need to be defined. The resulting combination

of representation and operator is often called *direct representation*.

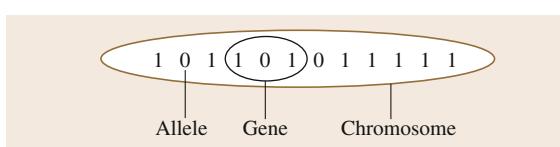

This section focuses on representations. It introduces genotypes and phenotypes (Sect. 53.1.1) and discusses properties of the resulting genotype and phenotype space (Sect. 53.1.2). Section 53.1.3 lists the benefits of using (indirect) representations. Finally, Sect. 53.1.4 gives an overview of standard genotypes.

### 53.1.1 Genotypes and Phenotypes

In 1866, Mendel recognized that nature stores the complete genetic information for an individual in pairwise alleles [53.4]. The genetic information that determines the properties, appearance, and shape of an individual is stored by a number of strings. Later, it was discovered that the genetic information is formed by a double string of four nucleotides, called **DNA** (deoxyribonucleic acid).

Mendel found that nature distinguishes between the genetic code of an individual and its outward appearance. The genotype represents all the information stored in the chromosomes and allows us to describe an individual on the level of genes. The phenotype describes the outward appearance of an individual. A transformation exists – a genotype–phenotype mapping or a representation – that uses the genotype information to construct the phenotype. To represent the large number of possible phenotypes with only four nucleotides, the genotype information is not stored in the allele itself, but in the sequence of alleles. By interpreting the sequence of alleles, nature can encode a large number of different phenotypes using only a few different types of alleles.

Figure 53.1 illustrates the differences between *chromosome*, *gene*, and *allele*. A chromosome is a string of some length  $l$  where all the genetic information of an individual is stored. Although nature often uses more than one chromosome, many **EAs** use only one chromosome for encoding all phenotype information. Each chromosome consists of many alleles. Alleles are the smallest information units in a chromosome. In nature, alleles exist pairwise, whereas in most **EA** implementations an allele is represented by only one symbol. For

**Fig. 53.1** Alleles, genes, and chromosomes

example, binary genotypes only have alleles with value zero or one. If a phenotypic property of an individual (solution), like its hair color or eye size is determined by one or more alleles, then these alleles together are called a gene. A gene is a region on a chromosome that must be interpreted together and which is responsible for a specific property of a phenotype.

We must carefully distinguish between genotypes and phenotypes. The phenotypic appearance of a solution determines its objective value. Therefore, when comparing the quality of different solutions, we must judge them on the phenotype level. However, when it comes to the application of variation operators we must view solutions on the genotype level. New solutions that are created using variation operators do not *inherit* the phenotypic properties of its parents, but only the genotype information regarding the phenotypic properties. Therefore, search operators work on the genotype level, whereas the evaluation of the solutions is performed on the phenotype level.

Formally, we define  $\Phi_g$  as the genotype space where the variation operators are applied. An optimization problem on  $\Phi_g$  could be formulated as  $f(x) : \Phi_g \rightarrow \mathbb{R}$ , where  $f$  assigns an element (fitness value) in  $\mathbb{R}$  to every element in the genotype space  $\Phi_g$ . A maximization problem is defined as finding the optimal solution  $x^* = \{x \in \Phi_g \mid \forall y \in \Phi_g : f(y) \leq f(x)\}$ , where  $x$  is usually a vector or string of decision variables (alleles) and  $f(x)$  is the objective or fitness function.  $x^*$  is the global maximum. To be able to apply **EAs** to a problem, the inverse function  $f^{-1}$  does not need to exist.

### 53.1.2 Genotype and Phenotype Search Spaces

When using a representation, we have to define – in analogy to nature – genotypes and a genotype–phenotype mapping [53.5, 6]. Therefore, the fitness function  $f$  can be decomposed into two parts.  $f_g$  maps the genotype space  $\Phi_g$  to the phenotype space  $\Phi_p$ , and  $f_p$  maps  $\Phi_p$  to the fitness space  $\mathbb{R}$

$$\begin{aligned} f_g(x^g) : \Phi_g &\rightarrow \Phi_p, \\ f_p(x^p) : \Phi_p &\rightarrow \mathbb{R}, \end{aligned} \tag{53.1}$$

where  $f = f_p \circ f_g = f_p(f_g(x^g))$ . The genotype–phenotype mapping  $f_g$  is determined by the type of genotype used.  $f_p$  represents the fitness function and assigns a fitness value  $f_p(x^p)$  to each solution  $x^p \in \Phi_p$ . The search operators are applied to the genotypes [53.7, 8].

The *search space* describes the set of feasible solutions of an optimization problem and defines relationships (for example, distances) between solutions. A *metric* defined on a search space can be used for measuring similarities between solutions [53.2]. Usually, defining a search space  $\Phi$  also defines a metric. Using a metric, the distance  $d(x, y)$  between two solutions  $x, y \in \Phi$  measures how different the two solutions are. The larger the distance, the more different two individuals are with respect to the metric used. In principle, different metrics can be used for the same search space. Different metrics result in different distances and different measurements for the similarity of solutions.

In *metric search spaces*, the similarities between solutions are measured by a distance. Therefore, we have a set  $X$  of solutions and a real-valued distance function (also called a metric)  $d : X \times X \rightarrow \mathbb{R}$  that assigns a real-valued distance to any combination of two elements  $x, y \in X$ .

An example of a metric space is the set of real numbers  $\mathbb{R}$ . Here, a metric can be defined by  $d(x, y) := |x - y|$ . Therefore, the distance between any solutions  $x, y \in \mathbb{R}$  is the absolute value of their differences. Extending this definition to two-dimensional spaces  $\mathbb{R}^2$ , we obtain the *city-block metric* (also known as the taxicab metric or the Manhattan distance). It is defined for two-dimensional spaces as  $d(x, y) := |x_1 - y_1| + |x_2 - y_2|$ , where  $x = (x_1, x_2)$  and  $y = (y_1, y_2)$ . This metric is named the city-block metric as it describes the distance between two points on a two-dimensional plane in a city like Manhattan or Mannheim with a rectangular ground plan. On  $n$ -dimensional search spaces  $\mathbb{R}^n$ , the city-block metric becomes  $d(x, y) := \sum_{i=1}^n |x_i - y_i|$ , where  $x, y \in \mathbb{R}^n$ .

Another example of a metric that can be defined on  $\mathbb{R}^n$  is the *Euclidean metric*. In Euclidean spaces, a solution  $x = (x_1, \dots, x_n)$  is a vector of continuous values ( $x_i \in \mathbb{R}$ ). The Euclidean distance between two solutions  $x$  and  $y$  is defined as  $d(x, y) := \sqrt{\sum_{i=1}^n (x_i - y_i)^2}$ . For  $n = 1$ , the Euclidean metric coincides with the city-block metric. For  $n = 2$ , we have a standard two-dimensional search space and the distance between two elements  $x, y \in \mathbb{R}^2$  is just a direct line between two points on a two-dimensional plane.

If we assume that we have a binary space ( $x \in \{0, 1\}^n$ ), a commonly used metric is the binary *Hamming metric* [53.9]  $d(x, y) = \sum_{i=1}^n |x_i - y_i|$ , where  $d(x, y) \in \{0, \dots, n\}$ . The binary Hamming distance between two binary vectors  $x$  and  $y$  of length  $n$  is just the number of binary decision variables on which  $x$  and  $y$

differ. For continuous and discrete decision variables, it becomes  $d(x, y) = \sum_{i=1}^n z_i$ , where

$$z_i = \begin{cases} 0, & \text{for } x_i = y_i, \\ 1, & \text{for } x_i \neq y_i. \end{cases} \quad (53.2)$$

In general, the Hamming distance measures the number of decision variables on which  $x$  and  $y$  differ. Two individuals are neighbors if the distance between them is minimal. For the binary Hamming metric, the minimal distance between two individuals is  $d_{min} = 1$ . Therefore, two individuals  $x$  and  $y$  are neighbors if their distance  $d(x, y) = 1$ .

Using the Euclidean or the Hamming metric only makes sense for measuring distances between solutions of the same length  $n$ . If solutions have different lengths, the *Levenshtein distance* (or edit distance) [53.10] can be used. This distance counts the minimum number of insertion, deletion, or substitution operations that transform one solution into the other. The Levenshtein distance between two solutions can be calculated with polynomial effort using dynamic programming [53.11]. For fixed-length solutions, the Levenshtein distance is equivalent to the Hamming distance.

Using a representation  $f_g$ , we obtain two different search spaces,  $\Phi_g$  and  $\Phi_p$ . Therefore, different metrics can be defined for the phenotype and the genotype space. The metric used on the phenotype search space  $\Phi_p$  is usually determined by the specific problem to be solved and describes which problem solutions are similar to each other. Examples of common phenotypes and corresponding metrics are given in Sect. 53.2.5. In contrast, the metric defined on  $\Phi_g$  is not defined by the specific problem but can be defined by the search operators selected for the optimization method. As we can define different types of genotypes to represent the phenotypes, we are able to define different metrics on  $\Phi_g$ . However, if the metrics on  $\Phi_p$  and  $\Phi_g$  are different, different neighborhoods can exist on  $\Phi_g$  and  $\Phi_p$ . For example, when encoding phenotype integers using genotype bitstrings, the phenotype  $x^p = 5$  has two neighbors,  $y^p = 6$  and  $z^p = 4$ . When using the Hamming metric and binary genotypes, the corresponding binary string  $x^g = 101$  has three different neighbors,  $y^g = 001$ ,  $z^g = 111$ , and  $w^g = 100$  [53.12].

Therefore, the metric on the genotype space should be chosen such that it fits the metric on the phenotype space well. A representation introduces an additional genotype–phenotype mapping and thus modifies the fit.

When designing optimization methods, we have to ensure that the metric on the genotype search space fits the original problem metric. We should choose the genotype metric in such a way that phenotypic neighbors remain neighbors in the genotype search space. Representations that ensure that neighboring phenotypes are also neighboring genotypes are called high-locality representations (Sect. 53.3.1).

### 53.1.3 Benefits of Representations

In principle, a representation is not necessary for the application of **EAs** as search operators may also be directly applied to phenotypes. However, the use of an additional genotype–phenotype mapping has some benefits:

- The use of representations is necessary for problems where a phenotype cannot be depicted as a string or in another way that is accessible to variation operators. A representative example is the shape of an object, for example the wing of an airplane. **EAs** that are used to find the optimal shape usually require a representation as the direct application of search operators to the *shape* of a wing is difficult. Therefore, additional genotype–phenotype mappings are used and variation operators are applied to genotypes that indirectly determine the shape.
- The introduction of a representation can be useful if there are constraints or restrictions on the phenotype space that can be advantageously modeled by a specific encoding. An example is a tree problem where the optimal solution is a star. Instead of applying search operators directly to trees, we can introduce genotypes that only encode stars resulting in a much smaller search space.
- The use of the same genotypes for different types of problems, and only interpreting them differently by using a different genotype–phenotype mapping, allows us to use standard search operators (Sect. 53.2.5) with known properties. In this case, we do not need to develop new operators with unknown properties and behavior.
- Finally, using an additional genotype–phenotype mapping can change the difficulty of a problem. A representation can reduce the difficulty of the problem and make it easier to solve for a particular optimization method. However, usually the definition of a proper representation is difficult and problem specific.

### 53.1.4 Standard Genotypes

We characterize some of the most important and widely used genotypes. For a more detailed overview of different types of genotypes, we refer to [53.13, Sect. C1].

#### Binary Genotypes

Binary genotypes are commonly used in genetic algorithms [53.14, 15]. Such **EA** types use recombination as the main search operator and mutation only serves as background noise. A typical search space is  $\Phi_g = \{0, 1\}^l$ , where  $l$  is the length of a binary vector  $x_g^g = (x_1^g, \dots, x_l^g)$ . The genotype–phenotype mapping  $f_g$  depends on the specific optimization problem to be solved. For many combinatorial optimization problems using binary genotypes allows a direct and very natural encoding.

When using binary genotypes for encoding integer phenotypes, specific genotype–phenotype mappings are necessary. Different types of binary representations for integers assign the integers  $x^p \in \Phi_p$  (phenotypes) in different ways to the binary vectors  $x^g \in \Phi_g$  (genotypes). The most common binary genotype–phenotype mappings are binary, Gray, and unary encoding [53.3, 16, Chap. 5].

When using binary genotypes to encode continuous phenotypes, the accuracy (precision) depends on the number of bits that represent one phenotype variable. By increasing the number of bits that are used to represent one continuous variable the accuracy of the representation can be increased.

#### Integer Genotypes

Instead of using binary strings with cardinality  $\chi = 2$ , higher  $\chi$ -ary alphabets, where  $\{\chi \in \mathbb{N} | \chi > 2\}$ , can also be used for the genotypes. Then, instead of a binary alphabet a  $\chi$ -ary alphabet is used for a string of length  $l$ . Instead of encoding  $2^l$  different individuals with a binary alphabet, we are able to encode  $\chi^l$  different possibilities. The size of the search space increases from  $|\Phi_g| = 2^l$  to  $|\Phi_g| = \chi^l$ .

For integer problems, users sometimes prefer to use binary instead of integer genotypes because schema processing is maximally efficient with binary alphabets when using standard recombination operators in genetic algorithms [53.17]. Goldberg [53.17] qualified this recommendation and emphasized that the alphabet used in the encoding should be as small as possible while still allowing a natural representation of solutions. To give general recommendations is difficult, as users often do not know *a priori* whether binary genotypes allow

a natural encoding of integer phenotypes [53.18, 19]. We recommend that users use binary genotypes for encoding binary decision variables and integer genotypes for integer decision variables.

### Continuous Genotypes

When using continuous genotypes, the search space is  $\Phi_g = \mathbb{R}^l$ , where  $l$  is the size of a real-valued string or vector. Continuous genotypes are often used in local search methods like evolution strategies or evolutionary programming. These types of optimization methods mainly rely on local search and search through the search space by adding a multivariate zero-mean Gaussian random variable to each continuous variable. In contrast, when using recombination-based genetic algorithms, continuous decision variables are often represented by using binary genotypes.

Continuous genotypes cannot only be used for encoding continuous problems, but also for permutation

and combinatorial problems. Trees, schedules, tours, or other combinatorial problems can easily be represented by using continuous genotypes and special genotype–phenotype mappings (for an example, see weighted encodings for trees [53.20, 21]).

### Messy Representations

In all previously discussed genotypes, the position of each allele is fixed along the chromosome and only the corresponding value is specified. A first gene-independent genotype was proposed by [53.22], where an inversion operator changes the relative order of the alleles in the string. The position of an allele and the corresponding value are coded together as a tuple in a string. This concept can be used for all types of genotypes such as binary, integer, and real-valued alleles, and allows an encoding which is independent of the position of the alleles in the chromosome. Later, Goldberg et al. [53.23] used this position-independent representation for the messy genetic algorithm.

## 53.2 Search Operators

This section distinguishes between standard search operators, which are applied to genotypes, and problem-specific search operators that can also be applied to phenotypes (often called *direct representations*). We start with an overview of general design guidelines. Sections 53.2.2 and 53.2.3 discuss local and recombination-based search operators. In Sect. 53.2.4, we focus on direct representations, where search operators are directly applied to phenotypes and no explicit genotype–phenotype mapping exists. Finally, Sect. 53.2.5 gives an overview of standard search operators.

### 53.2.1 General Design Guidelines

During the 1990s, Radcliffe developed guidelines for the design of search operators. It is important for search operators that the representation used is taken into account as search operators are based on the metric that is defined on the genotype space. Radcliffe introduced the principle of *formae*, which are subsets of the search space [53.24–29]. Formae are defined as *equivalence classes* that are induced by a set of equivalence relations. Any possible solution of an optimization problem can be identified by specifying the equivalence class to which it belongs for each of the equivalence re-

lations. For example, if we have a search space of faces [53.30], basic equivalence relations might be *same hair color* or *same eye color*, which would induce the formae *red hair*, *dark hair*, *green eyes*, etc. Formae of higher order like *red hair and green eyes* are then constructed by composing simple formae. The search space, which includes all possible faces, can be constructed with strings of alleles that represent the different formae. For the definition of formae, the structure of the phenotypes is relevant. For example, for binary problems, possible formae would be *bit i is equal to one/zero*.

It is an unsolved problem to find appropriate equivalences for a particular problem. From the equivalences, the genotype search space  $\Phi_g$  and the genotype–phenotype mapping  $f_g$  can be constructed. Usually, a solution is encoded as a string of alleles. The value of an allele indicates whether the solution satisfies a particular equivalence. Radcliffe [53.25] proposed several design guidelines for creating appropriate equivalences for a given problem. The most important one is that the generated formae should group together solutions of related fitness [53.28], in order to create a fitness landscape or structure of the search space that can be exploited by search operators.

Radcliffe recognized that the genotype search space, the genotype–phenotype mapping, and the search operators belong together, and their design cannot be separated from each other [53.26]. He assumed that search operators create offspring solutions from a set of parent solutions. For the development of appropriate search operators that are based on predefined formae, he formulated the following four design principles [53.25, 29]:

- *Respect*: offspring produced by recombination should be members of all formae to which both their parents belong. For the *face example* this means that offspring should have red hair and green eyes if both parents have red hair and green eyes.
- *Transmission*: an offspring should be equivalent to at least one of its parents under each of the basic equivalence relations. This means that every gene should be set to an allele which is taken from one of the parents. If one parent has dark hair and the other red hair, then the offspring has either dark or red hair.
- *Assortment*: an offspring can be formed with any compatible characteristics taken from the parents. Assortment is necessary as some combinations of equivalence relations may be infeasible. This means, for example, that the offspring inherits dark hair from the first parent and blue eyes from the second parent only if dark hair and blue eyes are compatible. Otherwise, the alleles are set to feasible values taken from a random parent.
- *Ergodicity*: an iterative use of search operators allows us to reach any point in the search space from all possible starting solutions.

Radcliffe developed a consistent concept of how to design efficient [EAs](#) once appropriate equivalence classes (formae) are defined. However, the finding of appropriate equivalence classes, which is equivalent to either defining the genotype search space and the genotype–phenotype mapping or appropriate direct search operators on the phenotypes, is often difficult and remains an unsolved problem.

As long as the genotypes are either binary, integer, or real-valued strings, standard recombination and mutation operators can be used. The situation is different if direct representations (Sect. 53.2.4) are used for problems whose phenotypes are not binary, integer, or real-valued. Specialized operators are necessary that allow offspring to inherit important properties from their parents [53.24, 25, 27, 31]. In general, these operators

are problem-specific and must be developed separately for every optimization problem.

### 53.2.2 Local Search Operators

Local search and the use of local search operators are at the core of [EAs](#). The goal of local search is to find fitter individuals by performing neighborhood search [53.32]. Usually, a local search operator creates offspring that have a small or sometimes even minimal distance to their parents. Therefore, local search operators and the metric on the corresponding search space cannot be decided independently of each other but determine each other. A metric defines possible local search operators and a local search operator determines the metric. As search operators are applied to the genotypes, the metric on  $\Phi_g$  is relevant for the definition of local search operators.

The basic idea behind using local search operators is that the structure of a fitness landscape should guide a search heuristic to high-quality solutions [53.33], and that good solutions can be found by performing small iterated changes. We assume that in most real-world problems high-quality solutions are not isolated in the search space but grouped together [53.34, 35]. Therefore, better solutions can be found by searching in the neighborhood of already found good solutions. The search steps must be small because too large search steps would result in randomization of the search, and guided search around good solutions would become impossible. In contrast, when using search operators that perform large steps in the search space it would not be possible to find better solutions by searching around already found good solutions but the search algorithm would jump randomly around the search space (Sect. 53.3.1).

The following paragraphs review some common local search operators for binary, integer, and continuous genotypes and illustrate how they are designed based on the underlying metric. The local search operators (and underlying metrics) are commonly used and are usually a good choice. However, in principle, we are free to choose other metrics and to define corresponding search operators. Then, the metric should be chosen such that high-quality solutions are neighboring solutions and the resulting fitness landscape leads guided search methods to an optimal solution. The choice of a proper metric and corresponding search operators are always problem specific and the ultimate goal is to choose a metric such that the problem becomes easy for [EAs](#). However, we want to emphasize that for most practical applications

the illustrated search operators are a good choice and allow us to design efficient and effective EAs.

### Binary Genotypes

When using binary genotypes, the distance between two solutions  $x, y \in \{0, 1\}^l$  is often measured using the Hamming distance. Local search operators based on this metric generate new solutions with the Hamming distance  $d(x, y) = 1$ . This type of search operator is also known as a *standard mutation operator* for binary strings or a *bit-flipping* operator. As each binary solution of length  $l$  has  $l$  neighbors, this search operator can create  $l$  different offspring. For example, applying the bit-flipping operator to  $(0, 0, 0, 0)$  can result in four different offspring  $(1, 0, 0, 0), (0, 1, 0, 0), (0, 0, 1, 0)$ , and  $(0, 0, 0, 1)$ .

Reeves [53.36] proposed another local search operator for binary strings based on a different neighborhood definition: for a randomly chosen  $k \in \{0, \dots, l\}$ , it complements the bits  $x_k, \dots, x_l$ . Again, each solution has  $l$  neighbors. For example, applying this search operator to  $(0, 0, 0, 0)$  can result in  $(1, 1, 1, 1), (0, 1, 1, 1), (0, 0, 1, 1)$ , or  $(0, 0, 0, 1)$ . Although the operator is of minor practical importance, it has some interesting theoretical properties. First, it is closely related to the one-point recombination crossover (see below) as it chooses a random point and inverts all  $x_i$  with  $i \geq k$ . Therefore, it has also been called the *complementary crossover operator*. Second, if all genotypes are encoded using Gray code [53.37, 38], the neighbors of a solution in the Gray-coded search space using Hamming distance are identical to the neighbors in the original binary-coded search space using the complementary crossover operator. Therefore, Hamming distances between Gray encoded solutions are equivalent to the distances between the original binary encoded solutions using the metric induced by the complementary crossover operator (neighboring solutions have distance one). For more information regarding the equivalence of different neighborhood definitions and search operators we refer to the literature [53.36, 39, 40].

### Integer Genotypes

For integer genotypes, different metrics are common, leading to different local search operators. When using the binary Hamming metric, two individuals are neighbors if they differ in one decision variable. Search operators based on this metric can assign a random value to a randomly chosen allele. Therefore, each solution  $x \in \{0, \dots, k\}^l$  has  $lk$  neighbors. For example,

$x = (0, 0)$  with  $x_i \in \{0, 1, 2\}$  has four different neighbors  $((1, 0), (2, 0), (0, 1)$ , and  $(0, 2))$ .

The situation changes when defining local search operators based on the city-block metric. Then, a local search operator can create new solutions by slightly increasing or decreasing one randomly chosen decision variable. For example, new solutions are generated by adding  $+/-1$  to a randomly chosen variable  $x_i$ . Each solution of length  $l$  has a maximum of  $2l$  different neighbors. For example,  $x = (0, 0)$  with  $x_i \in \{0, 1, 2\}$  has only two different neighbors  $(0, 1)$  and  $(1, 0)$ .

Finally, we can define search operators such that they do not modify values of decision variables but exchange values of two decision variables  $x_i$  and  $x_j$ . Therefore, using the Hamming distance, two neighbors have distance  $d = 2$  and each solution has a maximum of  $\binom{l}{2}$  different neighbors. For example,  $x = (3, 5, 2)$  has three different neighbors  $((5, 3, 2), (2, 5, 3)$ , and  $(3, 2, 5))$ .

### Continuous Genotypes

For continuous genotypes, we can define local search operators analogously to integer genotypes. Based on the binary Hamming metric, the application of a local search operator can assign a random value  $x_i \in [x_{i,\min}, x_{i,\max}]$  to the  $i$ -th decision variable. Furthermore, we can define a local search operator such that it exchanges the values of two decision variables  $x_i$  and  $x_j$ . The binary Hamming distance between old and new solutions is  $d = 2$ .

The situation is a little more complex in comparison to integer genotypes when designing a local search operator based on the city-block metric. We must define a search operator such that its iterative application allows us to reach all solutions in reasonable time. Therefore, a search step should be not too small (we want to have some progress in search) and not too large (the offspring should be similar to the parent solution). A commonly used concept for such search operators is to add a random variable with zero mean to the decision variables. This results in  $x'_i = x_i + m$ , where  $m$  is a random variable and  $x'$  is the offspring generated from  $x$ . Sometimes  $m$  is uniformly distributed in  $[-a, a]$ , where  $a < (x_{i,\max} - x_{i,\min})$ . More common is the use of a normal distribution  $\mathcal{N}(0, \sigma)$  with zero mean and standard deviation  $\sigma$ . The addition of zero-mean Gaussian random variables generates offspring that have, on average, the same statistical properties as their parents. For more information on local search operators for continuous variables, we refer to [53.41].

### 53.2.3 Recombination Operators

To be able to use recombination operators, a set of solutions (*population*) must exist as the goal of recombination is to recombine meaningful properties of parent solutions. Thus, for the application of recombination operators at least two parent solutions are necessary; otherwise local search operators are the only option. Recombination operators should be designed according to Radcliffe's recommendations (Sect. 53.2.1).

Analogously to local search operators, recombination operators should be designed based on the metric used [53.6, 30]. Given two parent solutions  $x^{p1}$  and  $x^{p2}$  and one offspring solution  $x^o$ , recombination operators should be designed such that

$$\max(d(x^{p1}, x^o), d(x^{p2}, x^o)) \leq d(x^{p1}, x^{p2}). \quad (53.3)$$

Therefore, the application of recombination operators should result in offspring where the distances between offspring and its parents are equal to or smaller than the distance between the parents. When viewing the distance between two solutions as a measurement of dissimilarity, this design principle ensures that offspring solutions are similar to parents. Consequently, applying a recombination operator to the same parent solutions  $x^{p1} = x^{p2}$  should also result in the same offspring ( $x^o = x^{p1} = x^{p2}$ ).

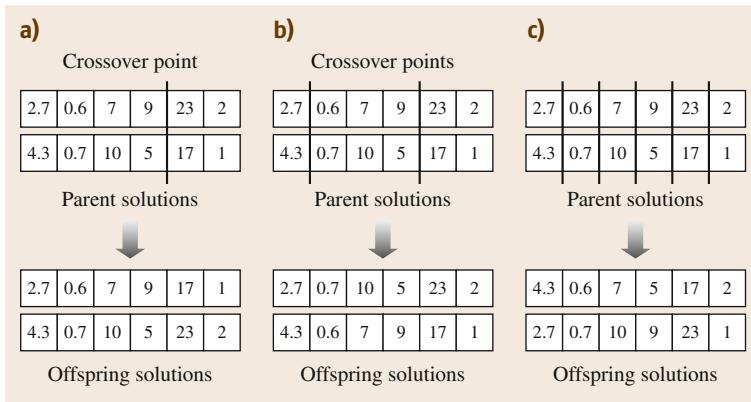

In the last few years, this basic concept of the design of recombination operators has been interpreted as *geometric crossover* [53.42–44]. This work builds upon previous work [53.6, 30, 45] and defines crossover and mutation representation-independently using the notion of distance associated with the search space.

Why should we use recombination operators in **EA**s? The motivation is that we assume that many real-world problems are decomposable. Therefore, problems can be solved by decomposing them into smaller subproblems, solving these smaller subproblems, and combining the optimal solutions of the subproblems to obtain overall problem solutions. The purpose of recombination operators is to form new overall solutions by recombining solutions of smaller subproblems that exist in different parent solutions. If this juxtaposition of smaller, highly fit, partial solutions (often denoted as building blocks) does not result in good solutions, search strategies that are based on recombination operators will show low performance. However, as many problems of practical relevance can be decomposed into smaller problems (they are decomposable), the use of recombination operators often results in good performance of **EA**s.

Common recombination operators for standard genotypes are *one-point crossover* [53.22] and *uniform crossover* [53.46–48]. We assume a vector or string  $x$  of decision variables of length  $l$ . When using one-point crossover, a *crossover point*  $c = \{1, \dots, l-1\}$  is initially chosen randomly. Usually, two offspring solutions are created from two parent solutions by swapping the partial strings. As a result, we obtain for the parents  $x^{p1} = [x_1^{p1}, x_2^{p1}, \dots, x_l^{p1}]$  and  $x^{p2} = [x_1^{p2}, x_2^{p2}, \dots, x_l^{p2}]$  the offspring  $x^{o1} = [x_1^{p1}, x_2^{p1}, \dots, x_c^{p1}, x_{c+1}^{p2}, \dots, x_l^{p2}]$  and  $x^{o2} = [x_1^{p2}, x_2^{p2}, \dots, x_c^{p2}, x_{c+1}^{p1}, \dots, x_l^{p1}]$ . A generalized version of one-point crossover is *n-point crossover*. For this type of crossover operator, we choose  $n$  different crossover points and create an offspring by alternately selecting alleles from parent solutions. For uniform crossover, we decide independently for every single allele of the offspring from which parent solution it inherits the value of the allele. In most implementations, no parent is preferred and the probability of an offspring inheriting the value of an allele from a specific parent is  $p = 1/m$ , where  $m$  denotes the number of parents that are considered for recombination. For example, when two possible offspring are considered with the same probability ( $p = 1/2$ ), we could obtain as offspring  $x^{o1} = [x_1^{p1}, x_2^{p1}, x_3^{p2}, \dots, x_{l-1}^{p1}, x_l^{p2}]$  and  $x^{o2} = [x_1^{p2}, x_2^{p2}, x_3^{p1}, \dots, x_{l-1}^{p2}, x_l^{p1}]$ .

Figure 53.2 presents examples for the three crossover variants. All three recombination operators are based on the binary Hamming distance and follow (53.3) as  $d(x^{p1}, x^{p2}) \geq \max(d(x^{p1}, x^o), d(x^{p2}, x^o))$ . Therefore, the similarity between offspring and parent is not lower than between the parents.

Uniform and *n*-point crossover can be used independently of the type of decision variables (binary, integer, continuous, etc.), since these operators only exchange alleles between parents. In contrast, *intermediate recombination* operators attempt to average or blend components across multiple parents and are designed for continuous and integer problems. Given two parents  $x^{p1}$  and  $x^{p2}$ , a crossover operator known as *arithmetic crossover* [53.49] creates an offspring  $x^o$  as  $x_i^o = \alpha x_i^{p1} + (1 - \alpha)x_i^{p2}$ , where  $\alpha \in [0, 1]$ . If  $\alpha = 0.5$ , the crossover just takes the average of both parent solutions. In general, for  $m$  parents, this operator becomes  $x_i^o = \sum_{i=1}^m \alpha_i x_i^{pi}$ , where  $\sum_{i=1}^m \alpha_i = 1$ . Arithmetic crossover is based on the city-block metric. With respect to this metric, the distance between offspring and parent is smaller than the distance between the parents. Another type of crossover operator that is based on the Euclidean metric is *geometrical crossover* [53.49].

**Fig. 53.2a–c** Different crossover variants. (a) One-point crossover. (b) Two-point crossover. (c) Uniform crossover

Given two parents, an offspring is created as  $x_i^o = \sqrt{x_i^{p1} x_i^{p2}}$ . For further information on crossover operators we refer to [53.50] (binary crossover) and [53.41] (continuous crossover).

### 53.2.4 Direct Representations

If we apply search operators directly to phenotypes, it is not necessary to specify a representation and a genotype space. Then, phenotypes are the same as genotypes

$$f(x^g) : \Phi_g \rightarrow \mathbb{R}. \quad (53.4)$$

$\Phi_g$  does not exist and we have a *direct representation*. Because there is no longer an additional mapping between  $\Phi_g$  and  $\Phi_p$ , a direct representation does not change any aspect of the phenotype problem such as difficulty or metric. However, when using direct representations, we often cannot use standard search operators, but have to define problem-specific operators.

Therefore, important for the success of EAs using a direct representation is not finding a *good* representation for a specific problem, but developing proper search operators defined on phenotypes.

The definition of the variation operators are relevant for different implementations of direct representations. Since we assume that local search operators always generate neighboring solutions, the definition of a local search operator induces a metric on the genotypes. Therefore, the metric that we use on the genotype space should be chosen in such a way that new solutions that are generated by local search operators have a small distance to the old solutions and the solutions are neighbors with respect to the metric used. Furthermore, the distance between two solutions  $x \in \Phi_g$  and  $y \in \Phi_g$  should be proportional to the minimal number

of local search steps that are necessary to move from  $x$  to  $y$ . Analogously, the definition of a recombination operator also induces a metric on the search space. The metric used should guarantee that the application of a recombination operator to two solutions  $x^p \in \Phi_g$  and  $y^p \in \Phi_g$  creates a new solution  $x^o \in \Phi_g$  whose distances to the parents are not larger than the distance between the parents (53.3).

For the definition of variation operators, we should also consider that for many problems we have a natural notion of similarity between phenotypes. When we create a problem model, we often *know* which solutions are similar to each other. Such a notion of similarity should be considered for the definition of variation operators. We should design local search operators in such a way that their application creates solutions which we *view* as similar. Such a definition of local search operators ensures that neighboring phenotypes are also neighbors with respect to the metric that is induced by the search operators.

At a first glance, it seems that the use of direct representations makes life easier as direct representations release us from the challenge to design efficient representations. However, we are confronted with some problems:

- There are many phenotypes to which no standard variation operators can be applied.
- The design of high-quality problem-specific search operators is difficult.
- We cannot use EAs that only work on standard genotypes.

For indirect representations with standard genotypes, the definition of search operators is straightforward as these are usually based on the metric of the genotype space (Sects. 53.2.2 and 53.2.3). The behav-

ior of **EAs** using standard search operators is usually well studied and well understood. However, when using direct representations, standard operators can often no longer be used. Instead, problem-specific operators must be developed for each phenotype. This is difficult, as we cannot use most of our knowledge about the behavior of **EAs** using standard genotypes and standard operators.

The design of proper search operators is often demanding as phenotypes are usually not string-like but are more complicated structures like trees, schedules, time tables, or other structures (Sect. 53.2.5). In this case, phenotypes cannot be depicted as a string or in another way that is accessible to variation operators. Other representative examples are the form or shape of an object. Search operators that can be directly applied to the shape of an object are often difficult to design.

Finally, using specific variants of **EAs** like estimation of distribution algorithms (**EDAs**) becomes very difficult. These types of **EAs** do not use standard search operators that are applied to genotypes but build new solutions according to a probabilistic model of previously generated solutions [53.51–56]. These search methods were developed for a few standard genotypes (usually binary and continuous) and result in better performance than, for example, traditional simple genetic algorithms for decomposable problems [53.57, 58]. However, because direct representations with non-standard phenotypes and problem-specific search operators can hardly be implemented in **EDAs**, direct representations cannot benefit from these optimization methods.

### 53.2.5 Standard Search Operators

We provide an overview of standard search spaces and the corresponding search operators. The search spaces can either represent genotypes (indirect representation) or phenotypes (direct representation). We order the search spaces by increasing complexity. With increasing complexity, the design of search operators becomes more demanding. An alternative to designing complex search operators for complex search spaces is to introduce additional mappings that map complex search spaces to simpler ones. Then, the design of the corresponding search operators becomes easier, however, a proper design of the additional mapping (representation) becomes more important.

#### Strings and Vectors

Strings and vectors of either fixed or variable length are the most elementary search spaces. They are the most

frequently used genotype structures. Vectors allow us to represent an ordered list of decision variables and are the standard genotypes for the majority of optimization problems. Strings are appropriate for sequences of characters or patterns. Consequently, strings are suited for problems where the objects modeled are *text*, *characters*, or *patterns*.

For strings and vectors with fixed length, we can use standard local search and recombination operators (Sects. 53.2.2 and 53.2.3) that are based on the Hamming metric or the binary Hamming metric. Search operators for strings and vectors with variable length are often based on the Levenshtein distance.

#### Coordinates/Points

To represent locations in a geometric space, coordinates can be used. Coordinates can be either integer or continuous. Common examples are locations of cities or other spots on two-dimensional grids. Coordinates are appropriate for problems that work on *sites*, *positions*, or *locations*.

We can use standard local and recombination operators for continuous variables and integers, respectively. For coordinates, the Euclidean metric is often used to measure the similarity of solutions.

#### Graphs

Graphs allow us to represent relationships between arbitrary objects. Usually, the structure of a graph is described by listing its edges. An edge represents a relationship between a pair of objects. Given a graph with  $n$  nodes (objects), there are  $n(n - 1)/2$  possible edges. Using graphs is appropriate for problems that seek a *network*, *circuit*, or *relationship*.

Common genotypes for graphs are lists of edges indicating which edges are used. For example, the characteristic vector representation encodes graphs of fixed size using a binary vector of length  $n(n - 1)/2$  [53.3, Sect. 6.3]. Standard search operators for the characteristic vector representation are based on the Hamming metric as the distance between two graphs can be calculated as the number of different edges. Standard search operators can be used if there are no additional constraints.

#### Subsets

Subsets represent selections from a set of objects. Given  $n$  different objects, the number of subsets having exactly  $k$  elements is equal to  $\binom{n}{k}$ . Thus, the number of possible subsets is  $\sum_{k=0}^n \binom{n}{k} = 2^n$ . For subsets, the order of the objects does not matter. The two example subsets  $\{1, 3, 5\}$  and  $\{3, 5, 1\}$  represent the same pheno-

type solution. Local search operators that can be applied directly to subsets often either modify the objects in the subset, or increase/reduce the number of objects in one subset. Recombination operators that are directly applied to subsets are more sophisticated as no standard operators can be used. We refer to [53.59] for detailed information on their design. Subsets are often used for problems that seek a *cluster*, *collection*, *partition*, *group*, *packaging*, or *selection*.

Given  $n$  different objects, a subset of fixed size  $k$  can be represented using an integer vector  $x$  of length  $k$ , where the  $x_i$  indicate the selected objects and  $x_i \neq x_j$ , for  $i \neq j$  and  $i, j \in [1, k]$ . Then, standard local search operators can be applied if we assume that each of the  $k$  selected objects is unique. The application of recombination operators is more demanding as each subset is represented by  $k!$  different genotypes (integer vectors) and the distances between the  $k!$  different genotypes that represent the same subset are large [53.60]. Recombination operators must be designed such that the distances between offspring and parents are smaller than the distances between parents (53.3) and the recombination of two genotypes that represent the same subset always results in the same subset. For guidelines on the design of appropriate recombination operators and examples, we refer to [53.61] and [53.60].

### Permutations

A large variety of **EAs** have been developed for permutation problems as many such problems are of practical relevance but **NP**-hard (**NP**: non-deterministic polynomial-time). Permutations are orderings of items. The order of the objects is relevant for permutations. The number of permutations on a set of  $n$  elements is  $n!$ . 1-2-3 and 1-3-2 are two examples of permutations of three integer numbers  $x \in \{1, 2, 3\}$ . The traveling salesperson problem (**TSP**) is a prominent example of a permutation problem. Permutations are commonly used for problems that seek an *arrangement*, *tour*, *ordering*, or *sequence*.

The design of appropriate search operators for permutations is demanding. In many approaches, permutations are encoded using an integer genotype vector of length  $n$ , where each decision variable  $x_i$  indicates an ob-

ject and has a unique value ( $x_i \neq x_j$  for  $i \neq j$  and  $i, j \in \{1, \dots, l\}$ ). Standard recombination and mutation operators applied to such genotypes fail since the resulting solutions usually represent no permutations. Therefore, in the literature a variety of different permutation-specific variation operators have been developed. They are either based on the absolute or relative ordering of the objects in a permutation. When using the absolute ordering of objects in a permutation as the distance metric, two solutions are similar to each other if the objects have the same position in the two solutions ( $x_i^1 = x_i^2$ ). For example, 1-2-3-4 and 2-3-4-1 have a maximum absolute distance of  $d = 4$ , as the two solutions have no common absolute positions. In contrast, when using relative ordering, two solutions are similar if the sequence of objects is similar for the two solutions. For example, 1-2-3-4 and 2-3-4-1 have distance  $d = 1$  as the two permutations are shifted by one position. Based on the metric used (relative versus absolute ordering), a large variety of different recombination and local search operators have been developed. Examples are the *order crossover* [53.62], *partially mapped crossover* [53.63], *cycle crossover* [53.64], *generalized order crossover* [53.65], or *precedence preservative crossover* [53.66]. For more information on the design of such permutation-specific variation operators, we refer to [53.67, 68], and [53.60].

### Trees

Trees are used to describe hierarchical relationships between objects. Trees are a specialized variant of graphs where only one path exists between each pair of nodes. As standard search operators cannot be applied to tree structures, we either need to define problem-specific search operators that are directly applied to trees or additional genotype–phenotype mappings that map each tree to simpler genotypes where standard variation operators can be applied.

We can distinguish between trees of fixed and variable size. For trees of fixed size, we refer to [53.2]. Search operators for tree structures of variable size are at the core of *genetic programming*. They are often based on the Levenshtein distance. Further information about appropriate search operators for trees of variable size can be found in [53.69] and [53.70].

## 53.3 Problem-Specific Design of Representations and Search Operators

Jones and Forrest [53.71] assumed that the difficulty of an optimization problem is determined by how the ob-

jective values are assigned to the solutions  $x \in X$  and what metric is defined on  $X$ . They classified fitness

landscapes into three classes, straightforward, difficult, and misleading.

1. Straightforward. For such problems, the fitness of a solution is correlated with the distance to the optimal solution. With lower distance, the fitness difference to the optimal solution decreases. As the structure of the search space guides search methods towards the optimal solution such problems are usually easy for guided search methods.
2. Difficult. There is no correlation between the fitness difference and the distance to the optimal solution. The fitness values of neighboring solutions are uncorrelated and the structure of the search space provides no information about which solutions should be sampled next by the search method.
3. Misleading. The fitness difference is negatively correlated to the distance to the optimal solution. Therefore, the structure of the search space misleads a guided search method to sub-optimal solutions.

The general idea is to measure how well the metric defined on the search space fits the structure of the objective function. A high fit between metric and structure of the fitness function makes a problem easy for guided search methods.

A fundamental assumption about the application of **EAs** is that the vast majority of optimization problems that we can observe in the real world are:

- Neither misleading nor difficult,
- Have high locality (distance between solutions is correlated with their fitness difference).

We assume that misleading problems have no importance in the real world as usually optimal solutions are not isolated in the search space surrounded by only low-quality solutions. Furthermore, we assume that the metric of a search space is meaningful and, on average, the fitness differences between neighboring solutions are smaller than between randomly chosen solutions. It is only because most real-world problems are neither difficult nor misleading that guided search methods which use information about previously sampled solutions can outperform random search for real-world problems [53.2, 34].

Since we assume that high locality is a general property of real-world problems, **EAs** must ensure that their design does not destroy the high locality of a problem. If the high locality of a problem is destroyed, straightforward problems turn into difficult problems and cannot be solved better than by random search [53.2]. Therefore, **EAs** must ensure that the search operators

used fit the metric on the search space and representations have high locality; this means phenotype distances must correspond to genotype distances.

The second aspect of this section is how we can consider knowledge about problem-specific properties for the design of **EAs**. For example, we have knowledge about the character and properties of high-quality (or low-quality) solutions. Such problem-specific knowledge can be exploited by introducing a *bias* into **EAs**. The bias should consider this knowledge and, for example, concentrate search on solutions that are expected to be of high quality or avoid solutions expected to be of low quality. A bias can be considered in the representation as well as the search operator. However, **EAs** should only be biased if we have obtained some particular knowledge about an optimization problem or problem instance. If we have no knowledge about properties of a problem, we should not bias **EAs** as this will mislead the search heuristics.

Section 53.3.1 discusses how the design of **EAs** can modify the locality of a problem. To ensure guided search, the search operators must fit the problem metric. Local search operators must generate neighboring solutions and recombination operators must generate offspring where the distances between offspring and parents do not exceed the distances between parents. Section 53.3.2 focuses on the possibility of biasing **EAs**. We discuss how problem-specific construction heuristics can be used as genotype–phenotype mappings (Sect. 53.3.2) and how redundant representations affect heuristic search (Sect. 53.3.2).

### 53.3.1 High Locality

The *locality* of a problem measures how well the distances  $d(x, y)$  between any two solutions  $x, y \in X$  correspond to the difference in their fitness values  $|f(x) - f(y)|$ . Locality is high if neighboring solutions have similar fitness values and fitness differences correlate positively with distances. In contrast, the locality of a problem is low if low distances do not correspond to low differences in the fitness values. Important for the locality of a problem is the metric defined on the search space.

The performance of guided search methods is high if the locality of a problem is relatively high; this means that the structure of the fitness landscape leads search algorithms to high quality solutions [53.2]. Local search methods show especially good performance if either high-quality or low-quality solutions are grouped together in the solution space. Optimization problems

with high locality can usually be solved well using **EAs**, as all **EAs** have some kind of local search elements.

The following paragraphs provide design guidelines for search operators and representations. Search operators must fit the metric of a search space, because otherwise **EAs** show low performance as they behave like random search. A representation introduces an additional genotype–phenotype mapping. The locality of a representation describes how well the metric on the phenotype space fits to the metric on the genotype space. Low locality, which means there is a poor fit, randomizes the search and also leads to low performance of **EAs**.

### Search Operator

**EAs** rely on the concept of local search. Local search iteratively generates new solutions similar to existing ones. Local search is a reasonable and successful search approach for real-world problems, as most real-world problems have high locality and are neither misleading nor difficult. In addition, to avoid being trapped in local optima, **EAs** use diversification steps. Diversification steps randomize search and allow **EAs** to jump through the search space.

Different types of **EAs** use different concepts for controlling intensification and diversification [53.2, Chap. 5]. Local search intensifies the search as it allows incremental improvements of already found solutions. Diversification steps must be relatively rare as they usually lead to inferior solutions. When designing search operators, we must have in mind that **EAs** use local search operators as well as recombination operators for *intensifying* the search. Solutions that are generated should be similar to the existing ones. Therefore, we must ensure that search operators (local search operators as well as recombination operators) generate similar solutions and do not jump around in the search space. This can be done by ensuring that local search operators generate neighboring solutions and recombination operators generate solutions where the distances between parent and offspring are smaller or equal to the distances between parents (Sect. 53.2.3 and 53.3).

Applying search operators to solutions defines a metric on the corresponding search space. With respect to the search operators, solutions are similar to each other if only a few local search steps suffice to transform one solution into another. Therefore, when designing search operators, it is important that the metric induced by the search operators fits the problem metric. If both metrics are similar (this means a local search operator creates neighboring solutions with

respect to the problem metric), guided search will perform well as it can systematically explore promising areas of the search space.

Therefore, we should make sure that local search operators generate neighboring solutions. The fit between the problem metric and the metric induced by the search operators should be high. Then, most real-world problems, where neighboring solutions have, on average, similar fitness values, are easy to solve for **EAs**.

For real-world problems, the design or choice of proper search operators can be difficult if it is unclear what a *natural* problem metric is. We want to illustrate this issue for a scheduling problem. Given a number of tasks, we want to find an optimal schedule. There are different metrics that can be relevant for such a permutation problem. We have the choice between metrics based either on the relative or absolute ordering of the tasks (Sect. 53.2.5). The choice of the *right* problem metric depends on the properties of the scheduling problem. For example, if we want to find an optimal class schedule, usually it is more natural to use a metric based on the absolute ordering of the tasks (classes). The relative ordering of the tasks is much less important as we have fixed time slots. The situation is reversed if we want to find an optimal schedule for a paint shop. For example, when painting different cars consecutively, color changes are time-consuming as paint tools have to be cleaned before a new color can be used. Therefore, the relative ordering of the tasks (paint jobs) is important, as the tasks should be grouped together such that tasks that require the same color are painted consecutively and ordered such that the paint shop starts with the brightest colors and ends with the darkest ones.

This example makes it clear that the most *natural* problem metric does not depend on the set of possible solutions but on the character of the underlying optimization problem and fitness function. The goal is to choose a metric such that the locality of the problem is high. The same is true for the design of operators. A high-quality local search operator should generate solutions with similar fitness. Then, problems become easy to solve for **EAs**.

### Representation

Representations introduce an additional genotype–phenotype mapping and thus modify the fit between the metric on the genotype space (which is induced by the search operators used), and the original problem metric on the phenotype space. High-quality representations ensure that the metric on the genotype space fits the original problem metric. The *locality of a rep-*

representation describes how well neighboring genotypes correspond to neighboring phenotypes [53.72–76]. In contrast to the locality of a problem, which measures the fit between fitness differences and phenotype distances, the locality of a representation measures the fit between phenotype distances and genotype distances.

The use of a representation can change the difficulty of problems (Sect. 53.1.2) [53.6]. The ability of representations to change the difficulty of a problem is closely related to their locality. The locality of a representation is high if all neighboring genotypes correspond to neighboring phenotypes. In contrast, it is low if neighboring genotypes do not correspond to neighboring phenotypes. Therefore, the locality  $d_m$  of a representation can be defined as [53.3, Sect. 3.3]

$$d_m = \sum_{d_{x,y}^g = d_{\min}^g} |d_{x,y}^p - d_{\min}^p|, \quad (53.5)$$

where  $d_{x,y}^p$  is the phenotype distance between the phenotypes  $x^p$  and  $y^p$ ,  $d_{x,y}^g$  is the genotypic distance between the corresponding genotypes, and  $d_{\min}^p$  and  $d_{\min}^g$  are the minimum distances between two (neighboring) phenotypes and genotypes, respectively. Without loss of generality, we assume that  $d_{\min}^g = d_{\min}^p$ . For  $d_m = 0$ , all genotypic neighbors correspond to phenotypic neighbors and the encoding has perfect (high) locality.

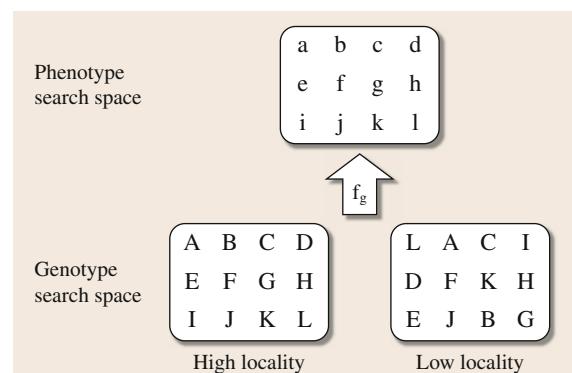

We want to emphasize that the locality of a representation depends on the representation  $f_g$  and the metrics that are defined on  $\Phi_g$  and  $\Phi_p$ .  $f_g$  alone only determines which phenotypes are represented by which genotypes and cannot be used for measuring similarities between solutions. To describe or measure the locality of a representation, a metric must be defined on  $\Phi_g$  and  $\Phi_p$ .

Figure 53.3 illustrates the difference between high-locality and low-locality representations. We assume 12 different phenotypes (a–l) and measure distances between solutions using the Euclidean metric. Each phenotype (lower case symbol) corresponds to one genotype (upper case symbol). The representation  $f_g$  has perfect (high) locality if neighboring genotypes correspond to neighboring phenotypes. Then, local search steps have the same effect in the phenotype and genotype search space.

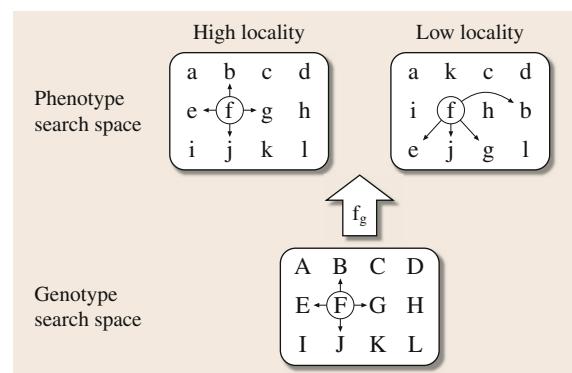

If we assume that  $f_g$  is a one-to-one mapping, every phenotype is represented by exactly one genotype and there are  $|\Phi_g|! = |\Phi_p|!$  different representations. Each of these many different representations assigns the genotypes to the phenotypes in a different way.

We want to ask how the locality of a representation influences the performance of EAs. Often, there is a *natural* problem metric describing which phenotypes are similar to each other. A representation introduces a new genotype metric based on the genotypes and search operators used. This metric can be different from the problem (phenotype) metric. Therefore, the character of search operators can be different for genotypes versus phenotypes. If the locality of a representation is high, then a search operator has the same effect on the phenotypes as on the genotypes. As a result, the original problem difficulty remains unchanged by a representation  $f_g$ . Easy (straightforward) problems remain easy and misleading problems remain misleading. Figure 53.4 (left) illustrates the effect of local search operators for high-locality representations. A local search step has the same effect on the phenotypes as on the genotypes.

For low-locality representations, the situation is different and the influence of a representation on the

**Fig. 53.3** High versus low-locality representations

**Fig. 53.4** The effect of local search operators for high versus low-locality representations

difficulty of a problem depends on its character. If a problem  $f_p$  is straightforward, a low-locality representation  $f_g$  randomizes the problem by destroying the correlation between distance and fitness and making the problem  $f = f_p(f_g(x^g))$  more difficult. When using low-locality representations, a small change in a genotype does not correspond to a small change in the phenotype, but larger changes in the phenotype are possible (Fig. 53.4, right). Therefore, when using low-locality representations, straightforward problems become, on average, difficult as low-locality representations lead to a more uncorrelated fitness landscape and heuristics can no longer extract meaningful information about the structure of the problem. Guided search becomes more difficult as many genotypic search steps do not result in a similar solution but in a random one.

Summarizing the results, low-locality representations have the same effect as using random search. Therefore, on average, straightforward problems become more difficult for guided search methods. As most real-world problems are straightforward, the use of low-locality representations makes these problems more difficult. Therefore, we strongly encourage users of **EAs** to use high-locality representations for problems of practical relevance. Of course, low-locality representations make misleading problems easier for guided search [53.3]; however, these are problems which we do not expect to meet in reality and we do not really want to solve.

For more information on the influence of the locality of representations on the performance of **EAs**, we refer the interested reader to [53.3, Sect. 3.3] and [53.2].

### 53.3.2 Biasing Search

This section discusses how to bias **EAs**. If we have some knowledge about the properties of either high-quality or low-quality solutions, we can make use of this knowledge for the design of **EAs**. For representations, we can incorporate heuristics or introduce redundant encodings and assign a larger number of genotypes to high-quality phenotypes. Search operators can be designed in such a way that they distinguish between high-quality and low-quality solution features (building blocks) and prefer the high-quality ones [53.2].

A representation or search operator is *biased* if the application of a variation operator generates some solutions in the search space with higher probability [53.12]. We can bias representations by incorporating heuristics into the genotype–phenotype mapping. Furthermore, representations can be biased if the num-

ber of genotypes exceeds the number of phenotypes. Then, representations are called *redundant* [53.77–80]. Redundant representations are biased if some phenotypes are represented by a larger number of genotypes. Analogously, search operators are biased if some solutions are generated with higher probability.

When biasing **EAs**, we must make sure that we have a priori knowledge about the problem and the bias exploits this knowledge in an appropriate way. Introducing an inappropriate or wrong bias into **EAs** would mislead search and result in low solution quality. Furthermore, we must make sure that a bias is not too strong. Using a bias can focus the search on specific areas of the search space and exclude solutions from consideration. If the bias is too strong, **EAs** can easily fail.

The following paragraphs discuss biasing representations and search operators. The next one gives an overview of how problem-specific construction heuristics can be used as genotype–phenotype mappings. Then, heuristic search varies either the input (problem space search) or the parameters (heuristic space search) of the construction heuristic. The following paragraph discusses redundant representations. Redundant representations with low locality randomize guided search and thus should not be used. Redundant representations with high locality can be biased by overrepresenting solutions similar to optimal solutions.

#### Incorporating Construction Heuristics in Representations

We focus on combining problem-specific construction heuristics with genotype–phenotype mappings. The possibility to design problem-specific representations and to incorporate relevant knowledge about the problem into the genotype–phenotype mapping by using construction heuristics is a promising line of research and is continuously discussed in the operations research and evolutionary computation communities [53.6, 22, 81–84].

Genotype–phenotype mappings map genotypes to phenotypes and can incorporate problem-specific construction heuristics. An early example of a problem-specific representation is the *ordinal representation* of [53.85], who studied the performance of genetic algorithms for the **TSP**. The ordinal representation encodes a tour (permutation of  $n$  integers) by a genotype  $x^g$  of length  $n$ , where  $x_i^g \in \{1, \dots, n-i\}$  and  $i \in \{0, \dots, n-1\}$ . For constructing a phenotype, a pre-defined permutation  $x^s$  of  $n$  integers representing the  $n$  different cities is used.  $x^s$  can be problem-specific and,

for example, consider edge weights. A phenotype (tour) is constructed from  $x^g$  by subsequently adding (starting with  $i = 0$ ) the  $x_i^g$ -th element of  $x^s$  to the phenotype (which initially contains no elements) and removing the  $x_i^g$ -th element of  $x^s$ . Problem-specific knowledge can be considered by choosing an appropriate  $x^s$  as genotypes define perturbations of  $x^s$  and using small integers for the  $x_i^g$  results in a bias of the resulting phenotypes towards  $x^s$ . For example, for  $x_i^g = 1$  ( $i \in \{0, \dots, n - 1\}$ ), the resulting phenotype is  $x^s$ .

Other early examples of problem-specific representations can be found in [53.86], where a problem-specific schedule builder was incorporated into representations for job shop scheduling problems, in [53.87] where representations that use a greedy adding heuristic for partitioning problems, and the more general *adaptive representation genetic optimization technique (ARGOT)* strategy was studied in [53.88, 89]. ARGOT dynamically changes either the structure of the genotypes or the genotype–phenotype mapping according to the progress made during search.

In parallel to, and independently from representations, Storer et al. [53.90] proposed *problem space search (PSS)* and *heuristic space search (HSS)* as approaches that also combine problem-specific heuristics with problem-independent EAs. PSS and HSS apply in each search iteration of a modern heuristic a problem-specific base heuristic  $H$  that exploits known properties of the problem. The base heuristic  $H$  should be fast and creates a phenotype from a genotype. Results presented for different applications show that this approach can lead to improved performance of EAs [53.82, 91, 92]. For PSS,  $H$  is applied to perturbed versions of the genotype. The perturbations of the genotypes are usually small and based on a definition of neighborhood in the genotype space. For HSS, in each search step of the modern heuristic, the genotypes remain unchanged, but (slightly) different variants of the base heuristic  $H$  are used. For scheduling problems, linear combinations of priority dispatching rules with different weights, or the application of different base heuristics to different parts of the genotype, have been proposed [53.91].

PSS and HSS use the same underlying concepts as problem-specific representations. The base heuristic  $H$  is equivalent to a (usually problem-specific) genotype–phenotype mapping and assigns phenotypes to genotypes. PSS performs heuristic search by modifying (perturbing) the genotypes, which is equivalent to the concept of representations originally proposed by [53.22] (for an early example, see [53.85]). HSS perturbs the base heuristic (genotype–phenotype map-

ping), which is similar to the concept of adaptive representations (for early examples, see [53.88] or [53.93]).

### Redundant Representation

We assume a combinatorial optimization problem with a finite number of phenotypes. If the size of the genotype search space is equal to the size of the phenotype search space ( $|\Phi_g| = |\Phi_p|$ ) and the representation maps all genotypes to all phenotypes (bijection), a representation cannot be biased. All solutions are represented with the same probability and a bias can only be a result of the search operator used.

The situation is different for representations where the number of genotypes exceeds the number of phenotypes. We still assume that all phenotypes are encoded by at least one genotype. Such representations are usually called (e.g., in [53.78, 94, 95], or [53.80]). Radcliffe and Surry [53.28] introduced a different notion of redundancy and distinguished between *degenerated representations*, where more than one genotype encodes one phenotype, and redundant representations where parts of the genotypes are not used for the construction of a phenotype. However, this distinction has not generally been accepted in the EA community. Therefore, we follow the majority of the literature and define encodings to be redundant if the number of genotypes exceeds the number of phenotypes (which is equivalent to the notion of degeneracy of [53.28]).

Rothlauf and Goldberg [53.80] distinguished between different types of redundant representations based on the similarity of the genotypes that are assigned to the same phenotype. A representation is defined to be *synonymously redundant* if the genotypes that are assigned to the same phenotype are similar to each other. Consequently, representations are *non-synonymously redundant* if the genotypes that are assigned to the same phenotype are not similar to each other. Therefore, the synonymity of a representation depends on the genotype and phenotype metric. Figure 53.5 illustrates the differences between synonymous and non-synonymous redundant encodings. Distances between solutions are measured using a Euclidean metric. The symbols indicate different genotypes and their corresponding phenotypes. When using synonymously redundant representations (left), genotypes that represent the same phenotype are similar to each other. When using non-synonymously redundant representations (right), genotypes that represent the same phenotype are not similar to each other but distributed over the whole search space.

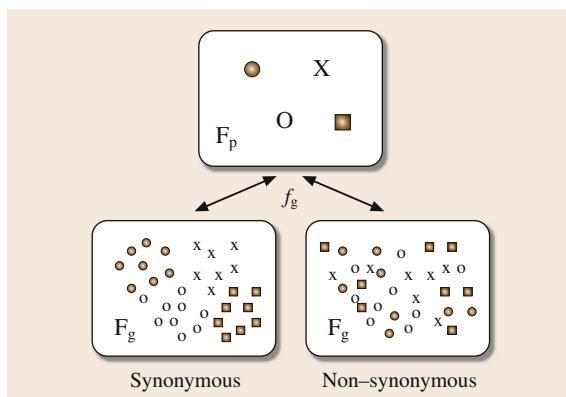

Formally, a redundant representation  $f_g$  assigns a phenotype  $x^p$  to a set of different genotypes  $x^g \in \Phi_g^{x^p}$ , where  $\forall x^g \in \Phi_g^{x^p} : f_g(x^g) = x^p$ . All genotypes  $x^g$  in the genotype set  $\Phi_g^{x^p}$  represent the same phenotype  $x^p$ . A representation is synonymously redundant if the genotype distances between all  $x^g \in \Phi_g^{x^p}$  are small for all different  $x^p$ . Therefore, if for all phenotypes the sum over the distances between all genotypes that correspond to the same phenotype

$$\sum_{x^p} \frac{1}{2} \left( \sum_{x^g \in \Phi_g^{x^p}} \sum_{y^g \in \Phi_g^{x^p}} d(x^g, y^g) \right), \quad (53.6)$$

where  $x^g \neq y^g$ , is reasonably small, a representation is called synonymously redundant.  $d(x^g, y^g)$  depends on the metric used and measures the distance between two genotypes  $x^g \in \Phi_g^{x^p}$  and  $y^g \in \Phi_g^{x^p}$ , which both represent the same phenotype  $x^p$ .

**Non-Synonymously Redundant Representations.** The synonymity of a representation can have a large influence on the performance of **EAs**. When using non-synonymously redundant representations, a local search operator can result in solutions that are phenotypically completely different from their parents. For recombination operators, the distances between offspring and parents are not necessarily smaller than the distances between parents.

Local search methods outperform random search if solutions with similar fitness are grouped together in the search space and are not scattered over the whole search space [53.25, 33–35, 96, 97]. Furthermore, problems are easy for guided search methods if distances

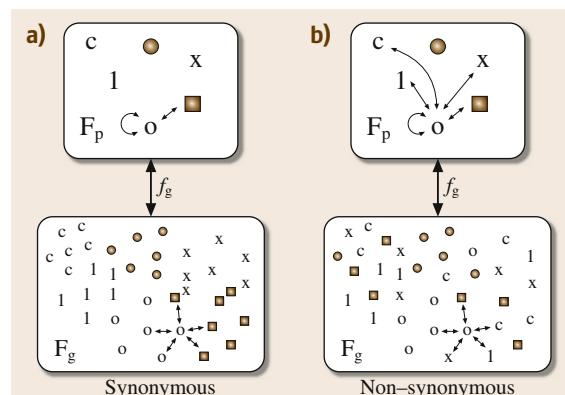

**Fig. 53.5** Synonymous versus non-synonymous redundancy

between solutions are related to corresponding fitness differences. However, non-synonymously redundant representations destroy existing correlations between solutions and their corresponding fitness values. Thus, search heuristics cannot use any information learned during the search for determining future search steps. As a result, it makes no sense for guided search approaches to search around already found high-quality genotypes and guided search algorithms become random search. A local search step does not result in a solution with similar properties but in a random solution. Analogously, recombination is not able to create new solutions with similar properties to their parents, but creates new, random solutions. Therefore, non-synonymously redundant representations have the same effect on **EAs** as low-locality representations (Sect. 53.3.1).

The use of non-synonymously redundant representations allows us to reach many different phenotypes in a single local search step (Fig. 53.6). However, increasing the *connectivity* between phenotypes results in random search and decreases the efficiency of **EAs**. As for low-locality representations, a genotype search step does not result in a similar phenotype but creates a random solution. Therefore, guided search is no longer possible but becomes random search. As a result, we obtain reduced performance of **EAs** on straightforward problems when using non-synonymously redundant representations.

On average, non-synonymously redundant representations transform straightforward (as well as misleading) problems into difficult problems where the fitness differences between two solutions are not cor-

**Fig. 53.6a,b** The effects of local search steps for (a) synonymously versus (b) non-synonymously redundant representations. The arrows indicate search steps

related to their distances. Easy problems become more difficult. Therefore, we do not recommend using non-synonymously redundant encodings. A more detailed discussion of non-synonymously redundant representations can be found in [53.3, Sect. 3.1] and [53.60].

### Bias of Synonymously Redundant Representations.

The use of synonymously redundant representations allows local search to generate neighboring solutions. Small variations of genotypes cannot result in large phenotypic changes but result either in the same or a similar phenotype (Fig. 53.6, left).

To describe relevant properties of synonymously redundant representations, we can use the *order of redundancy*,  $k_r$ , which is defined as  $k_r = \log(|\Phi_g|) / \log(|\Phi_p|)$  [53.3, Sect. 3.1].  $k_r$  measures the amount of redundant information in the encoding. Furthermore, we are especially interested in biases of synonymously redundant representations.  $r$  measures a bias and denotes the number of genotypes that represent the optimal solution. When using non-redundant representations, every phenotype is assigned to exactly one genotype ( $r = 1$ ). In general,  $1 \leq r \leq |\Phi_g| - |\Phi_p| + 1$ .

Synonymously redundant representations are unbiased (*uniformly redundant*) if each phenotype is, on average, encoded by the same number of genotypes. In contrast, encodings are biased (*non-uniformly redundant*) if some phenotypes are represented by a different number of genotypes. Rothlauf and Goldberg [53.80] studied how the bias of synonymously redundant representations influence the performance of **EAs**. If representations are uniformly redundant, unbiased search operators generate each phenotype with the same probability as for a non-redundant representation. Furthermore, variation operators have the same effect on the genotypes and phenotypes and the performance of **EAs** using a uniformly and synonymously redundant encoding is similar to non-redundant representations.

The situation is different for non-uniformly redundant encodings. The probability  $P$  of finding the correct solution depends on  $P \propto 1 - \exp(-r/2^{k_r})$  [53.3]. Therefore, uniformly redundant representations do not change the behavior of **EAs**. Only by increasing  $r$ , which means overrepresenting optimal solutions, does the performance of **EAs** increase. In contrast, the performance of **EAs** decreases if the optimal solution is underrepresented. Therefore, non-uniformly redundant representations can only be used advantageously if a priori information exists regarding optimal solutions.

For more information on redundant representations, we refer the reader to [53.80].

### Search Operators

Search operators are applied either to genotypes or phenotypes and subsequently create new solutions. Search operators can be either *biased* or *unbiased*. In the unbiased case, each solution in the search space has the same probability of being created. If some phenotypes have higher probabilities to be created by applying a search operator to a randomly chosen solution, we call this a *bias* towards those phenotypes [53.3, 98].

Using biased search operators can be helpful if some knowledge about the structure of high-quality solutions exists and the search operators are biased such that high-quality solutions are preferred. Then, the average fitness of solutions that are generated by the biased search operator is higher than randomly generated solutions or search operators without a bias. Identifying high-quality solutions is often difficult, as exact optimization methods usually need exponential effort to find optimal solutions for relevant (often NP-hard) problems, and heuristic optimization methods usually do not provide any guarantee on solution quality. Possible approaches to overcome these problems are to exactly solve small problem instances and to deduce the structure of high-quality solutions from the solutions obtained. However, this assumes that relevant properties of optimal solutions are independent from the problem size. Second, solutions of higher quality can be identified by heuristic optimization methods if we increase the time spent on the heuristic search. Although heuristic optimization methods usually do not provide any guarantee of finding optimal solutions, the probability of finding high-quality solutions increases with the time spent on the heuristics search. For an example, we refer the reader to [53.99].

Problems can occur if a bias induced by a search operator is either too strong or towards solutions that have a large distance to an optimal solution. If the bias is too strong, the diversity of a population is reduced and the individuals in a population quickly converge towards those solutions to which the search operators are biased. Then, after a few search steps, heuristic search is no longer possible. Furthermore, the performance of **EAs** decreases if a bias exists towards solutions that have a large distance to optimal solutions. The biased search operators push a population of solutions in the *wrong direction* and it is difficult for **EAs** to find optimal solutions. Therefore, biased search operators should be used with care.

Standard search operators for binary, integer, or continuous genotypes (Sect. 53.2.5) are unbiased. The situation is slightly different for standard recombination operators. Recombination operators never introduce new solution features but only recombine existing properties. Thus, once some solution features are lost in a population of solutions they can never be regained later by using recombination operators alone. Given a randomly generated and unbiased initial population of solutions, the iterative application of recombination operators can result in a random fixation of some decision variables, which reduces the of solutions that exist in a population. This effect is known as *genetic drift*. The existence of genetic drift is widely known and has been addressed in the field of population genetics [53.100–104] and also in the field of evolutionary algorithms [53.105–108].

When using more sophisticated phenotypes and direct search operators, identifying bias of search operators may be difficult. For example, in standard approaches, programs and syntactical expressions are encoded as trees of variable size. Daida et al. [53.109] showed that the two standard search operators in ge-

netic programming (sub-tree swapping crossover and sub-tree mutation) are biased as they do not effectively search all tree shapes. In particular, very full or very narrow tree solutions are extraordinarily difficult to find, even when the fitness function provides good guidance to the optimum solutions. Therefore, genetic programming approaches will perform poorly on problems where optimal solutions require full or narrow trees. Furthermore, since the search operators do not find solutions that are at both ends of this *fullness* spectrum, problems may arise if we use those search operators to solve problems whose solutions are restricted to a particular shape, of whatever degree of fullness. Hoai et al. [53.110] studied approaches to overcome these problems and introduced a new tree-based representation and local insertion and deletion search operators with a lower bias.

In general, the bias of search operators can be measured by comparing the properties of randomly generated solutions with solutions that are created by subsequent applications of search operators. Examples of how to analyze the bias of search operators can be found in [53.2].

## 53.4 Summary and Conclusions

This chapter discusses the design of representations and search operators. Representations and search operators cannot be designed independently of each other, as together they define the structure of the search space. Section 53.1 summarized the benefits of representations and gave an overview of standard genotypes. Section 53.2 reviewed design guidelines for local, as well as recombination operators and gave an overview of standard search operators. Section 53.3 discussed possibilities for a problem-specific design of representations and search operators.

Representations and search operators should have high locality; this means that applying a local search operator to a genotype should result in a neighboring phenotype. If we have some knowledge about the properties of high-quality solutions, we can bias evolutionary algorithms by either incorporating problem-specific heuristics in the representation, using biased representations, or biased search operators.

For problems of practical relevance, we assume that the metric of a search space is meaningful and, on average, the fitness differences between neighboring solutions are smaller than between randomly chosen solutions. Search operators and representations should be

designed in such a way that they fit the metric of the search space. If local as well as recombination-based search operators are not able to generate similar solutions, intensification of search is not possible, and **EAs** behave like random search. For a representation which introduces an additional genotype–phenotype mapping, we must make sure that it does not alter the character of the search operators. Therefore, its locality must be high; this means that the phenotype metric must fit the genotype metric. Low locality of a representation randomizes the search and leads to low performance of evolutionary algorithms.

There is a general trade-off between the effectiveness and application range of optimization methods. Usually, the more problems that can be solved with one particular optimization method, the lower its resulting average performance. Therefore, standard **EAs** that are not problem-specific often only work for small or toy problems. As the problem becomes larger and more realistic, performance degrades. To improve the performance for selected optimization problems, we must design them in a more problem-specific way. By assuming that most problems in the real world have high locality, **EAs** already exploit a specific property

of problems, namely their high locality. We can further increase the performance of EAs if we have some idea about properties of high-quality solutions. Such problem-specific knowledge can be exploited by intro-

ducing a bias into EAs. The bias should consider this knowledge and, for example, concentrate search on solutions that are expected to be of high quality or avoid solutions expected to be of low quality.

# 54. Stochastic Local Search Algorithms: An Overview

Holger H. Hoos, Thomas Stützle

In this chapter, we give an overview of the main concepts underlying the stochastic local search (**SLS**) framework and outline some of the most relevant **SLS** techniques. We also discuss some major recent research directions in the area of stochastic local search. The remainder of this chapter is structured as follows. In Sect. 54.1, we situate the notion of **SLS** within the broader context of fundamental search paradigms and briefly review the definition of an **SLS** algorithm. In Sect. 54.2, we summarize the main issues and trends in the design of greedy constructive and iterative improvement algorithms, while in Sects. 54.3–54.5, we provide a concise overview of some of the most widely used simple, hybrid, and population-based **SLS** methods. Finally, in Sect. 54.6, we discuss some recent topics of interest, such as the systematic design of **SLS** algorithms and methods for the automatic configuration of **SLS** algorithms.

Stochastic local search (**SLS**) algorithms are the method of choice for solving computationally hard decision and optimization problems from a wide range of areas, including computing science, operations research, engineering, chemistry, biology and physics. **SLS** comprises a spectrum of techniques ranging from simple constructive and iterative improvement procedures to more complex methods, such as simulated annealing (**SA**), iterated local search or evolutionary algorithms (**EAs**). As evident from the term *stochastic* local search, randomization can, and often does, play a prominent role in these methods. Randomized choices may be used in the generation of initial solutions or in the decision which of several possible

search steps to perform next – sometimes merely to break ties between equivalent alternatives, and sometimes to heuristically and probabilistically select from large and diverse sets of possible candidates. Judicious use of randomization can arguably simplify algorithm design and help achieve robust algorithm behavior.

The concept of an **SLS algorithm** has been defined formally [54.1] and not only provides a unifying framework for many different types of algorithms, including the previously mentioned constructive and iterative improvement procedures, but also provides a wide range of more complex search methods commonly known as metaheuristics.

Greedy constructive and iterative improvement procedures are important **SLS** algorithms, since they typically serve as building blocks for more complex **SLS** algorithms, whose performance critically depends on the design choices and fine tuning of these underlying components. Greedy constructive algorithms and iterative improvement procedures terminate naturally when a complete solution has been generated or a local optimum of a given evaluation function is reached, respectively. One possible way to obtain better solutions is to restart these basic **SLS** procedures from randomly chosen initial search positions. However, this approach has shown to be relatively ineffective in practice for reasonably sized problem instances (and it breaks down for large instances [54.2]).

To overcome these limitations, over the last decades, a large number of more sophisticated, general-purpose **SLS** methods [54.1] have been introduced; these are often called metaheuristics [54.3], since they are based on higher level schemes for controlling one or more subsidiary heuristic search procedures. We divide these general-purpose **SLS** methods into three broad classes: simple, hybrid and population-based **SLS** methods. Simple **SLS** methods typically use one neighborhood relation during the search and either modify the acceptance criterion for search steps, allowing to occasionally accept worsening steps, or modify the evaluation function that is used during the local search process. Examples of simple **SLS** methods include **SA** [54.4, 5] and (simple) tabu search [54.6–9]. A number of **SLS** methods combine different types of search steps – for example, construction steps and perturbative local search steps – or introduce occasional larger modifications into current candidate solutions, to provide appropriate starting points for subsequent iterative improvement search. Examples of such hy-

brid **SLS** methods include greedy randomized adaptive search procedures (**GRASP**) [54.10] and iterated local search [54.11]. Finally, several **SLS** methods maintain and manipulate at each iteration a set, or population, of candidate solutions, which provides a natural way of increasing search diversification. Examples of such population-based **SLS** methods include **EAs** [54.12–15], scatter search [54.16, 17] and ant colony optimization [54.18–20].

Our classification into simple, hybrid and population-based **SLS** methods is not the only possible one, and certain **SLS** algorithms could be seen as belonging to more than one category. For example, many population-based **SLS** methods are also hybrid, as they use different search operators or combine the manipulation of the population of candidate solutions with iterative improvement on members of the population to achieve increased performance. In fact, there is an increasing trend to design and apply **SLS** algorithms that are not merely based on a single, well-established general-purpose **SLS** method, but rather combine flexibly elements of different **SLS** methods or incorporate mechanisms taken from systematic search algorithms, such as branch and bound or dynamic programming. The conceptual framework of **SLS** naturally accommodates this development, and the composition of more complex **SLS** algorithms from conceptually simpler components is explicitly supported, for example, by the concept of generalized local search machines [54.1]. In this context, methodological issues concerning the engineering of **SLS** algorithms [54.21, 22] are increasingly gaining importance. Similarly, the exploitation of automatic algorithm configuration techniques and, more generally, the programming by optimization paradigm [54.23] enable the systematic development of high-performance **SLS** algorithms.

## 54.1 The Nature and Concept of SLS

Computational approaches for the solution of hard, combinatorial problems can all be viewed as performing some form of search. Essentially, search algorithms generate and evaluate candidate solutions for the problem instance at hand. For combinatorial decision problems, the evaluation of a candidate solution requires to check whether the candidate solution is a feasible solution satisfying all given constraints; for combinatorial optimization problems, it involves computing the value of the given objective function. For NP-complete decision problems and NP-equivalent optimization prob-

lems, even the most efficient algorithms known to date require running time exponential in the instance size in the worst case, while candidate solutions can be evaluated in polynomial time.

A candidate solution for an instance of a combinatorial problem is generally composed of *solution components*. Consider, for example, the well-known traveling salesperson problem (**TSP**). In the **TSP**, one is given a weighted, fully connected graph  $G = (V, E, w)$ , where  $V = \{v_1, v_2, \dots, v_n\}$  is the set of  $|V| = n$  vertices,  $E \subset V \times V$  is the set of edges that fully connects the

graph, and  $w : E \mapsto \mathbb{R}_0^+$  is a function that assigns to each edge  $e \in E$  a nonnegative weight  $w(e)$ . The objective is to find a minimum-weight Hamiltonian cycle in  $G$ . A candidate solution for a **TSP** instance can be represented by a permutation  $\pi = (\pi(1), \pi(2), \dots, \pi(n))$  of the vertex indices, and the objective function  $w$  is given as

$$\begin{aligned} w(\pi) := & w(v_{\pi(n)}, v_{\pi(1)}) \\ & + \sum_{i=1}^{n-1} w(v_{\pi(i)}, v_{\pi(i+1)}). \end{aligned} \quad (54.1)$$

In the **TSP**, a (complete) candidate solution, commonly also called a tour, can be seen as consisting of  $n$  out of the  $n \cdot (n - 1)$  possible edges, and each edge represents a solution component.

Any given tour can be modified by removing two edges and introducing two unique new edges such that another valid tour is obtained. This modification is an example of a *perturbation* of a complete candidate solution, and we refer to search algorithms that make systematic use of such solution modifications as *perturbative search methods*. In practice, such perturbative search methods iteratively modify a current candidate solution according to some rule, and this process ends when a given termination criterion is met.

Perturbative search methods start from some complete candidate solution. The task of generating such candidate solutions is commonly accomplished by *constructive search methods* or *construction heuristics*. Constructive search methods iteratively extend an initially *empty* candidate solution by one or several solution components until a complete candidate solution is obtained. Constructive search methods can thus be seen as operating in a search space of *partial candidate solutions*. An example of a constructive search method is the nearest neighbor heuristic for the **TSP**. An initial vertex is chosen randomly, and at each construction step, the nearest neighbor heuristic follows a minimal weight edge to one of the vertices that have not yet been visited. These steps are iterated until all vertices have been visited, and the tour is completed by returning to the initial vertex.

Generally speaking, local search algorithms start at some initial search position and iteratively move, based on local information, from the current position to neighboring positions in the search space. Both perturbative and constructive search methods match this general description. While in the literature, the term local search is mostly used for perturbative search methods, it also

applies to constructive search methods: A partial solution corresponds to a position in the search space of partial candidate solutions, and the neighbors of a partial solutions are obtained by extending it with one or more solution components. In fact, there are a number of well-known generic **SLS** methods, such as **GRASP**, iterated greedy and ant colony optimization, that are based on constructive local search.

Many local search algorithms use randomized decisions, for example, for generating initial solutions or when determining search steps. We therefore refer to such methods as stochastic local search (**SLS**) *algorithms*. The following components need to be specified to define an **SLS** algorithm (for a formal definition, we refer to Chap. 1 of [54.1]).

- *Search space* – comprises the set of *candidate solutions* (or *search positions*) for the given problem instance.
- *Solution set* – consists of the search positions that are considered to be solutions of the given problem instance. In the case of decision problems, the solution set comprises all feasible candidate solutions; in the case of optimization problems, the solution set typically comprises all optimal feasible candidate solutions.
- *Neighborhood relation* – specifies the direct neighbors of each candidate solution  $s$ , i.e., the search positions that can be reached from  $s$  in a single search step of the **SLS** algorithm.
- *Memory states* – hold additional information about the search beyond the search position. If an algorithm is memoryless, the memory may consist of a single, constant state.
- *Initialization function* – specifies the search initialization in the form of a probability distribution over initial search positions and memory states.
- *Step function* – determines the computation of search steps by mapping each search position and memory state to a probability distribution over its neighboring search positions and memory states.
- *Termination predicate* – used to decide search termination based on the current search position and memory state.

The formal definition of an **SLS** algorithm specifies the initialization function, the step function, and the termination predicate as probability distributions, which the algorithm samples at each step during any given run. In practice, however, the initialization function, the step function, and the termination predicate

will be specified by procedures, and the corresponding probability distributions are only implicitly defined. Note that the definition of an **SLS** algorithm is general enough to include deterministic local search algorithms. In fact, formally we can describe deterministic local search algorithms as special cases of **SLS** algorithms – deterministic decisions can be modeled using degenerate probability distributions (Dirac delta).

The working principle of an **SLS** algorithm is then as follows. The search process starts from some initial search state that is generated by the initialization function. While some termination criterion is not satisfied, search steps are performed according to the step function. In the case of optimization problems, the **SLS** algorithm keeps track of the best solution found so far, which is then returned upon termination of the algorithm. In the case of decision problems, the **SLS** algorithm typically stops as soon as a (feasible) solution is found or another termination criterion is satisfied.

In all but the simplest cases, the search process is guided by an *evaluation function*, which measures the quality of candidate solutions. The efficacy of this guidance depends on the properties of the evaluation function and the way in which it is integrated into the search process. Evaluation functions are generally problem specific. For many optimization problems, the objective function given by the problem definition is used; however, different evaluation functions can sometimes provide better guidance, for example, in the sense of approximation guarantees [54.24]. In decision problems, an appropriate evaluation function has to be defined by the algorithm designer. Often, the objective function used for optimization variants of the decision problem can provide useful guidance. For example, for the satisfiability problem in propositional logic (**SAT**), the objective function of MAX-SAT, which, in a nutshell, counts the number of constraint violations, provides effective guidance. Some **SLS** methods, such as dynamic local search (briefly discussed in Sect. 54.3), modify the evaluation function during the search process.

The general concept of **SLS** algorithms, as introduced above and discussed in depth by *Hoos* and *Stützle* [54.1], provides a unified view of constructive and perturbative local search techniques that range from rather simplistic greedy constructive heuristics and iterative improvement algorithms to rather complex hybrid and population-based **SLS** methods. Population-based algorithms, which manipulate sets of candidate solutions at each iteration, fall under the definition of an **SLS** algorithm by considering search positions consist-

ing of sets of candidate solutions. In this case, the step function also operates on sets of candidate solutions for the given problem instance. For example, in the case of typical **EAs**, recombination, mutation, and selection can all be modeled as operations on sets of candidate solutions, which are formally parts of a single-step function used for mapping one generation to the next.

It is instructive to contrast the concept of an **SLS** algorithm with that of a metaheuristic. Metaheuristics have been described as heuristics that are *superimposed on another heuristic* [54.6], a [54.25]:

*master strategy that guides and modifies other heuristics to produce solutions beyond those that are normally generated in a quest for local optimality,*

as [54.20]:

*a set of algorithmic concepts that can be used to define heuristic methods applicable to a wide set of different problems,*

and as [54.26]:

*a high-level problem-independent algorithmic framework that provides a set of guidelines or strategies to develop heuristic optimization algorithms.*

However, the term metaheuristic [54.26]:

*is also used to refer to a problem-specific implementation of a heuristic optimization algorithm according to the guidelines expressed in such a framework.*

As is evident from these characterizations, there is no formal definition of the term metaheuristic, and its precise meaning has evolved over time. The term metaheuristic is commonly used to refer to the high-level guidance strategies that in many occasions are used to extend underlying greedy constructive or perturbative search procedures. Hence, the scope of the term metaheuristic differs from that of an **SLS** algorithm; it comprises what can be similarly loosely characterized as general-purpose **SLS** methods, but extends naturally to higher-level search strategies involving paradigms other than **SLS**, such as systematic search methods based on backtracking.

Conversely, the term metaheuristic is usually not applied to simple **SLS** procedures (such as random

sampling, random walk and iterative improvement), nor to problem-specific **SLS** algorithms with provable properties. Therefore, there are **SLS** algorithms based on metaheuristics (such as ant colony optimization, iterated local search or **EAs** for various problems), **SLS** algorithms that are not metaheuristics (such as 2-opt for the **TSP** or conflict-directed random walk for **SAT**) and metaheuristics that are not based on **SLS** (such as various branch and bound

methods and hybrids between systematic and local search).

Because the notion of an **SLS** algorithm explicitly refers to aspects that are not related to the high-level guidance of the search process, such as the choice of a neighborhood relation, evaluation function and termination predicate, research on **SLS** also covers the design, implementation and analysis of these more problem-specific components.

## 54.2 Greedy Construction Heuristics and Iterative Improvement

The main **SLS** techniques underlying more complex **SLS** methods (or metaheuristics) comprise (greedy) constructive search and iterative improvement algorithms. In the following, we discuss the main principles and choices underlying these methods.

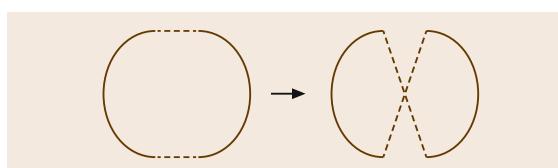

Constructive search procedures (or construction heuristics) typically evaluate at each construction step the quality of the available solution components based on a heuristic function. *Greedy construction heuristics* choose to add at each step a solution component with best heuristic value, breaking ties either randomly or by means of a secondary heuristic function. For several polynomially solvable problems, such as the minimum spanning tree problem, greedy construction heuristics (for example, Kruskal's algorithm) are guaranteed to produce optimal solutions [54.27]; unfortunately, for NP-hard problems, this is generally not the case, due to the myopic decisions taken during solution construction.

A useful distinction can be made between static and adaptive construction heuristics. In *static* construction heuristics, the heuristic values associated with solution components are precomputed before the actual construction process is executed and remain unchanged throughout. In *adaptive* construction heuristics, the heuristic values are recomputed at each construction step to take into account the impact of the current par-

tial solution. Adaptive construction heuristics tend to be more accurate and result in better quality candidate solutions than static heuristics, but they are also computationally more expensive.

Construction heuristics are often used to provide good initial candidate solutions for perturbative local search algorithms. One of the most basic **SLS** methods is to iteratively improve a candidate solution for a given problem instance. Such an *iterative improvement* algorithm starts from some initial search position and iteratively replaces the current candidate solution  $s$  by an improving neighboring candidate solution  $s'$ . The local search is terminated once no improving neighbor is available, that is,  $\forall s' \in N(s) : g(s) \leq g(s')$ , where  $g(\cdot)$  is the evaluation function to be minimized, and  $N(s)$  denotes the set of neighbors of  $s$ . In the literature, iterated improvement algorithms are also referred to as *iterated descent* or (in the case of maximization problems) *hill-climbing procedures*.

Neighborhoods are problem specific, and it is generally difficult to predict a priori which of several possible neighborhoods results in best performance. However, for most problems, standard neighborhoods exist. Under the  $k$ -exchange neighborhood, two candidate solutions are neighbors if they differ by at most  $k$  solution components. An example is the 2-exchange neighborhood for the **TSP**, where two tours are neighbors if they differ by a pair of edges. Figure 54.1 illustrates a move in this neighborhood. In a  $k$ -exchange neighborhood, each candidate solution has  $\mathcal{O}(n^k)$  direct neighbors, where  $n$  is the number of solution components in each candidate solution. Thus, the neighborhood size is exponential in  $k$ , as is the time to identify improving neighbors. While using larger neighborhoods typically makes it possible to reach better solutions, finding those solutions also takes more time. In other words, there is a tradeoff between the quality of the local optima

**Fig. 54.1** A 2-exchange move for the symmetric **TSP**. Note that the pair of edges to be introduced is uniquely determined to ensure that the neighbor is again a tour

reachable by an iterative improvement algorithm and its run time. In practice, neighborhoods that involve a quadratic or cubic time-complexity may already result in prohibitive computation times for large problem instances.

The overall time-complexity of searching a given neighborhood is determined by its size and the cost of evaluating each neighbor. The power of local search crucially relies on the fact that *caching and incremental updating techniques* can significantly reduce the cost of evaluating neighbors compared to computing the respective evaluation function values from scratch. For example, the quality of a 2-exchange neighbor of a tour for a **TSP** instance with  $n$  vertices can be computed from the quality of the current tour by subtracting and adding two edge weights (that is, two numbers) each; computing the weight of such a tour from scratch, on the other hand, requires  $n$  additions. Sometimes, to render the computation of the incremental updates as efficient as possible, additional data structures need to be implemented, but the net effect is often a very large reduction in computational effort.

A second important technique for reducing the time-complexity of evaluating a given neighborhood is based on the idea of excluding from consideration neighbors that are unlikely or provably unable to lead to improvements. These *neighborhoods pruning techniques* play a crucial role in many high-performance **SLS** algorithms. Examples of such pruning techniques are the fixed radius searches and nearest neighbors lists used for the **TSP** [54.28–30], the use of so-called *don't look bits* [54.28], as well as reduced neighborhoods for the job-shop scheduling problem [54.31] and pre-tests for search steps, as done for the single machine total weighted tardiness problem [54.32].

The speed and performance of iterative improvement algorithms also depends on the mechanism used to determine search steps, the so-called *pivoting rule* [54.33]. *Iterative best improvement* chooses at each step a neighboring candidate solution that mostly improves the evaluation function value. Any ties that occur can be broken either randomly, according to the order in which the neighborhood is searched, or based on a secondary criterion (as in [54.34]). In order to find a most improving neighbors, iterative best improvement needs to examine the entire neighborhood in each step. *Iterative first improvement*, in contrast, examines the neighborhood in some given order and moves to the first improving neighboring candidate solution found during this neighborhood scan. Iterative first improvement applies improving search steps earlier than iterative best

improvement, but the amount of improvement achieved in each step tends to be smaller; therefore, it usually requires more improvement steps to reach a local optimum. If a candidate solution is a local optimum, first-and best-improvement algorithms detect this only by inspecting the entire neighborhoods of that solution; don't look bits [54.28, 29] offer a particularly useful mechanism for reducing the time required by this final check, the so-called check-out time.

Interestingly, the local optimum found by iterative first improvement depends on the order in which the neighborhood is examined. This property can be exploited by using a random order for scanning the neighborhood, and repeated runs of random-order first improvement algorithms can identify very different local optima, even if each run is started from the same initial position [54.1, Sect. 2.1]. Thus, the search process in random-order first improvement is more diversified than in the first improvement algorithms that scan local neighborhoods in fixed order.

The notion of local optimality is defined with respect to a specific neighborhood. Thus, changing the neighborhood during the local search process may provide an effective means for escaping from poor quality local optima, and offers the opportunity to benefit from the advantages of large neighborhoods without incurring the computational burden associated with using them exclusively. In the context of iterative improvement algorithms, this idea forms the basis of *variable neighborhood descent (VND)*, a variant of a general-purpose **SLS** method known as variable neighborhood search (**VNS**) [54.35, 36]. **VND** uses a sequence of neighborhoods  $N_1, N_2, \dots, N_k$ ; this sequence is typically ordered according to increasing neighborhood size or increasing time complexity of searching the neighborhoods. **VND** starts by using the first neighborhood,  $N_1$ , until a local optimum is reached. Every time the exploration of a neighborhood  $N_i$  does not identify an improving local search step, that is, a local optimum w.r.t. neighborhood  $N_i$  is found, **VND** switches to the next neighborhood,  $N_{i+1}$  in the given sequence. Whenever an improving move has been made in a neighborhood  $N_i$ , **VND** switches back to  $N_1$  and continues using the subsequent neighborhoods,  $N_2$  etc., from there. The search is terminated when a local optimum w.r.t.  $N_k$  has been reached. The central idea of this scheme is to use small neighborhoods whenever possible, since they allow for the most efficient local search process. The **VND** scheme typically results in a significant reduction of computation time when compared to an iterative improvement algorithm that uses the largest

neighborhood only. **VND** typically finds high-quality local optima, because upon termination, the resulting candidate solution is locally optimal with respect to all  $k$  neighborhoods examined.

Finally, recent years have seen an explosion in the development of iterative improvement methods that exploit *very large scale neighborhood*, whose size is typically exponential in the size of the given problem instance [54.37]. In fact, there are two main approaches to searching these neighborhoods. The first is to perform a heuristic search in the neighborhood, since an exact search would be computationally too demanding. This idea forms the basis of variable-depth search algorithms, where the number of solution components that are modified in each step is not determined a priori. Interestingly, the two best-known variable-depth search algorithms, the *Kernighan–Lin* algorithm for graph partitioning [54.38] and the *Lin–*

*Kernighan* algorithm for the **TSP** [54.39], have been devised about in the early 1970s, a fact that illustrates the lasting interest in these types of methods. The more recent concept of ejection chains [54.40] is related to variable-depth search. Another interesting approach is to devise neighborhoods with a special structure that allows them to be searched either in polynomial time or at least very efficiently in practice [54.37, 41–43]. This is the central idea behind many recent developments in very large scale neighborhoods, which include techniques such as Dynasearch [54.32, 44] and cyclic exchange neighborhoods [54.45, 46]. As a result of these research efforts, current state-of-the-art methods for a variety of combinatorial problems such as the **TSP** [54.47] or the single machine total weighted tardiness problem [54.48] rely on iterative improvement algorithms based on very large scale neighborhoods.

## 54.3 Simple SLS Methods

Iterative improvement algorithms accept only improving neighbors as new current candidate solutions, and they terminate when encountering a local optimum. To allow the search process to progress beyond local optima, many **SLS** methods permit moves to worsening neighbors. We refer to the methods discussed in the following as *simple SLS* methods, because they essentially only use one type of search steps, in a single, fixed neighborhood relation.

### 54.3.1 Randomized Iterative Improvement

The key idea behind randomized iterative improvement (**RII**) is to occasionally perform moves to random neighboring candidate solutions irrespective of their evaluation function value. The simplest way of implementing this idea is to apply, with a given probability  $w_p$ , a so-called *uninformed random walk* step, which chooses a neighbor of the current candidate solution uniformly at random, while with probability  $1 - w_p$ , an improvement step is performed. Often, the improvement step will correspond to one iteration of a best improvement procedure. The parameter  $w_p$  is referred to as *walk probability* or, simply, *noise parameter*. **RII** algorithms have the property that they can perform arbitrarily long sequences of random walk steps; the length of these sequences (i.e., the number of consecutive random walk steps) follows a geometric distribution

with parameter  $w_p$ . This allows effective escapes from local optima and renders **RII** probabilistically approximately complete [54.1, Sect. 4.1]. A main advantage of **RII** is ease of implementation – often, only a few additional lines of code are required to extend an iterative improvement procedure to an **RII** procedure – and its behavior is effectively controlled by a single parameter.

**RII** algorithms have been shown to perform quite well in a number of applications. For example, in the 1990s, minor variations of **RII**, in which random walk steps are determined based on the status of constraint violations rather than chosen uniformly at random, have been *state of the art* for solving the **SAT** [54.49, 50] and other constraint satisfaction problems [54.51]. Due to their simplicity, **RII** algorithms also facilitate theoretical analyses, including characterization of performance in dependence of parameter settings [54.52].

### 54.3.2 Probabilistic Iterative Improvement

Instead of accepting worsening search steps regardless of the amount of deterioration in evaluation function value they caused (as is the case for random walk steps), it may be preferable to have the probability of acceptance depend on the change of the evaluation function value incurred. This is the key idea underlying probabilistic iterative improvement (**PII**). Unlike **RII**,

each step of **PII** involves two phases: first, a neighboring candidate solution  $s' \in N(s)$  is selected uniformly at random (proposal mechanism); then, a probabilistic decision is made whether to accept  $s'$  as the new search position (acceptance test). For minimization problems, the acceptance probability is often based on the *Metropolis condition* and defined as

$$p_{\text{accept}}(T, s, s') := \begin{cases} 1 & \text{if } g(s') < g(s) \\ \exp\left(\frac{g(s) - g(s')}{T}\right) & \text{otherwise,} \end{cases} \quad (54.2)$$

where  $p_{\text{accept}}(T, s, s')$  is the acceptance probability,  $g$  is the evaluation function to be minimized, and  $T$  is a parameter that influences the probability of accepting a worsening search step. **PII** is closely related to simulated annealing (**SA**), discussed next; in fact, when using the acceptance mechanism given above, **PII** is equivalent to constant-temperature **SA**. In light of this connection, parameter  $T$  is also called *temperature*. For various applications, such **PII** procedures have been shown to perform quite well, provided that  $T$  is chosen carefully [54.53, 54]. It is worth noting that in the limit for  $T = 0$ , **PII** effectively turns into an iterative improvement procedure (i.e., never accepts worsening steps), while for  $T = \infty$ , it performs a uniform random walk.

### 54.3.3 Simulated Annealing

Simulated annealing (**SA**) [54.4, 5] is similar to **PII**, except that the parameter  $T$  is modified at run time. Following the analogy of the physical annealing of solid materials (e.g., metals and glass), which inspired **SA**, the temperature  $T$  is initially set to some high value and then gradually decreased. At the beginning of the search process, high temperature values result in relatively high probabilities of accepting worsening candidate solutions. As the temperature is decreased, the search process becomes increasingly greedy; for very low settings of the temperature, almost only improving neighbors or neighbors with evaluation function value equal to the current candidate solution are accepted.

Standard **SA** algorithms iterate over the same two stage process as **PII**, typically using uniform sampling (with or without replacement) from the neighborhood as a proposal mechanism and a parameter-

ized acceptance test based on the Metropolis condition (54.2) [54.4, 5]. The modification of temperature  $T$  is managed by a so-called *annealing (or cooling) schedule*, which is a function that determines the temperature value at each search step. One of the most common choices is a geometric cooling schedule, defined by an initial temperature,  $T_0$ , a parameter  $\alpha$  between 0 and 1, and a value  $k$ , called the temperature length, which defines the number of candidate solutions that are proposed at each fixed value of the temperature; every  $k$  steps, the temperature is updated as  $T := \alpha \cdot T$ . Important parameters of **SA** are often determined based on characteristics of the problem instance to be solved. For example, the initial temperature may be based on statistics derived from an initial, short random walk, the temperature length may be set to a multiple of the neighborhood size, and the search process may be terminated when the frequency with which proposed search steps are accepted falls below a given threshold.

**SA** is one of the oldest and most studied **SLS** methods. It has been applied to a very broad range of computational problems, and many types of annealing schedules, proposal mechanisms, and acceptance tests have been investigated. **SA** has also been subject to a substantial amount of theoretical analysis, which has yielded various convergence results. For more details on **SA**, we refer to [54.55, 56].

### 54.3.4 Tabu Search

Tabu search (**TS**) differs significantly from the previously discussed **SLS** methods, in that it makes a direct and systematic use of memory to direct the search process [54.25]. In its most basic form, which is also called *simple tabu search*, **TS** expands an iterative improvement procedure with a short-term memory to prevent the local search process from returning to recently visited search positions. Instead of memorizing complete candidate solutions and forbidding these explicitly, **TS** usually associates a tabu status with specific solution components. In the latter case, **TS** stores for each solution component the time (i.e., the iteration number) at which it was last modified. Each solution component is then considered as potentially tabu if the difference between the stored iteration number and the current iteration number is larger than the value of a parameter called *tabu tenure* (or tabu list length). The tabu status of a local search step is then determined based on specific tabu criteria, which are a function of the tabu status of solution components that are affected by it. One ef-

fect is that once a search step has been performed, it is tabu in that it cannot be reversed for a certain number of iterations.

Seen from a neighborhood perspective, **TS** dynamically restricts the set of neighbors permissible at each local search step by excluding neighbors that are currently tabu. Since the tabu mechanism through prohibition of solution components is quite restrictive, many simple **TS** algorithms use an *aspiration criterion*, which overrides the tabu status of neighbors if specific conditions are satisfied; for example, if a local search step leads to a new best solution, aspiration allows it to be accepted regardless of its tabu status.

As an example, consider a simple **TS** algorithm for the **TSP**, based on the 2-exchange neighborhood. Edges that are removed (or introduced) by a 2-exchange step may then not be reintroduced into (or removed from) the current tour for  $tt$  search steps, where  $tt$  is the tabu tenure.

For several problems, even simple **TS** algorithms have been shown to perform quite well. However, the performance of **TS** strongly depends on the tabu tenure setting. To avoid the difficulty of finding fixed settings suitable for a given problem, mechanisms such as reactive tabu search [54.57] have been devised to adapt the tabu tenure at run time. Simple **TS** algorithms can be improved in many different ways. In particular, various mechanisms have been developed that make use of intermediate-term and long-term memory to further enhance the performance of simple **TS**. For a detailed description of such techniques, which aim either at intensifying the search in specific areas of the search space or at diversifying the search to explore unvisited search space regions, we refer to the book by *Glover and Laguna* [54.25].

### 54.3.5 Dynamic Local Search

In contrast to the *simple SLS* methods discussed so far, dynamic local search (**DLS**) does not accept worsening search steps, but rather modifies the evaluation function during the search in order to escape from local optima. These modifications of the evaluation function  $g$  are commonly triggered whenever the underlying local search algorithm, typically an iterative improvement procedure, has reached a locally optimal solution with respect to  $g'$ , the current evaluation function. Next, the evaluation function is modified and the subsidiary local search algorithm is run until a local optimum (with respect to the new  $g'$ ) is encountered. These local search phases and evaluation function updates are

iterated until some termination criterion is met (see Algorithm 54.1).

---

#### Algorithm 54.1 High-level outline of dynamic local search

```

Dynamic local search (DLS):
determine initial candidate solution  $s$ 
initialize penalties
while termination criterion is not satisfied do
    compute modified evaluation function  $g'$ 
        from  $g$  and penalties
    perform subsidiary local search on  $s$  using  $g'$ 
    update penalties based on  $s$ 
end while
```

---

The modified evaluation function  $g'$  is typically computed as the sum of the original evaluation function and penalties associated with each solution component, that is

$$g'(s) := g(s) + \sum_{i \in SC(s)} \text{penalty}(i), \quad (54.3)$$

where  $g$  is the original evaluation function,  $SC(s)$  is the set of solution components of candidate solution  $s$ , and  $\text{penalty}(i)$  is the penalty of solution component  $i$ . Initially, all penalties are set to zero. Variants of **DLS** differ in the details of their penalty update mechanism (e.g., additive vs. multiplicative updates, occasional reduction of penalties) and the choice of the solution components whose penalties are adjusted. For example, *guided local search* [54.58, 59] uses the following mechanism for choosing the solution components whose penalties are increased: First, a utility value  $u(i) := g_i(s)/(1 + \text{penalty}(i))$  is computed for each solution component  $i$ , where  $g_i(s)$  measures the impact of  $i$  on the evaluation function; then, the penalties of solution components with maximal utility are increased.

**DLS** algorithms are sometimes referred to as a soft form of tabu search, since solution components are not strictly forbidden, but the effect of the penalties resembles a soft prohibition. There are also conceptual links to Lagrangian methods [54.60, 61]. **DLS** algorithms have been shown to reach state-of-the-art performance for **SAT** [54.62] and for the maximum clique problem [54.63].

## 54.4 Hybrid SLS Methods

The performance of basic **SLS** techniques can often be improved by combining them with each other. In fact, even **RI** can be seen as a combination of iterative improvement and random walk, using the same neighborhood. Several other **SLS** methods combine different types of search steps, and in the following, we briefly discuss some prominent examples.

### 54.4.1 Greedy Randomized Adaptive Search Procedures

As mentioned previously, construction heuristic can be easily and effectively combined with perturbative local search procedures. While greedy construction heuristics generally generate only one or very few different candidate solutions, randomization of the constriction process makes it possible to generate many different high-quality solutions. The idea underlying **GRASP** [54.10, 64] is to combine randomized greedy construction with a subsequent perturbative local search phase, whose goal is to improve the candidate solutions produced by the construction heuristic. The two phases of solution construction and perturbative local search are repeated until a termination criterion, e.g., maximum computation time, is met. The term *adaptive* in **GRASP** refers to the fact that the hybrid search process typically uses an adaptive construction heuristic. Randomization in **GRASP** is realized based on the concept of a *restricted candidate list*, which contains the best-scoring solution components according to the given heuristic function. In the simplest and most common **GRASP** variants, elements are chosen uniformly at random from this restricted candidate list during the construction process. For a detailed description, various extensions, and an overview of applications of **GRASP**, we refer to [54.64].

### 54.4.2 Iterated Greedy Algorithms

A disadvantage of **GRASP** is that new candidate solutions are constructed from scratch and independently of previously found solutions. Iterated greedy (**IG**) algorithms iteratively apply greedy construction heuristics to generate a chain of high-quality candidate solutions. The central idea is to alternate between solution construction and destruction phases, and thus to combine at least two different types of search steps. **IG** algorithms first build an initial, com-

plete candidate solution  $s$ . Then, they iterate over the following phases, until a termination criterion is met:

1. Starting from the current candidate solution,  $s$ , a destruction phase is executed, during which some solution components are removed from  $s$ , resulting in a partial candidate solution  $s'$ . The solution components that are removed in this phase may be chosen at random or, for example, based on their impact on the evaluation function.
2. Starting from  $s'$ , a construction heuristic is used to generate another candidate solution,  $s''$ . This construction heuristic may differ from the one used to generate the initial candidate solution.
3. Based on an acceptance criterion, a decision is made whether to continue the search from  $s$  or  $s''$ . Additionally, it is often useful to further improve complete candidate solutions by means of a subsidiary perturbative local search procedure (see Algorithm 54.2 for a high-level outline of **IG**).

---

#### Algorithm 54.2 High-level outline of an iterated greedy (**IG**) algorithm

##### Iterated greedy (**IG**):

construct initial candidate solution  $s$

perform subsidiary local search on  $s$

**while** termination criterion is not satisfied **do**

    apply destruction to  $s$ , resulting in  $s'$

    apply constructive heuristic starting from  $s'$ , resulting in  $s''$

    perform subsidiary local search on  $s''$  (*optional*)

    based on acceptance criterion, keep  $s$  or

        accept  $s := s''$

**end while**

---

The principle underlying **IG** methods has been rediscovered several times, and consequently, can be found under various names, including *ruin-and-recreate* [54.65], *iterative flattening* [54.66], and *iterative construction heuristic* [54.67]; it has also been used in the context of **SA** [54.68]. **IG** algorithms, especially when combined with perturbative local search methods, have reached state-of-the-art performance for a number of problems, including several variants of flowshop scheduling [54.69, 70].

### 54.4.3 Iterated Local Search

Iterated local search (**ILS**) generates a sequence of solutions by alternating applications of a perturbation mechanism and of a subsidiary local search algorithm. Consequently, **ILS** can be seen as a hybrid between the search methods underlying the local search and perturbation phases.

An **ILS** algorithm is specified by four main components. The first is the mechanism used for generating an initial solution, for example, a greedy constructive heuristic. The second is a subsidiary (perturbative) local search procedure; typically, this is an iterative improvement algorithm, but often, other simple **SLS** methods are used. The third component is a perturbation procedure that introduces a modification to a given candidate solution. These perturbations should be complementary to the modifications introduced by the subsidiary local search procedure; in particular, the effect of the perturbation procedure should not be easily reversible by the local search procedure. The fourth component is an acceptance criterion, which is used to decide whether to accept the outcome of the latest perturbation and local search phase.

**ILS** starts by generating an initial candidate solution, to which then subsidiary local search is applied. It then iterates over the following phases, until a termination criterion is met:

1. Perturbation is applied to the current candidate solution  $s$ , to obtain an intermediate candidate solution  $s'$ .
2. Subsidiary local search is applied to  $s'$ .
3. Based on the acceptance criterion, a decision is made whether to continue the search from  $s$  or  $s'$  (see Algorithm 54.3 for a high-level outline of **ILS**).

Often, the subsidiary search is based on iterative improvement and ends in a local optimum; **ILS** can therefore be seen as performing a biased random walk in the space of local optima produced by the given subsidiary local search procedure. The acceptance criterion (together with the strength of the perturbation mechanism) then determines the degree of search intensification: if only improving candidate solutions are accepted, **ILS** performs a randomized first-improvement search in the space of local optima; if any new local optimum is accepted, **ILS** performs a random walk in the space of local optima.

---

**Algorithm 54.3 High-level outline of iterated local search**

**Iterated local search (**ILS**):**

```
generate initial candidate solution  $s$ 
perform subsidiary local search on  $s$ 
while termination criterion is not satisfied do
    apply perturbation to  $s$ , resulting in  $s'$ 
    perform subsidiary local search on  $s'$ 
    based on acceptance criterion, keep  $s$ 
    or accept  $s := s'$ 
end while
```

An attractive feature of **ILS** is that basic versions can be quickly and easily implemented, especially if a simple **SLS** algorithm or an iterative improvement procedure is already available. Using some additional refinements, **ILS** methods define the current state of the art for solving many combinatorial problems, including the **TSP** [54.71]. Similar to **IG**, **ILS** is based on an idea that has been rediscovered several times and is known under various names, including *large-step Markov chains* [54.29] and *chained local optimization* [54.72]. There is also a close conceptual connection with several variants of variable neighborhood search (**VNS**) [54.35]; in fact, the so-called basic **VNS** and skewed **VNS** algorithms can be seen as variants of **ILS** that adapt the perturbation strength at run time. For more details on iterated local search, we refer to [54.73].

## 54.5 Population-Based SLS Methods

The use of a population of candidate solutions offers a convenient way to increase diversification in **SLS**. For example, population-based extensions of **ILS** algorithms have been proposed with this aim in mind [54.74, 75]. A further potential benefit comes from the inherent parallelizability of the most population-based **SLS**

methods, although the parallelization thus achieved is not necessarily more effective than the simple and generic approach of performing multiple independent runs of an **SLS** algorithm in parallel (see also [54.1], Sect. 4.4). As previously remarked, population-based methods can be cast into the **SLS** framework described

in Sect. 54.1 by defining search positions to consist of sets of candidate solutions and by using neighborhood relations, initialization, and step functions that operate on such populations.

Unfortunately, the benefits derived from the use of populations come at the cost of increased complexity, in terms of implementation effort, and parameters that need to be set appropriately. In what follows, we describe two of the most prominent population-based methods, one based on a constructive search paradigm (ant colony optimization), and the other based on a perturbative search paradigm (evolutionary algorithms).

### 54.5.1 Ant Colony Optimization

Ant colony optimization (**ACO**) algorithms have originally been inspired by the trail-following behavior of real ant species, which allows them to find shortest paths [54.76, 77]. This biological phenomenon gave rise to a surprisingly effective algorithm for combinatorial optimization [54.18, 19]. In **ACO**, the artificial ants perform a randomized constructive search that is biased by (artificial) pheromone trails and heuristic information derived from the given problem instance. The pheromone trails are numerical values associated with solution components that are adapted at run time to reflect experience gleaned from the search process so far.

During solution construction, at each step every ant chooses a solution component, probabilistically preferring those with high-pheromone trail and heuristic information values. For illustration, consider the **TSP** – the first problem to which **ACO** has been applied [54.18]. Each edge  $(i, j)$  has an associated pheromone value  $\tau_{ij}$  and a heuristic value  $\eta_{ij}$ , which for the **TSP** is typically defined as  $1/w(i, j)$ , that is, the inverse of the edge weight. In ant system [54.19], the first **ACO** algorithm for the **TSP**, an ant located at vertex  $i$  would add vertex  $j$  to its current partial tour  $s'$  with probability

$$p_{ij} = \frac{\tau_{ij}^\alpha \cdot \eta_{ij}^\beta}{\sum_{l \in N(i)} \tau_{il}^\alpha \cdot \eta_{il}^\beta}, \quad (54.4)$$

where  $N(i)$  is the feasible neighborhood of vertex  $i$ , i. e., the set of all vertices that have not yet been visited in  $s'$ , and  $\alpha$  and  $\beta$  are parameters that control the relative importance of pheromone trails and heuristic information, respectively. Note that the tour construction procedure

implemented by the artificial ants is a randomized version of the nearest neighbor construction heuristic. In fact, randomizing a greedy construction heuristic based on pheromone trails associated with the decisions to be made would generally be a good initial step toward an effective **ACO** algorithm for a combinatorial problem.

Once every ant has constructed a complete candidate solution, it is typically highly advantageous to apply an iterative improvement procedure or a simple **SLS** algorithm [54.20, 78]. Next, the pheromone trail values are updated by means of two counteracting mechanisms. The first models pheromone evaporation and decreases some or all pheromone trail values by a constant factor. The second models pheromone deposit and increases the pheromone trail levels of solution components that have been used by one or more ants. The amount of pheromone deposited typically depends on the quality of the respective solutions. In the best performing **ACO** algorithms, only some of the ants with the highest quality solutions are allowed to deposit pheromone. The overall result of the pheromone update is an increased probability of choosing solution components in subsequent solution constructions that have previously been found to occur in high-quality solutions. **ACO** algorithms then cycle through these phases of solution construction, application of local search, and pheromone update until some termination criterion is met (see Algorithm 54.4 for a high-level outline of **ACO**).

---

#### Algorithm 54.4 High-level outline of ant colony optimization

##### **Ant colony optimization (**ACO**):**

initialize pheromone trails

**while** termination criterion is not satisfied **do**

    generate population  $sp$  of candidate solutions

        using subsidiary randomized

        constructive search

    perform subsidiary local search on  $sp$

    update pheromone trails

**end while**

---

Many different variants of **ACO** algorithms have been studied. Along with many additional details on **ACO**, these are described in the book by *Dorigo and Stützle* [54.20]; for more recent surveys, we refer the reader to [54.79, 80]. The **ACO** metaheuristic [54.81, 82] provides a general framework for these variants and a generic view of how to apply **ACO** algorithms. **ACO** is also one of the most successful algorithmic

techniques within the broader field of swarm intelligence [54.83].

### 54.5.2 Evolutionary Algorithms

Evolutionary algorithms (**EAs**) are a prominent class of population-based **SLS** methods that are loosely inspired by concepts from biological evolution. Unlike **ACO** algorithms, **EAs** work with a population of complete candidate solutions. The initial set of candidate solutions is typically created randomly, but greedy construction heuristics may also be used to seed the population. This population then undergoes an artificial evolution, where at each iteration, the population of candidate solutions is modified by means of mutation, recombination and selection.

*Mutation operators* typically introduce small, random perturbations into individual candidate solutions. The strength of these perturbations is usually controlled by a parameter called *mutation rate*; alternatively, a specific, fixed perturbation, akin to a random walk step in **RII**, may be performed. *Recombination operators* generate one or more new candidate solutions by combining information from two or more parent candidate solutions. The most common type of recombination is *crossover*, inspired by the homonymous mechanism in biological evolution; it generates offspring by assembling partial candidate solutions from linear representations of two parents. In addition to mutation and recombination, *selection mechanisms* are used to determine the candidate solutions that will undergo mutation and recombination, as well as those that will form the population used in the next iteration of the evolutionary process. Selection is based on the *fitness*, i. e., evaluation function values, of the candidate solutions, such that better candidate solutions have a higher probability to be selected.

Details of the mutation, recombination and selection mechanisms all have a strong impact on the performance of an **EA**. Generally, the use of problem specific knowledge within these mechanisms leads to better performance. In fact, much research in **EAs** has been devoted to the design of effective mutation and

recombination operators; a good example for this is the **TSP** [54.84, 85]. To achieve cutting-edge performance in an **EA**, it is often useful to improve at least the best candidate solutions in a given population by means of a perturbative local search method, such as iterative improvement. The resulting class of hybrid algorithms, which are also known as *memetic algorithms* (**MA**) [54.86], are enjoying increasing popularity as a broadly applicable method for solving solving combinatorial problems (see Algorithm 54.5 for a high-level outline of an **MA**).

---

*Algorithm 54.5 High-level outline of a memetic algorithm*

```

Memetic algorithm (MA):
  initialize population  $p$ 
  perform subsidiary local search on each
    candidate solution in  $p$ 
  while termination criterion is not satisfied do
    generate set  $pr$  of candidate solutions
      through recombination
    perform subsidiary local search on each
      candidate solution of  $pr$ 
    generate set  $pm$  of candidate solutions
      from  $p \cup pr$  through mutation
    perform subsidiary local search on each
      candidate solution of  $pm$ 
    select new population  $p$  from candidate
      solutions in  $p \cup pr \cup pm$ 
  end while

```

---

Several other techniques are conceptually related to evolutionary algorithms but have different roots. *Scatter search* and *path relinking* are **SLS** methods whose origins can be traced back to the mid-1970s [54.16]. Scatter search can be seen as a memetic algorithm that uses special types of recombination and selection mechanisms. Path relinking corresponds to a specific form of interpolation between two (or possibly more) candidate solutions and is thus conceptually related to recombination operators. Both methods have recently become increasingly popular; details can be found in [54.17, 87].

## 54.6 Recent Research Directions

In this section, we concisely discuss three research directions that we regard as particularly timely and promising: combinations of **SLS** and systematic search

techniques, **SLS** algorithm engineering, and automated configuration and design of **SLS** algorithms. For other topics of interests, such as **SLS** algorithms for mul-

tiobjective [54.88–90], stochastic [54.91] or dynamic problems [54.92, 93], we refer to the literature for more details.

### 54.6.1 Combination of SLS Algorithms with Systematic Search Techniques

Systematic search and **SLS** are traditionally seen as two distinct approaches for solving challenging combinatorial problems. Interestingly, the particular advantages and disadvantages of each of these approaches render them rather complementary. Therefore, it is hardly surprising that over the last few years, there has been increased interest in the exploration and development of hybrid algorithms that combine ideas from both paradigms. For example, related to the area of mathematical programming, the term *Matheuristics* has recently been coined to refer to methods that combine elements from mathematical programming techniques (which are primarily based on systematic search) and (meta)heuristic search algorithms [54.94].

Hybrids between **SLS** and systematic search fall into two main classes. The first of these consists of approaches where the systematic search algorithm plays the role of the master process, and an **SLS** procedure is used to solve subproblems that arise during the systematic search process. Probably, the simplest, yet potentially effective method is to use an **SLS** algorithm to provide an initial high-quality (primal) bound on the optimal solution of the problem, which is then used by the systematic search algorithm for pruning parts of the search tree. Several more elaborate schemes have been devised, e.g., in the context of column generation and separation routines in integer programming [54.95]. Other approaches introduce the spirit of local search into integer programming solvers; examples of these include *local branching* [54.96] and *relaxation-induced neighborhood search* [54.97]. We refer to [54.95] for a recent overview of such combinations.

The second class of hybrid approaches is based on the idea of using systematic search procedures to deal with specific tasks arising while running an **SLS** algorithm. Very-large neighborhood search [54.37], as discussed in Sect. 54.2, is probably one of the best-known examples. Elements of tree search methods can also be exploited within constructive search algorithms, as exemplified by the use of branch and bound techniques in **ACO** algorithms [54.98, 99]. Other examples include *tour merging* [54.100] and the usage of information derived from integer programming formulations

of optimization problems in heuristic methods [54.101]. We refer to [54.102] for a survey of this general approach. A taxonomy of the possible combinations of exact and local search algorithms has been introduced by *Jourdan et al.* [54.103].

Despite an increasing number of efforts on combining systematic search methods and **SLS** methods, as reviewed in [54.94], much work remains to be done in this direction, especially considering that the two underlying fundamental search paradigms are developed primarily in rather disjoint communities. We believe that much can be gained by overcoming the traditional view of these two approaches as being competing with each other in favour of focusing on synergies due to their complementarity.

### 54.6.2 SLS Algorithm Engineering

Despite the impressive successes in **SLS** research and applications – **SLS** algorithms are now firmly established as the method of choice for tackling a broad range of combinatorial problems – there are still significant shortcomings. Perhaps most prominently, there is a lack of guidelines and best practices regarding the design and development of effective **SLS** algorithms. Current practice is to implement one specific **SLS** method, based on one or more construction heuristics or iterative improvement procedures. However, general-purpose **SLS** methods are not fully defined recipes: they leave many design choices open, and typically only specific combinations of these choices will result in an effective algorithms for a given problem. Even worse, the underlying basic construction and iterative improvement procedures have a tremendous influence on the final performance of the **SLS** algorithms built on them, and this influence is frequently neglected.

We firmly believe that a more methodological approach needs to be taken toward the design and implementation of **SLS** algorithms. The research direction dedicated to developing such an approach is called *stochastic local search algorithm engineering* or, for short, *SLS engineering*; it is conceptually related to algorithm engineering [54.104] and software engineering [54.105], where similar methodological issues are tackled in a different context. Algorithm engineering is rather closely related to **SLS** engineering; it has been conceived as an extension to the traditionally more theoretically oriented research on algorithms. Algorithm engineering, according to [54.104], deals with the iterative process of designing, analyzing, implementing, tuning and experimentally evaluating algorithms. **SLS**

engineering shares this motivation; however, the algorithms that are dealt with in the context of **SLS** approaches have substantially more complex and unpredictable behavior than those typically considered in algorithm engineering. There are several reasons for this: **SLS** algorithms are usually used for solving NP-hard problems, they allow for many more degrees of freedom in the choice of algorithm components, and their stochasticity makes analysis more complex.

From a high-level perspective, an initial approach to a successful **SLS** engineering process would proceed in a bottom-up fashion. Starting from knowledge about the problem, it would build **SLS** algorithms by iteratively adding complexity to simple, basic algorithms. More concretely, a tentative first attempt at such a process could be as follows:

1. Study existing knowledge on the problem to be solved and its characteristics;
2. Implement basic and advanced constructive and iterative improvement procedures;
3. Starting from these, add complexity (for example, by moving to simple **SLS** methods);
4. Improve performance by gradually adding concepts from more complex **SLS** techniques (for example, perturbations, prohibition mechanisms, populations);
5. Further configure and fine-tune parameters and design choices;
6. If found to be useful: iterate over steps 4–5.

Obviously, such a process would not necessarily strictly follow this outline, but insights gained at later stages could prompt revisiting earlier design decisions. Several high-performance **SLS** algorithms have already been developed following roughly the process outlined above (see [54.106] for an explicit example).

The **SLS** engineering process can be supported in various ways. Algorithm development, implementation and testing is facilitated by the use of programming frameworks like Paradiseo [54.107, 108] and EasyLocal++ [54.109, 110], dedicated languages and systems like COMET [54.111], libraries of data types (such as LEDA [54.112]), and statistical tools, such as the comprehensive, open-source R environment [54.113]. We expect that software environments specifically designed for the automated empirical analysis and design of algorithms, such as HAL [54.114, 115], will be especially useful in this context. Tools for the automatic configuration and tuning of algorithms, discussed

further in the next section are also of considerable importance.

Furthermore, we see an improved understanding of the relationship between problem and instance features on the one side, and the properties and the behavior of **SLS** methods on the other side as key enabling factors for advanced **SLS** engineering approaches. The potential insights to be gained are not only of practical value to **SLS** engineering but also of considerable scientific interest. Progress in this direction is facilitated by advanced search space analysis techniques, statistical methods and machine learning approaches (see, e.g., Merz and Freisleben [54.116], Xu et al. [54.117] and Watson et al. [54.118]). Another promising avenue for future research involves the integration of theoretical insights into the design process, for example, by restricting design alternatives or parameter choices.

It is important to note that research toward **SLS** engineering adopts a *component-wise view of SLS methods*. For example, iterated local search (**ILS**) uses perturbations to diversify the search as well as acceptance tests (components: perturbations, acceptance tests), while evolutionary algorithms prominently involve the use of a population of solutions (component: population of solutions). Each of these components can be instantiated in different ways, and various combinations are possible. An effective **SLS** engineering process should provide guidance to the algorithm designer regarding the choice and configuration of these components. It would naturally and incrementally lead to combinations of algorithmic components taken from different **SLS** methods (or other paradigms, such as mathematical programming – [54.94]), if these contribute to desirable performance characteristics of the algorithm under design. Such an engineering process would therefore rather naturally produce hybrid algorithms that are effective for solving the given computational problem.

Finally, **SLS** engineering highlights more the importance of decisions concerning the underlying basic **SLS** techniques (such as construction heuristics, neighborhoods, efficient data structures, etc.) than the general-purpose **SLS** methods (or metaheuristics) used in a given algorithm design scenario. In fact, in our experience, such fundamental choices together with: (i) the level of expertise of the **SLS** algorithm developer and implementer, (ii) the time invested in designing and configuring the **SLS** algorithm, (iii) the creative use of insights into algorithm behavior and interaction with problem characteristics play a considerably more im-

portant role in the design of effective **SLS** algorithms than the focus on specific features prescribed by so-called metaheuristics.

### 54.6.3 Automatic Configuration of SLS Algorithms

The performance of algorithms for virtually any computationally challenging problem (and in particular, for any NP-hard problem) depends strongly on appropriate settings of algorithm parameters. In many cases, there are tens of such parameter; for example, the well-known commercial CPLEX solver for integer programming problems has more than 130 user-specifiable parameters that influence its search behavior. Likewise, the behavior of most **SLS** algorithms is controlled by parameters, and many design choices can be exposed in the form of parameters. This gives rise to algorithms with many categorical and numerical parameters. Categorical parameters are used to make choices from a discrete set of design variants, such as search strategies, neighborhoods or perturbation mechanisms. Numerical parameters often arise as subordinate parameters that directly control the behavior of a search strategy (e.g., temperature in **SA** and tabu tenure in simple tabu search). The goal in automated algorithm configuration is to find settings of these parameters that achieve optimized performance w.r.t. a performance metric of interest (for example, solution quality or computation time).

Automated algorithm configuration methods are an active area of research and have been demonstrated to achieve very substantial performance gains on many widely studied and challenging problems [54.119]. So-called *offline configuration methods*, which determine performance-optimizing parameter settings on a representative set of benchmark instances during a training phase before algorithm deployment, have arguably been studied most intensely been studied. These in-

clude procedures that are limited to tuning numerical parameters, such as CALIBRA [54.120], experimental design-based approaches [54.69, 121], SPO [54.122] and SPO<sup>+</sup> [54.123]. Methods that can handle categorical as well as numerical parameters are considerably more versatile; these include racing procedures [54.124, 125], model-free configuration procedures [54.126–128], and recent sequential model-based techniques [54.129, 130].

In *online configuration*, algorithm parameters are modified while attempting to solve a given problem instance. There are some inherent advantages of online configuration methods w.r.t. offline methods, especially when targeting very heterogeneous instances, where appropriate algorithm parameters may depend strongly on the problem instance to be solved. Some of these methods fall into the realm of reactive search methods [54.131]; others have been studied in the area of evolutionary computation (for an overview, we refer to [54.132]). Unfortunately, most online configuration methods presently available deal with very few parameters primarily responsible for algorithm performance (often only one) and rely on specific insight into the working principles of the given algorithm.

There are also various approaches for determining configurations of a given algorithm that result in good performance on a given problem instance. These *per-instance configuration methods* typically make use of computationally cheap instance features, which provide the basis for selecting the configuration to be used for solving a given instance [54.133–135].

Finally, we believe that there is significant promise in approaches for automating large parts of the design process of performance-optimized **SLS** algorithms as, for example, outlined in recent work on computer-aided algorithm design for generalized local search machines [54.136] and the *programming by optimization* (**PbO**) software design paradigm [54.23].

# 55. Parallel Evolutionary Combinatorial Optimization

El-Ghazali Talbi

In this chapter, a clear difference is made between the parallel design aspect and the parallel implementation aspect of evolutionary algorithms (EAs). From the algorithmic design point of view, the main parallel models for EAs are presented. A unifying view of parallel models for EAs is outlined. This chapter is organized as follows. In Sect. 55.2, the main parallel models for designing EAs are presented. Section 55.3 deals with the implementation issues of parallel EAs. In this section, the main concepts of parallel architectures and parallel programming paradigms, which interfere with the design and implementation of parallel EAs, are outlined. The main performance indicators that can be used to evaluate a parallel EAs in terms of efficiency are detailed. Finally, Sect. 55.4 deals with the design and implementation of different parallel models for EAs based on the software framework ParadisEO.

## 55.1 Motivation

On one hand, optimization problems are more and more complex and their resource requirements to solve them are ever increasing. Real-life optimization problems are often NP-hard, and CPU time, and/or memory consuming. Although the use of evolutionary algorithms (EAs) allows us to significantly reduce the computational complexity of the solving algorithm, the latter remains time-consuming for many problems in diverse domains of application, where the objective function and the constraints associated with the problem are resource (e.g., CPU, memory) intensive and the size of the search space is huge. Moreover, more and more complex and resource intensive EAs are developed (e.g., hybrid EAs, multiobjective EAs) [55.1].

On the other hand, the rapid development of technology in designing processors (e.g. multicore processors, dedicated architectures), networks (local networks (LAN) such as Myrinet and Infiniband or wide area networks (WAN) such as optical networks), and data storage make the use of parallel computing more and more popular. Such architectures represent an effective opportunity for the design and implementation of parallel EAs. Indeed, sequential architectures are reaching physical limitations (speed of light, thermodynamics). Nowadays, even laptops and workstations are equipped with multicore processors, which represent one class of parallel architecture. Moreover, the ratio cost/performance is constantly decreasing. The

proliferation of powerful workstations and fast communication networks have shown the emergence of dedicated architectures (e.g., **GPUs**), clusters of processors (**COPs**), networks of workstations (**NOWs**), and large-scale networks of machines (Grids) as platforms for high-performance computing.

Parallel and distributed computing can be used in the design and implementation of **EAs** for the following reasons:

- *Speedup the search:* One of the main goals in parallelizing an **EA** is to reduce the search time. This helps designing real time and interactive optimization methods. This is a very important aspect for some class of problems where there are hard requirements on search time such as in dynamic optimization problems and time-critical control problems such as *real-time* planning.
- *Improve the quality of the obtained solutions:* Some parallel models for **EAs** allow us to improve the quality of solutions. Indeed, exchanging information between algorithms will alter their behavior in terms of searching in the landscape associated with the problem. The main goal in the cooperation between algorithms is to improve the quality of solutions. Both convergence to better solutions and reduced search time may happen. Let us note that a parallel model for **EAs** may be more effective than a sequential algorithm even on a single processor [55.2].
- *Improve the robustness:* A parallel **EA** may be more robust in terms of solving in an effective manner different optimization problems and different instances of a given problem. Robustness may be measured in terms of the sensitivity of the algorithm to its parameters.

- *Solve large-scale problems:* Parallel **EAs** allow to solve large-scale instances of complex optimization problems. A challenge here is to solve very large instances that cannot be solved on a sequential machine. Another similar challenge is to solve more accurate mathematical models associated with different optimization problems. Improving the accuracy of mathematical models increases in general the size of the associated problems to be solved. Moreover, some optimization problems need the manipulation of huge databases such as data mining problems.

The implementation point of view deals with the efficiency of a parallel **EAs** on a target parallel architecture using a given parallel language, programming environment, or middleware. The focus is on the parallelization of **EAs** on general-purpose parallel and distributed architectures, since this is the most widespread computational platform. This chapter also deals with the implementation of **EAs** on dedicated architectures such as reconfigurable architectures and **GPUs** (graphical processing units). Different architectural criteria, which affect the efficiency of the implementation, will be considered: shared memory versus distributed memory, homogeneous versus heterogeneous, shared versus nonshared by multiple users, local network versus large network. Indeed, those criteria have a strong impact on the deployment technique employed such as load balancing and fault tolerance. Depending on the type of parallel architecture used, different parallel and distributed languages, programming environments, and middlewares may be used such as message passing (e.g., **MPI**), shared memory (e.g., multithreading, OpenMP, **CUDA**), remote procedural call (e.g., Java **RMI**, **RPC**), high-throughput computing (e.g., Condor), and grid computing (e.g., Globus).

## 55.2 Parallel Design of **EAs**

In terms of designing parallel **EAs**, three major parallel models are identified. They follow the following three hierarchical levels (Table 55.1):

- *Algorithmic level:* In this model, independent or cooperating self-contained **EAs** are used. It is a problem-independent interalgorithm parallelization. If the different **EAs** are independent, the search will be equivalent to the sequential execution of the

algorithms in terms of the quality of solutions. However, the cooperative model will alter the behavior of the **EAs** and enable the improvement in terms of the quality of solutions.

- *Iteration level:* In this model, each iteration of an **EA** is parallelized. It is a problem-independent intra-algorithm parallelization. The behavior of the **EA** is not altered. The main objective is to speedup the algorithm by reducing the search time. Indeed,

**Table 55.1** Parallel models of EAs

| Parallel model    | Problem dependency | Behavior   | Granularity | Goal          |
|-------------------|--------------------|------------|-------------|---------------|
| Algorithmic level | Independent        | Altered    | EA          | Effectiveness |
| Iteration level   | Independent        | Nonaltered | Iteration   | Efficiency    |
| Solution level    | Dependent          | Nonaltered | Solution    | Efficiency    |

the iteration cycle of EAs on large populations, especially for real-world problems, requires a large amount of computational resources.

- *Solution level:* In this model, the parallelization process handles a single solution of the search space. It is a problem-dependent intra-algorithm parallelization. In general, evaluating the objective function(s) or constraints for a generated solution is frequently the most costly operation in EAs. In this model, the behavior of the EA is not altered. The objective is mainly the speedup of the search.

In the following sections, different parallel models are detailed and analyzed in terms of algorithmic design.

### 55.2.1 Algorithmic-Level Parallel Model

In this model, many EAs are launched in parallel. They may cooperate or not to solve the target optimization problem.

#### Independent Algorithmic-Level Parallel Model

In the *independent* algorithmic-level parallel model, different EAs are executed without any cooperation. The different EAs may be initialized with different populations. Different parameter settings may be used for the EAs such as the mutation and crossover probabilities, etc. Moreover, each search component of an EA may be designed differently: encoding, search operators (e.g., variation operators), objective function, constraints, stopping criteria, etc.

This parallel model is straightforward to design and implement. The master/worker paradigm is well suited to this model. A worker implements an EA. The master defines different parameters to use by the workers and determines the best found solution from those obtained by different workers. In addition to speeding up the algorithm, this parallel model enables us to improve its robustness [55.3].

This model raises particularly the following question: Is it equivalent to execute  $k$  EAs during a time  $t$  and to execute a single EA during  $k * t$ ? The answer depends on the landscape properties of the problem (e.g., the presence of multiple basins of attraction,

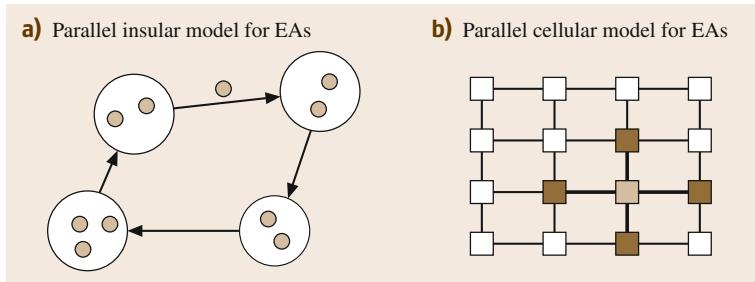

distribution of the local optima, and fitness distance correlation) [55.4].

#### Cooperative Algorithmic-Level Parallel Model

In the *cooperative* model for parallel EAs, different algorithms are exchanging informations related to the search with the intent to compute better and more robust solutions.

In designing a parallel cooperative model for any EA, the same design questions need to be answered:

- *The exchange decision criterion (When?):* The exchange of information between the EAs can be decided either in a *blind* (periodic or probabilistic) way or according to an *intelligent* adaptive criterion. Periodic exchange occurs in each algorithm after a fixed number of iterations; this type of communication is synchronous. Probabilistic exchange consists in performing a communication operation after each iteration with a given probability. Conversely, adaptive exchanges are guided by some run-time characteristics of the search. For instance, it may depend on the evolution of the quality of the solutions or the search memory. A classical criterion is related to the improvement of the best found local solution.
- *The exchange topology (Where?):* The communication exchange topology indicates for each EA its neighbor(s) regarding the exchange of information, i. e., the source/destination algorithm(s) of the information. Several works have been dedicated to the study of the impact of the topology on the quality of the provided results, and show that cyclic graphs are better [55.5, 6]. The ring, mesh, and hypercube regular topologies are often used.
- *The information exchanged (What?):* This parameter specifies the information to be exchanged between the EAs. In general, this information can be composed of:
  - *Solutions:* This information deals with a selection of the solutions found during the search. In general, it contains elite solutions that have been found such as the best solution at the current iteration, local best solutions, global best solution, neighborhood best solution, best diversification, etc.

**Fig. 55.1a,b** The traditional parallel (a) island and (b) cellular models for evolutionary algorithms

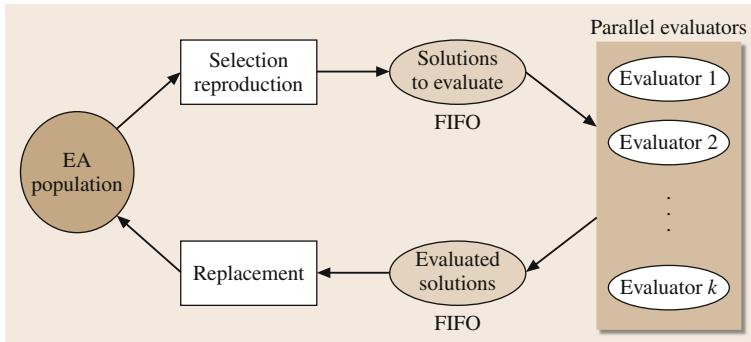

fied solutions, and randomly selected solutions. The number of solutions to exchange may be an absolute value or a given percentage of the population. Any selection mechanism can be used to select the solutions.

- *Search memory:* This information deals with any element of the search memory that is associated with the involved EA.
- *The integration policy (How?):* Analogously to the information exchange policy, the integration policy deals with the usage of the received information. In general, there is a local copy of the received information. The local variables are updated using the received ones. For instance, the best found solution is simply updated by the best between the local best solution and the neighboring best solution. Any replacement strategy may be applied on the local population by the set of received solutions.

**Traditional Parallel Models for EAs.** Historically, the cooperative parallel model has been largely used in EAs [55.7]. In sequential genetic algorithms (the sequential model is known as the panmictic genetic algorithm), the selection takes place globally. Any individual can potentially reproduce with any other individual of the population. Among the best-known parallel algorithmic-level models for evolutionary algorithms are the island model and the cellular model. In the island model (also known as the migration model, distributed model, multimeme EA, or coarse-grained EA) for genetic algorithms, the population is decomposed into several subpopulations distributed among different nodes (Fig. 55.1). Each node is responsible of the evolution of one subpopulation. It executes all the steps of a classical EA from the selection to the replacement on the subpopulation. Each island may use different parameter values and different strategies for any search component such as selection, replacement, variation operators (mutation, crossover), and encodings. After a given number of generations (synchronous exchange),

or when a condition holds (asynchronous exchange), the migration process is activated. Then, exchanges of some selected individuals between subpopulations are realized, and received individuals are integrated into the local subpopulation. The selection policy of emigrants indicates for each island in a *deterministic* or *stochastic* way the individuals to be migrated. The stochastic or random policy does not guarantee that the best individuals will be selected, but its associated computation cost is relatively lower. The deterministic strategy allows the selection of the best individuals. The number of emigrants can be expressed as a fixed or variable number of individuals, or through a percentage of individuals from the population. The choice of the value of such parameter is crucial. Indeed, if the number of emigrants is low, the migration process will be less efficient as the islands will have the tendency to evolve in an independent way. Conversely, if the number of emigrants is high, the EAs will likely converge to the same solutions [55.8]. In EAs, the replacement/integration policy of immigrants indicates in a stochastic or deterministic way the local individuals to be replaced by the newcomers. The objective of the model is to delay the global convergence and encourage diversity [55.9, 10].

The other well-known parallel model for EAs, the cellular model (also known as the diffusion or fine-grained model), may be seen as a special case of the island model where an island is composed of a single individual. Traditionally, an individual is assigned to a cell of a grid. The selection occurs in the neighborhood of the individual [55.11–13]. Hence, the selection pressure is less important than in sequential EAs. The overlapped small neighborhood in cellular EAs helps exploring the search space because a slow diffusion of solutions through the population provides a kind of exploration, while exploitation takes place inside each neighborhood. Cellular models applied to complex problems can have a higher convergence probability to better solutions than panmictic EAs [55.14, 15].

**Fig. 55.2** Parallel asynchronous evaluation of a population

### 55.2.2 Iteration-Level Parallel Model

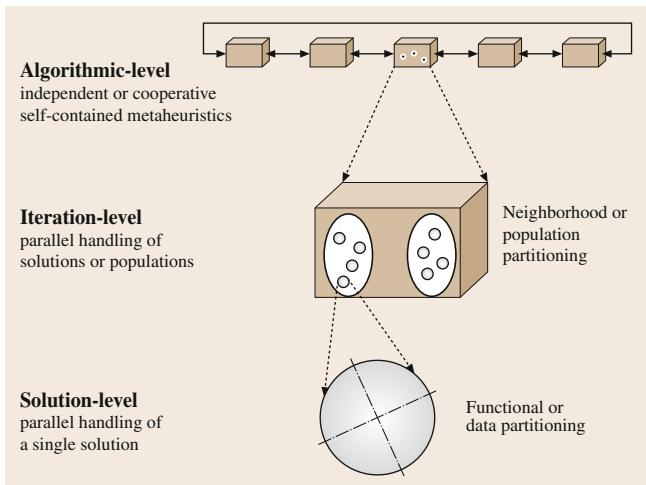

In this parallel model, a focus is made on the parallelization of each iteration of **EAs**. The iteration-level parallel model is generally based on the distribution of the handled solutions. Indeed, the most resource-consuming part in an **EA** is the evaluation of the generated solutions. Our concerns in this model are only search mechanisms that are problem-independent operations such as the generation of successive populations. Any *search operator* of an **EA** which is not specific to the tackled optimization problem is involved in the iteration-level parallel model. This model keeps the sequentiality of the original algorithm, and, hence, the behavior of the **EA** is not altered.

Parallel iteration level models arise naturally when dealing with **EAs**, since each element belonging to the population is an independent unit. The iteration-level parallel model involves the distribution of the population. The operations commonly applied to each of the population elements are performed in parallel.

The population of individuals can be decomposed and handled in parallel. In the beginning of the parallelization of **EAs** the well-known *master-worker* (also known as *global parallelization*) method was used. In this scheme, a master performs the selection operations and the replacement. The selection and replacement are generally sequential procedures, as they require a global management of the population. The associated workers perform the recombination, mutation and the evaluation of the objective function. The master sends the partitions (subpopulations) to the workers. The workers return back newly evaluated solutions to the master.

According to the order in which the evaluation phase is performed in comparison with the other parts of the **EA**, two modes can be distinguished:

- **Synchronous:** In the synchronous mode, the worker manages the evolution process and performs in a serial way the different steps of selection and replacement. At each iteration, the master distributes the set of new generated solutions among the workers and waits for the results to be returned back. After the results are collected, the evolution process is restarted. The model does not change the behavior of the **EA** compared to a sequential model. The synchronous execution of the model is always synchronized with the return back of the last evaluated solution.
- **Asynchronous:** In the asynchronous mode, the evaluation phase is not synchronized with the other parts of the **EA**. The worker does not wait for the return of all evaluations to perform the selection, reproduction, and replacement steps. The *steady-state EA* is a good example illustrating the asynchronous model and its advantages. In the asynchronous model applied to a steady-state **EA**, the recombination and the evaluation steps may be done concurrently. The master manages the evolution engine and two queues of individuals of a given fixed size: individuals to be evaluated, and solutions being evaluated. The individuals of the first queue wait for a free evaluating node. When the queue is full the process blocks. The individuals of the second queue are assimilated into the population as soon as possible (Fig. 55.2). The reproduced individuals are stored in a FIFO data structure, which represents the individuals to be evaluated. The **EA** continues its execution in an asynchronous manner, without waiting for the results of the evaluation phase. The selection and reproduction phase are carried out until the queue of nonevaluated individuals is full. Each evaluator agent picks an individual from the data structure, evaluates it, and stores the results into another data structure storing the evaluated in-

**Fig. 55.3** Combination of the three parallel hierarchical models of [EAs](#)

dividuals. The order of evaluation defined by the selection phase may not be the same as in the replacement phase. The replacement phase consists in receiving, in a synchronous manner, the results of the evaluated individuals, and applying a given replacement strategy of the current population.

In some [EAs](#) (e.g., blackboard-based ones) some information must be shared. For instance, in ant colony optimization ([ACO](#)), the pheromone matrix must be shared by all ants. The master has to broadcast the pheromone trails to each worker. Each worker handles an ant process. It receives the pheromone trails, constructs a complete solution, and evaluates it. Finally, each worker sends back to the master the constructed and evaluated solution. When the master receives all the constructed solutions, it updates the pheromone trails [55.16–19].

### 55.2.3 Solution-Level Parallel Model

In this model, problem-dependent operations performed on solutions are parallelized. In general, the interest here is the parallelization of the evaluation of a single solution (also called acceleration move parallel model; objective and/or constraints). This model is particularly interesting when the objective function or the constraints are time and/or memory consuming,

and/or input/output intensive. Indeed, most of real-life optimization problems need the intensive calculation of the objectives and/or the access to large input files or databases.

Two different solution-level parallel models may be carried out:

- *Functional decomposition:* In functional oriented parallelization, the objective function(s) and/or constraints are partitioned into different partial functions. The objective function(s) or the constraints are viewed as the aggregation of some partial functions. Each partial function is evaluated in parallel. Then, a reduction operation is performed on the results returned back by the computed partial functions. By definition, this model is synchronous, so one has to wait the termination of all workers calculating the partial functions.
- *Data partitioning:* For some problems, the objective function may require the access to a huge database that could not be managed on a single machine. Due to a memory requirement constraint, the database is distributed among different sites, and data parallelism is exploited in the evaluation of the objective function. In data-oriented parallelization, the same identical function is computed on different partitions of the input data of the problem. The data is then partitioned or duplicated over different workers.

In the solution-level parallel model, the maximum number of parallel operations will be equal to the number of partial functions or the number of data partitions. A hybrid model can also be used in which a functional decomposition and a data partitioning are combined.

### 55.2.4 Hierarchical Combination of the Parallel Models

The three presented models for parallel [EAs](#) may be used in conjunction within a hierarchical structure [55.20, 21] (Fig. 55.3). The parallelism degree associated with this hybrid model is very important. Indeed, this hybrid model is very scalable; the degree of concurrency is  $k * m * n$ , where  $k$  is the number of [EAs](#) used,  $m$  is the size of the population, and  $n$  is the number of partitions or tasks associated with the evaluation of a single solution.

## 55.3 Parallel Implementation of EAs

Parallel implementation of **EAs** deals with the efficient mapping of a parallel model of **EAs** on a given parallel architecture.

### 55.3.1 Parallel and Distributed Architectures

Parallel architectures are evolving quickly. The main criteria of parallel architectures, which will have an impact on the implementation of parallel **EAs**, are: memory sharing, homogeneity of resources, resource sharing by multiple users, scalability, and volatility (Fig. 55.4). Those criteria will be used to analyze different parallel models and their efficient implementation. A guideline is given for the efficient implementation of each parallel model of **EAs** according to each class of parallel architectures.

**Shared Memory/Distributed Memory Architectures.** In shared memory parallel architectures, the processors are connected by a shared memory. There are different interconnection schemes for the network (e.g., bus, crossbar, multistage crossbar). This architecture is easy to program. Conventional operating systems and programming paradigms of sequential programming can be used. There is only one address space for data exchange but the programmer must take care of synchronization in memory access, such as the mutual exclusion in critical sections. This type of architecture has a poor scalability (from 2 to 128 processors in current technologies) and a higher cost. An example of such shared memory architectures are symmetric multi-processors (**SMPs**) machines and multicore processors.

In distributed memory architectures, each processor has its own memory. The processors are connected by a given interconnection network using different topo-

gies (e.g., hypercube, 2D or 3D torus, fat-tree, and multistage crossbars). This architecture is harder to program; data and/or tasks have to be explicitly distributed to processors. Exchanging information is also explicitly handled using message passing between nodes (synchronous or asynchronous communications). The cost of communication is not negligible and must be minimized to design an efficient parallel **EA**. However, this architecture has a good scalability in terms of the number of processors. In recent years, clusters of processors (**COWs**) became one of the most popular parallel distributed memory architectures. A good ratio between cost and performance is obtained with this class of architectures.

**Homogeneous/Heterogenous Parallel Architectures.** Parallel architectures may be characterized by the homogeneity of the used processors, communication networks, operating systems, etc. For instance, **COWs** are in general homogeneous parallel architectures. The proliferation of powerful workstations and fast communication networks have shown the emergence of heterogeneous networks of workstations (**NOWs**) as platforms for high-performance computing. This type of architecture is present in any laboratory, company, campus, institution, etc. These parallel platforms are generally composed of an important number of owned heterogeneous workstations shared by many users.

**Shared/Nonshared Parallel Architectures.** Most massively parallel machines (**MPP**) and clusters of workstations (**COWs**) are generally nonshared by the applications. Indeed, at a given time, the processors composing those architectures are dedicated to the

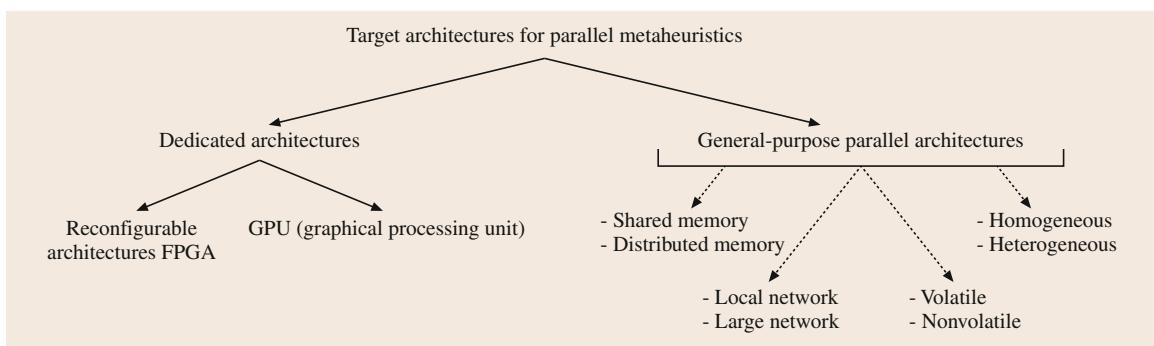

Fig. 55.4 Hierarchical and flat classification of target parallel architectures for **EAs**

**Table 55.2** Characteristics of the main parallel architectures. Hom: Homogeneous, Het: Heterogeneous

| Criteria      | Memory      | Homogeneity | Sharing   | Network | Volatility |
|---------------|-------------|-------------|-----------|---------|------------|
| SMP Multicore | Shared      | Hom         | Yes or No | Local   | No         |
| COW           | Distributed | Hom or Het  | No        | Local   | No         |
| NOW           | Distributed | Het         | Yes       | Local   | Yes        |
| HPC Grid      | Distributed | Het         | No        | Large   | No         |
| Desktop grid  | Distributed | Het         | Yes       | Large   | Yes        |

execution of a single application. NOWs constitute a low-cost hardware alternative to run parallel algorithms but are in general shared by multiple users and applications.

**Local Network (LAN)/Wide-Area Network (WAN).** Massively parallel machines, clusters, and local networks of workstations may be considered as tightly coupled architectures. Large networks of workstations and grid computing platforms are loosely coupled and are affected by a higher cost of communication. During the last decade, *grid computing* systems have been largely deployed to provide high-performance computing platforms. A computational grid is a scalable pool of heterogeneous and dynamic resources geographically distributed across multiple administrative domains and owned by different organizations [55.22]. Two types of grids may be distinguished:

- **High-Performance Computing Grid (HPC grid):** This grid interconnect supercomputers or clusters via a dedicated high-speed network. In general, this type of grid is nonshared by multiple users (at the level of processors).
- **Desktop Grid:** This class of grids is composed of numerous owned workstations connected via nondedicated network such as the internet. This grid is volatile and shared by multiple users and applications.

**Peer-to-peer** networks have been developed in parallel to grid computing technologies. Peer-to-peer infrastructures have been focused on sharing data and are increasingly popular for sharing computation.

**Volatile/Nonvolatile Parallel Architectures.** Desktop grids constitute an example of volatile parallel architectures. In a volatile parallel architecture, there is a dynamic temporal and spatial availability of resources. In a desktop grid or a large network of shared workstations, volatility is not an exception but a rule. Due to the large-scale nature of the grid, the probability of resource failure is high. For instance, desktop grids

have a faulty nature (e.g., reboot, shutdown, and failure).

Table 55.2 recapitulates the characteristics of the main parallel architectures according to the presented criteria. Those criteria will be used to analyze the efficient implementation of the different parallel models of EAs.

### 55.3.2 Dedicated Architectures

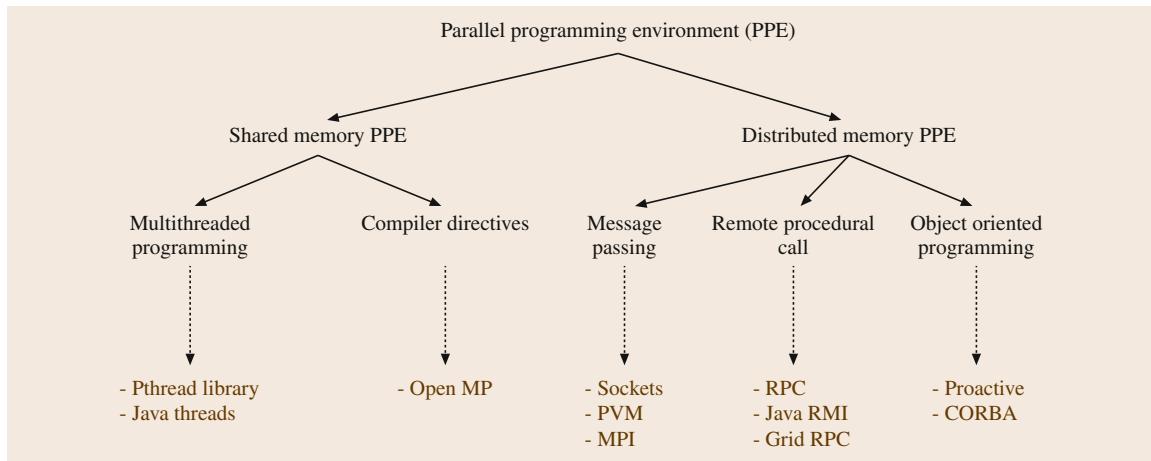

Dedicated hardware represents programmable hardware or specific architectures that can be designed or reused to execute a parallel EA. The best-known dedicated hardware is represented by field programmable gate arrays (**FPGA**) and **GPU** (Fig. 55.4).

**FPGAs** are hardware devices that can be used to implement digital circuits by means of a programming process (do not confuse with evolvable hardware where the architecture is reconfigured using EAs) [55.23]. The use of the Xilinx's **FPGAs** to implement different EAs is more and more popular. The design and the prototyping of a **FPGA**-based hardware board to execute parallel EAs may restrict the design of some search components. However, for some specific challenging optimization problems with a high use rate such as in bioinformatics, dedicated hardware may be a good alternative.

**GPU** is a dedicated graphics rendering device for a workstation, personal computer, or game console. Recent **GPUs** are very efficient at manipulating computer graphics, and their parallel SIMD structure makes them more efficient than general-purpose **CPUs** for a range of complex algorithms [55.24]. The main companies producing **GPUs** are AMD (ATI Radeon series) and NVIDIA (NVIDIA GeForce series). The use of **GPUs** for an efficient implementation of EAs is a challenging issue [55.25].

### 55.3.3 Parallel Programming Environments and Middlewares

The architecture of the target parallel machine strongly influences the choice of the parallel programming

**Fig. 55.5** Main parallel programming languages, programming environments and middlewares

model to use. There are two main parallel programming paradigms: shared memory and message passing (Fig. 55.5).

Two main alternatives exist to program shared memory architectures:

- *Multithreading*: A thread may be viewed as a lightweight process. Different threads of the same process share some resources and the same address space. The main advantages of multithreading are the fast context switch, the low resource usage, and the possible recovery between communication and computation. Each thread can be executed on a different processor or core. Multithreaded programming may be used within libraries such as the standard Pthreads library [55.26] or programming languages such as Java threads [55.27].
- *Compiler directives*: One of the standard shared memory paradigms is OpenMP and CUDA. It represents a set of compiler directives interfaced with the languages Fortran, C and C++ [55.28]. Those directives are integrated in a program to specify which sections of the program to be parallelized by the compiler.

Distributed memory parallel programming environments are based mainly on the following three paradigms:

- *Message passing*: Message passing is probably the most widely used paradigm to program parallel architectures. In the message passing paradigm, processes of a given parallel program communi-

cate by exchanging messages in a synchronous or asynchronous way. The well-known programming environments based on message passing are sockets and message passing interface (MPI).

- *Remote Procedure Call*: Remote procedure call (RPC) represents a traditional way of programming parallel and distributed architectures. It allows a program to cause a procedure to execute on another processor.
- *Object-oriented models*: As in sequential programming, parallel object oriented programming is a natural evolution of RPC. A classical example of such a model is Java RMI (Remote Method Invocation).

In the last decade, great work has been carried out on the development of grid middlewares. The Globus toolkit represents the *de facto* standard grid middleware. It supports the development of distributed service-oriented computing applications [55.29].

It is not easy to propose a guideline on which environment to use in programming a parallel EA. It will depend on the target architecture, the parallel model of EAs, and the user preferences. Some languages are more system oriented such as C and C++. More portability is obtained with Java but the price is less efficiency. This tradeoff represents the classical efficiency/portability compromise. A Fortran programmer will be more comfortable with OpenMP. RPC models are more adapted to implement services. Condor represents an efficient and easy way to implement parallel programs on shared and volatile distributed architectures such as large networks of heterogeneous workstations and desktop grids, where fault tolerance is

**Table 55.3** Parallel programming environments for different parallel architectures

| Architecture  | Examples of suitable programming environment                                      |
|---------------|-----------------------------------------------------------------------------------|
| SMP           | Multithreading library within an operating system (e.g., Pthreads)                |
| Multicore     | Multithreading within languages: Java<br>OpenMP interfaced with C, C++ or Fortran |
| COW           | Message passing library: MPI interfaced with C, C++, Fortran                      |
| Hybrid ccNUMA | MPI or Hybrid models: MPI/OpenMP,<br>MPI/Multithreading                           |
| NOW           | Message passing library: MPI interfaced with C, C++, Fortran                      |
| HPC grid      | Condor or object models (JavaRMI)                                                 |
| Desktop grid  | Condor-G or object models (Proactive)                                             |

ensured by a checkpoint/recovery mechanism. The use of MPI within Globus is more or less adapted to high-performance computing (HPC) grids. However, the user has to deal with complex mechanisms such as dynamic load balancing and fault tolerance. Table 55.3 presents a guideline depending on the target parallel architecture.

#### 55.3.4 Performance Evaluation

For sequential algorithms, the main performance measure is the execution time as a function of the input size. In parallel algorithms, this measure also depends on the number of processors and the characteristics of the parallel architecture. Hence, some classical performance indicators such as speedup and efficiency have been introduced to evaluate the scalability of parallel algorithms [55.30]. The scalability of a parallel algorithm measures its ability to achieve performance proportional to the number of processors.

The speed-up  $S_N$  is defined as the time  $T_1$  it takes to complete a program with one processor divided by the time  $T_N$  it takes to complete the same program with  $N$  processors

$$S_N = \frac{T_1}{T_N} . \quad (55.1)$$

One can use *wall-clock time* instead of *CPU time*. The CPU time is the time a processor spends in the execution of the program, and the wall-clock time is the time of the whole program including the input and out-

put. Conceptually the speed-up is defined as the gain achieved by parallelizing a program. If  $S_N > N$  (resp.,  $S_N = N$ ), a superlinear (resp., linear) speedup is obtained [55.14]. Mostly, a sublinear speedup  $S_N < N$  is obtained. This is due to the overhead of communication and synchronization costs. The case  $S_N < 1$  means that the sequential time is smaller than the parallel time which is the worst case. This will be possible if the communication cost is much higher than the execution cost.

The efficiency  $E_N$  using  $N$  processors is defined as the speed-up  $S_N$  divided by the number of processors  $N$ .

$$E_N = \frac{S_N}{N} \quad (55.2)$$

Conceptually the efficiency can be defined as how well  $N$  processors are used when the program is computed in parallel. An efficiency of 100% means that all of the processors are fully used all the time. For some large real-life applications, it is impossible to have the sequential time as the sequential execution of the algorithm cannot be performed. Then, the incremental efficiency  $E_{NM}$  may be used to evaluate the efficiency extending the number of processors from  $N$  to  $M$  processors

$$E_{NM} = \frac{N \times E_N}{M \times E_M} . \quad (55.3)$$

Different definitions of speedup may be used depending on the definition of the sequential time reference  $T_1$ . Asking what is the best measure is useless; there is no global dominance between the different measures. The choice of a given definition depends on the objective of the performance evaluation analysis. Then, it is important to specify clearly the choice and the objective of the analysis.

The *absolute speedup* is used when the sequential time  $T_1$  corresponds to the best-known sequential time to solve the problem. Unlike other scientific domains such as numerical algebra where for some operations the best sequential algorithm is known, in EA search, it is difficult to identify the best sequential algorithm. So, the absolute speedup is rarely used. The *relative speedup* is used when the sequential time  $T_1$  corresponds to the parallel program executed on a single processor.

Moreover, different stopping conditions may be used:

- *Fixed number of iterations*: This condition is the most used to evaluate the efficiency of a parallel EA.

Using this definition, a superlinear speedup is possible  $S_N > N$ . This is due to the characteristics of the parallel architecture where there is more resources (e.g. size of main memory and cache) than in a single processor (Fig. 55.6a). For instance, the search memory of an EA executed on a single processor may be larger than the main memory of a single processor and then some swapping will be carried out, which represents an overhead in the sequential time. When using a parallel architecture, the whole memory of the EA may fit in the main memory of its processors, and then the memory swapping overhead will not occur.

- *Convergence to a solution with a given quality:* This measure is interesting to evaluate the effectiveness of a parallel EA. It is only valid for parallel models of EAs based on the algorithmic level, which alters the behavior of the sequential EA. A superlinear speedup is possible and is due to the characteristics of the parallel search (Fig. 55.6b). Indeed, the order of searching different regions of the search space may be different from sequential search. The sequences of visited solutions in parallel and sequential search are different. This is similar to the superlinear speedups obtained in exact search algorithms such as branch and bound (this phenomenon is called speedup anomaly) [55.31].

Most of evolutionary algorithms are stochastic algorithms (scatter search, if considered as an evolutionary algorithm, is a deterministic algorithm). When the stopping condition is based on the quality of the solution, one cannot use the speedup metric as defined previously. The original definition may be extended to the average speedup

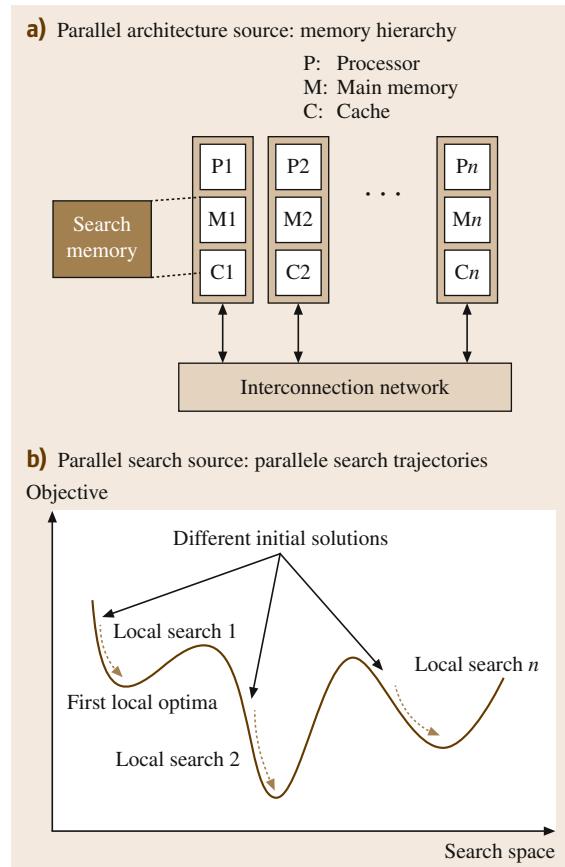

$$S_N = \frac{E(T_1)}{E(T_N)}. \quad (55.4)$$

The same *seed* for the generation of random numbers must be used for a more fair experimental performance evaluation.

The speedup metrics have to be reformulated for heterogeneous architectures. The efficiency metric may be used for this class of architectures. Moreover, it can be used for shared parallel machines with multiple users.

### 55.3.5 Main Properties of Parallel EAs

The performance of a parallel EA on a given parallel architecture depends mainly on its *granularity*.

**Fig. 55.6a,b** Superlinear speedups for a parallel EA.  
**(a)** Parallel architecture source. **(b)** Parallel search source

The granularity of a parallel program is the amount of computation performed between two communications. It computes the ratio between the computation time and the communication time. The three parallel models (algorithmic level, iteration level, and solution level) have a decreasing granularity from coarse-grained to fine-grained. The granularity indicator has an important impact on the speedup. The larger is the granularity the better is the obtained speedup.

The *degree of concurrency* of a parallel EA is represented by the maximum number of parallel processes at any time. This measure is independent from the target parallel architecture. It is an indication of the number of processors that can be employed usefully by the parallel EA.

Asynchronous communications and the recovery between computation and communication is also an important issue for a parallel efficient implementation.

Indeed, most of the actual processors integrate different parallel elements such as arithmetic logic unit (**ALU**), floating point unit (**FPU**), graphical processing unit (**GPU**), direct memory access (**DMA**), etc. Most of the computing part takes part in cache. Hence, the random access memory (**RAM**) bus is often free and can be used by other elements such as the **DMA**. Hence, input/output operations can be recovered by computation tasks.

Scheduling different tasks composing a parallel **EA** is another classical issue to deal with for their efficient implementation. Different scheduling strategies may be used depending on whether the number and the location of works (tasks, data) depend or not on the load state of the target machine:

- *Static scheduling*: This class represents parallel **EAs** in which both the number of tasks of the application and the location of work (tasks, data) are generated at compile time. Static scheduling is useful for homogeneous, and nonshared and nonvolatile heterogeneous parallel architectures. Indeed, when there are noticeable load or power differences between processors, the search time of an iteration is derived by the maximum execution time over all processors, presumably on the most highly loaded processor or the least powerful processor. A significant number of tasks are often idle waiting for other tasks to complete their work.
- *Dynamic scheduling*: This class represents parallel **EAs** for which the number of tasks is fixed at compile time, but the location of work is determined and/or changed at run time. The tasks are dynamically scheduled on different processors of the parallel architecture. Dynamic load balancing is important for shared (multiuser) architectures, where the load of a given processor cannot be determined at compile time. Dynamic scheduling is also important for *irregular* parallel **EAs** in which the execution time cannot be predicted at compile time and varies during the search. For instance, this happens when the evaluation cost of the objective function depends on the solution. Many dynamic load-balancing strategies may be applied. For instance, during the search, each time a processor finishes its work, it proceeds to a work-demand. The degree of parallelism of this class of scheduling algorithms is not related to load variations in the target machine. When the number of tasks exceeds the number of idle nodes, multiple tasks are assigned to the same node. Moreover,

when there are more idle nodes than tasks, some of them will not be used.

- *Adaptive scheduling*: Parallel adaptive algorithms are parallel computations with a dynamically changing set of tasks. Tasks may be created or killed as a function of the load state of the parallel machine. A task is created automatically when a node becomes idle. When a node becomes busy, the task is killed. Adaptive load balancing is important for volatile architectures such as desktop grids.

For some parallel and distributed architectures such as shared networks of workstations and grids, fault tolerance is an important issue. Indeed, in volatile shared architectures and large-scale parallel architectures, the fault probability is relatively important. Checkpointing and recovery techniques constitute one answer to this problem. Application-level checkpointing is much more efficient than system-level checkpointing. Indeed, in system-level checkpointing, a checkpoint of the global state of a distributed application composed of a set of processes is carried out. In application-level checkpointing, only minimal information will be checkpointed (e.g., population of individuals, generation number). Compared to system-level checkpointing, a reduced cost is then obtained in terms of memory and time.

Finally, security issues may be important for large-scale distributed architectures such as grids and peer-to-peer systems (multidomain administration, firewall, etc.) and some specific applications such as medical and bioinformatics research applications of industrial concern.

### 55.3.6 Algorithmic-Level Parallel Model

#### Granularity

The algorithmic-level parallel model has the largest granularity. Indeed, the time for exchanging the information is in general much less than the computation time of an **EA**. There are relatively low communication requirements for this model. The more important is the frequency of exchange and the size of exchanged information, the smaller is the granularity. This parallel model is the most suited to large-scale distributed architectures over internet such as grids. Moreover, the trivial model with independent algorithms is convenient for low-speed networks of workstations over intranet. As there is no essential dependency and communication between the algorithms, the speedup is generally linear for this parallel model.

For an efficient implementation, the frequency of exchange (resp., the size of the exchanged data) must be correlated to the latency (resp., bandwidth) of the communication network of the parallel architecture.

To optimize the communication between processors, the exchange topology can be specified according to the interconnection network of the parallel architecture. The specification of the different parameters associated with the blind or intelligent migration decision criterion (migration frequency/probability and improvement threshold) is particularly crucial on a computational grid. Indeed, due to the heterogeneous nature of computational grids these parameters must be specified for each EA in accordance with the machine it is hosted on.

### Scalability

The degree of concurrency of the algorithmic-level parallel model is limited by the number of EAs involved in solving the problem. In theory, there is no limit. However, in practice, it is limited by the owned resources of the target parallel architectures, and also by the effectiveness aspect of using a large number of EAs.

### Synchronous Versus Asynchronous Communications

The implementation of the algorithmic level model is either *asynchronous* or *synchronous*. The asynchronous mode associates with each EA an exchange decision criterion, which is evaluated at each iteration of the EA from the state of its memory. If the criterion is satisfied, the EA communicates with its neighbors. The exchange requests are managed by the destination EAs within an undetermined delay. The reception and integration of the received information is thus performed during the next iterations. However, in a computational grid context, due to the material and/or software heterogeneity issue, the EAs could be at different evolution stages leading to the *noneffect* and/or *supersolution* problem. For instance, the arrival of poor solutions at a very advanced stage will not bring any contribution as these solutions will likely not be integrated. In the opposite situation, the cooperation will lead to premature convergence.

From another point of view, as it is nonblocking, the model is more efficient and fault tolerant to such a degree a threshold of wasted exchanges is not exceeded. In the synchronous mode, the EAs perform a synchronization operation at a predefined iteration by exchanging some data. Such operation guarantees that the EAs are at the same evolution stage, and so prevents

the noneffect and supersolution problem quoted before. However, in heterogeneous parallel architectures, the synchronous mode is less efficient in term of consumed CPU time. Indeed, the evolution process is often hanging on powerful machines waiting the less powerful ones to complete their computation. The synchronous model is also not fault tolerant as a fault of a single EA implies the blocking of the whole model in a volatile environment. Then, the synchronous mode is globally less efficient on a computational grid.

Asynchronous communication is more efficient than synchronous communication for shared architectures such as NOWs and desktop grids (e.g., multiple users, multiple applications). Indeed, as the load of networks and processors is not homogeneous, the use of synchronous communication will degrade the performances of the whole system. The least powerful machine will determine the performance.

On a volatile computational grid, it is difficult to efficiently maintain topologies such as rings and torus. Indeed, the disappearance of a given node (i.e., EA) requires a dynamic reconfiguration of the topology. Such reconfiguration is costly and makes the migration process inefficient. Designing a cooperation between a set of EAs without any topology may be considered. For instance, a communication scheme in which the target EA is selected randomly is more efficient for volatile architecture such as desktop grids. Many experimental results show that such topology allows a significant improvement of the robustness and quality of solutions. The random topology is therefore thinkable and even commendable in a computational grid context.

### Scheduling

Concerning the scheduling aspect, in the algorithmic-level parallel model the tasks correspond to EAs. Hence, the different scheduling strategies will differ as follows:

- *Static scheduling*: The number of EAs is constant and correlated to the number of processors of the parallel machine. A static mapping between the EAs and the processors is realized. The localization of EAs will not change during the search.
- *Dynamic scheduling*: EAs are dynamically scheduled on different processors of the parallel architecture. Hence, the migration of EAs during the search between different machines may happen.
- *Adaptive scheduling*: The number of EAs involved into the search will vary dynamically. For example, when a machine becomes idle, a new EA is

launched to perform a new search. When a machine becomes busy or faulty, the associated EA is stopped.

### Fault Tolerance

The memory state of the algorithmic-level parallel model required for the checkpointing mechanism is composed of the memory of each EA and the information being migrated (i. e., population, generation number).

### 55.3.7 Iteration-Level Parallel Model

#### Granularity

A medium granularity is associated with the iteration-level parallel model. The ratio between the evaluation of a partition and the communication cost of a partition determines the granularity. This parallel model is then efficient if the evaluation of a solution is time-consuming and/or there are a large number of candidate solutions to evaluate. The granularity will depend on the number of solutions in each subpopulation.

#### Scalability

The degree of concurrency of this model is limited by the size of the population. The use of large populations will increase the scalability of this parallel model.

#### Synchronous Versus Asynchronous Communications

Introducing asynchronism in the iteration-level parallel model will increase the efficiency of parallel EAs. In the iteration-level parallel model, asynchronous communications are related to the asynchronous evaluation of partitions and construction of solutions. Unfortunately, this model is more or less synchronous. Asynchronous evaluation is more efficient for heterogeneous or shared or volatile parallel architectures. Moreover, asynchronism is necessary for optimization problems where the computation cost of the objective function (and constraints) depends on the solution and different solutions may have different evaluation cost.

Asynchronism may be introduced by relaxing the synchronization constraints. For instance, steady-state algorithms may be used in the reproduction phase.

The two main advantages of the asynchronous model over the synchronous model are fault tolerance and robustness if the fitness computation takes very different computations time. Whereas some time-out detection can be used to address the former issue, the latter one can be partially overcome if the grain is set

to very small values, as individuals will be sent out for evaluations upon request of the workers. Therefore, the model is blocking and, thus, less efficient on a heterogeneous computational grid. Moreover, as the model is not fault tolerant, the disappearance of an evaluating agent requires the redistribution of its individuals to other agents. As a consequence, it is essential to store all the solutions not yet evaluated. The scalability of the model is limited to the size of the population.

#### Scheduling

In the iteration-level parallel model, tasks correspond to the construction/evaluation of a set of solutions. Hence, the different scheduling strategies will differ as follows:

- *Static scheduling:* Here, a static partitioning of the population is applied. For instance, the population is decomposed into equal size partitions depending on the number of processors of the parallel homogeneous nonshared machine. A static mapping between the partitions and the processors is realized. For a heterogeneous nonshared machine, the size of each partition must be initialized according to the performance of the processors. The static scheduling strategy is not efficient for variable computational costs of equal partitions. This happens for optimization problems where different costs are associated with the evaluation of solutions. For instance, in genetic programming individuals may widely vary in size and complexity. This makes a static scheduling of the parallel evaluation of the individuals not efficient [55.32, 33].
- *Dynamic scheduling:* A static partitioning is applied but a dynamic migration of tasks can be carried out depending on the varying load of processors. The number of tasks generated may be equal to the size of the population. Many tasks may be mapped on the same processor. Hence, more flexibility is obtained for the scheduling algorithm. For instance, the approach based on the master-workers cycle stealing may be applied. To each worker is first allocated a small number of solutions. Once it has performed its iterations, the worker requests from the master additional solutions. All the workers are stopped once the final result is returned. Faster and less loaded processors handle more solutions than the others. This approach allows us to reduce the execution time compared to the static one.
- *Adaptive scheduling:* The objective in this model is to adapt the number of partitions generated to the load of the target architecture. More effi-

cient scheduling strategies are obtained for shared, volatile, and heterogeneous parallel architectures such as desktop grids.

### Fault Tolerance

The memory of the iteration-level parallel model required for the checkpointing mechanism is composed of different partitions. The partitions are composed of a set of (partial) solutions and their associated objective values.

### 55.3.8 Solution-Level Parallel Model

#### Granularity

This parallel model has a fine granularity. There is a relatively high communication requirements for this model. In the functional decomposition parallel model, the granularity will depend on the ratio between the evaluation cost of the subfunctions and the communication cost of a solution. In the data decomposition parallel model, it depends on the ratio between the evaluation of a data partition and its communication cost.

The fine granularity of this model makes it less suitable for large-scale distributed architectures where the communication cost (in terms of latency and/or bandwidth) is relatively important, such as in grid computing systems. Indeed, its implementation is often restricted to clusters or network of workstations or shared memory machines.

#### Scalability

The degree of concurrency of this parallel model is limited by the number of subfunctions or data partitions. Although its scalability is limited, the use of the solution-level parallel model in conjunction with the two other parallel models enables to extend the scalability of a parallel EA.

#### Synchronous Versus Asynchronous Communications

The implementation of the solution-level parallel model is always synchronous following a master-workers paradigm. Indeed, the master must wait for all partial results to compute the global value of the objective function. The execution time  $T$  will be bounded by the maximum time  $T_i$  of the different tasks. An exception occurs for hard-constrained optimization problems, where feasibility of the solution is first tested. The master terminates the computations as soon as a given task detects that the solution does not satisfy a given hard constraint. Due to its heavy synchronization steps, this

parallel model is worth applying to problems in which the calculations required at each iteration are time consuming. The relative speedup may be approximated as follows:

$$S_n = \frac{T}{\alpha + T/n}, \quad (55.5)$$

where  $\alpha$  is the communication cost.

#### Scheduling

In the solution-level parallel model, tasks correspond to subfunctions in the functional decomposition and to data partitions in the data decomposition model. Hence, different scheduling strategies will differ as follows:

- *Static scheduling:* Usually, the subfunctions or data are decomposed into equal size partitions depending on the number of processors of the parallel machine. A static mapping between the subfunctions (or data partitions) and the processors is applied. As for the other parallel models, this static scheme is efficient for parallel homogeneous nonshared machines. For a heterogeneous nonshared machine, the size of each partition in terms of subfunctions or data must be initialized according to the performance of the processors.
- *Dynamic scheduling:* Dynamic load balancing will be necessary for shared parallel architectures or variable costs for the associated subfunctions or data partitions. Dynamic load balancing may be easily achieved by evenly distributing at run time the subfunctions or the data among the processors. In optimization problems, where the computing cost of the subfunctions is unpredictable, dynamic load balancing is necessary. Indeed, a static scheduling cannot be efficient because there is no appropriate estimation of the task costs (i.e., unpredictable costs).
- *Adaptive scheduling:* In adaptive scheduling, the number of subfunctions or data partitions generated is adapted to the load of the target architecture. More efficient scheduling strategies are obtained for shared, volatile and heterogeneous parallel architectures such as desktop grids.

#### Fault Tolerance

The memory of the solution-level parallel model required for the checkpointing mechanism is straightforward. It is composed of the solution and its partial objective value calculations.

Depending on the target parallel architecture, Table 55.4 presents a general guideline for the efficient

**Table 55.4** Efficient implementation of parallel EAs according to some performance metrics and used strategies

| Property                       | Algorithmic level                                   | Iteration level                         | Solution level                                   |
|--------------------------------|-----------------------------------------------------|-----------------------------------------|--------------------------------------------------|
| Granularity                    | Coarse (frequency of exchange, size of information) | Medium (nb. of solutions per partition) | Fine (eval. subfunctions, eval. data partitions) |
| Scalability                    | Number of EAs                                       | Neighborhood size, populations size     | Nb. of subfunctions, nb. data partitions         |
| Asynchronism                   | High (information exchange)                         | Moderate (eval. of solutions)           | Exceptional (feasibility test)                   |
| Scheduling and fault tolerance | EA                                                  | Solution(s)                             | Partial solution(s)                              |

implementation of the different parallel models of EAs. For each parallel model (algorithmic level, iteration level, and solution level), the table shows its char-

acteristics according to the outlined criteria (granularity, scalability, asynchronism, scheduling and fault tolerance).

## 55.4 Parallel EAs Under ParadisEO

Designing generic software frameworks to deal with the design and efficient *transparent* implementation of parallel and distributed EAs is an important challenge. Indeed, efficient implementation of parallel EAs is a complex task, which depends on the type of the parallel architecture used. In designing a software framework for parallel EAs, one has to keep in mind the following important properties: portability, efficiency, easiness of use, and flexibility in terms of parallel architectures and models.

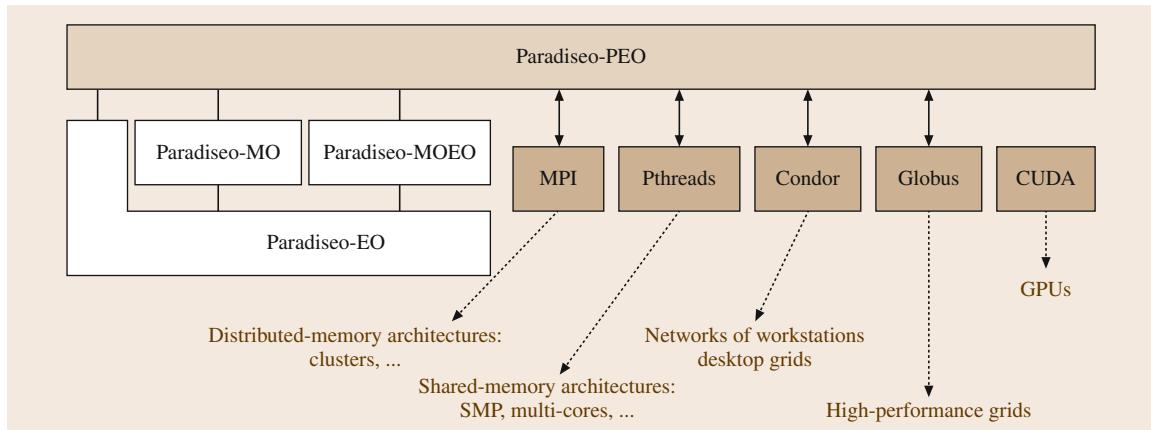

Several white-box frameworks for the reusable design of parallel EAs have been proposed and are available from the Web. The most important of them are: **DREAM** (distributed resource evolutionary algorithm machine) [55.34], **ECJ** (Java evolutionary computation) [55.35], **JDEAL** (Java distributed evolutionary algorithms library) and Distributed BEAGLE (distributed Beagle engine advanced genetic learning environment) [55.36]. These frameworks are reusable as they are based on a clear object-oriented conceptual separation. They are also portable as they are developed in Java, an exception is the last system, which is programmed in C++. However, they are limited regarding the parallel distributed models. Indeed, in **DREAM** and **ECJ** only the island model is implemented using Java threads and TCP/IP sockets. **DREAM** is particularly deployable on peer-to-peer platforms. Furthermore, **JDEAL** provides only the master-worker model (iteration-level parallel model) using TCP/IP sockets. The latter also designs the synchronous migration-based island model, but implemented on a single processor.

Few frameworks available on the Web are devoted to EAs, and their hybridization. MALLBA [55.37],

**MAFRA** (Java MimeticAlgorithms Framework) [55.38] and ParadisEO are good examples of such frameworks. **MAFRA** is developed in Java using design patterns [55.39]. It is strongly hybridization-oriented, but it is very limited regarding parallelism and distribution. MALLBA and ParadisEO have numerous similarities. They are C++/MPI open source frameworks. They provide all the previously presented distributed models, and different hybridization mechanisms. However, they are quite different as ParadisEO is more flexible thanks to the finer granularity of its classes. Moreover, ParadisEO also provides the MPI-based communication layer and Pthreads-based multithreading. MALLBA is deployable on wide area networks using *NetStream*, a message passing service upon MPI [55.37]. ParadisEO is deployable on grid computing platforms using the Globus toolkit [55.21].

ParadisEO-PEO offers transparent implementation of the different parallel models on different architectures using suitable programming environments. ParadisEO-PEO offers an easy implementation of the three main parallel models. The algorithmic-level parallel model allows several optimization algorithms to cooperate and exchange any kind of data. The iteration-level parallel model proposes to parallelize and distribute a set of identical operations. In the solution-level parallel model, any calculation block specific to the optimization problem can be divided into smaller units to speed-up the treatment and gain efficiency.

ParadisEO contains three interconnected modules (Fig. 55.7): EO for evolutionary algorithms (population-based metaheuristics), MO for single solution-based metaheuristics (e.g., local search, tabu search simulated annealing), and MOEO for multi-

**Fig. 55.7** ParadisEO-PEO implementation under different parallel programming environments and middlewares

objective evolutionary algorithms. ParadisEO offers transparency in the sense that the user has not to deal explicitly with parallel programming. One has just to instantiate the needed ParadisEO components. The implementation is portable on distributed-memory machines as well as on shared-memory multiprocessors. The user has not to manage the communications and threads-based concurrency. Moreover, the same parallel design (i.e., the same program) is portable

over different architectures. Hence, ParadisEO-PEO has been implemented on different parallel programming environments and middlewares (**MPI**, Pthreads, Condor, Globus, **CUDA**) which are adapted to different target architectures (shared and distributed memory, cluster and network of workstations, Desktop and high-performance grid computing platforms, **GPUs**) (Fig. 55.7). The deployment of the presented parallel and distributed models is transparent for the user.

## 55.5 Conclusions and Perspectives

Parallel and distributed computing can be used in the design and implementation of **EAs** to speedup the search, to improve the quality of the obtained solutions, to improve the robustness, and to solve large-scale problems. The clear separation between parallel design and parallel implementation aspects of **EAs** is important to analyze parallel **EAs**. The most important lessons of this chapter can be summarized as follows:

- In terms of parallel design, the different parallel models for mono-objective **EAs** have been unified. Three hierarchical parallel models have been extracted: algorithmic level, iteration level, and solution level parallel models.
- In terms of parallel implementation, the question of an efficient mapping of a parallel model of **EAs** on a given parallel architecture and programming environment (i.e., language, library, and middleware) is handled. The focus was made on the key criteria of

parallel architectures that influence the efficiency of an implementation of parallel **EAs**.

- The use of the ParadisEO-PEO software framework allows the parallel design of the different parallel models of **EAs**. It also allows their transparent and efficient implementation on different parallel and distributed architectures (e.g., clusters and networks of workstations, multicores, **GPUs**, high-performance computing and desktop grids) using suitable programming environments (e.g., **MPI**, Threads, Globus, Condor, **CUDA**).

One of the perspectives in the coming years is to achieve Petascale performance. The emergence of heterogeneous platforms composed of multicore chips and many-core chips technologies will speedup the achievement of this goal. In terms of programming models, cloud computing will become an important alternative to traditional high-performance computing for the

development of large-scale **EAs** that harness massive computational resources. This is a great challenge as nowadays cloud frameworks for parallel **EAs** are just emerging.

In the future design of high-performance computers, the ratio between power and performance will be increasingly important. The power represents the electrical power consumption of the computer. An excess in power consumption uses unnecessary energy, generates waste heat and decreases reliability. Very few vendors of high-performance architecture publicize the power consumption data compared to the performance data (the web site [www.green500.org](http://www.green500.org) ranks the top 500 ma-

chines using the number of megaflops they produce for each watt of power and complements the [www.top500.org](http://www.top500.org) site).

In terms of target optimization problems, parallel **EAs** constitute unavoidable approaches to solve large-scale real-life challenging problems (e.g., engineering design, drug design) [55.23]. They are also an important alternative to solve dynamic and robust optimization problems, in which the complexities in terms of time and quality are more difficult to handle by traditional sequential approaches. Moreover, parallel models for optimization and learning problems under the presence of uncertainty have to be deeply investigated.

# How to Create Generalizable Results

Thomas Bartz-Beielstein

Basically, this chapter tries to find answers for the following fundamental questions in experimental research.

- (Q-1) How can problem instances be generated?
- (Q-2) How can experimental results be generalized?

The chapter is structured as follows. Section 56.2 introduces real-world and artificial optimization problems. Algorithms are described in Sect. 56.3. Objective functions and statistical models are introduced in Sect. 56.4; these models take problem and algorithm features into consideration. Section 56.5 presents case studies that illustrate our methodology. The chapter closes with a summary and an outlook.

## 56.1 Test Problems in Computational Intelligence

*Computational intelligence (CI)* methods have gained importance in several real-world domains such as process optimization, system identification, data mining, or statistical quality control. Tools to determine the applicability of CI methods in these application domains in an objective manner are missing. Statistics provide methods for comparing algorithms on certain data sets. In the past, several test suites were presented and considered as state of the art. However, these test suites have several drawbacks, namely:

- Problem instances are mostly artificial and have no direct link to real-world settings.
- Since there is a fixed number of test instances, algorithms can be fitted or tuned to this specific and very limited set of test functions. As a consequence, studies (benchmarks) provide insight how these algorithms perform on this specific set of test

instances, but no insight on how they perform in general.

- Statistical tools for comparisons of several algorithms on several test problem instances are relatively complex and not easy to analyze.

We propose a methodology to overcome these difficulties. This methodology, which generates problem classes rather than uses one instance, is constructed as follows:

1. First, we pre-process the underlying real-world data.
2. In a second step, features from these data are extracted. This extraction relies on the assumption that mathematical variables can be used to represent real-world features. For example, decomposition techniques can be applied to model the underlying data structures, if we are using time-series data. The

- original time series is deconstructed into a number of component series, where each of these reflects a certain type of behavior, e.g., a trend or seasonality [56.1]. We obtain an analytical model of the data.
3. Then, we parameterize this model. Based on this parametrization and randomization, we can generate infinitely many new problem instances.
  4. If no real-world data are available, problem instances can be generated using test-problem generators. The generation of test problems, which are well-founded and have practical relevance, has been an on-going field of research for several decades.
  5. From this infinite set, we can draw a limited number of problem instances which will be used for the comparison.
  6. Since problem instances are selected randomly, we apply random and mixed models for the analysis [56.2]. Mixed models include fixed and random effects. A fixed effect is an unknown constant. Its estimation from the data is a common practice in analysis of variance (**ANOVA**) or regression. A random effect is a random variable. We estimate the parameters that describe its distribution, because – in contrast to fixed effects –

it makes no sense to estimate the random effect itself.

This chapter combines ideas from two approaches: problem generation and statistical analysis of computer experiments. The work presented by Chiarandini and Goegebeur [56.3] provides the basis of our statistical analysis. They present a systematic and well-developed framework for mixed models. Related modeling approaches were suggested by McGeoch [56.4] and Birattari [56.5]. Gallagher and Yuan [56.6] present a problem instance (landscape) generator that is parameterized by a small number of parameters, and the values of these parameters have a direct and intuitive interpretation in terms of the geometric features of the landscapes that they produce. Castiñeiras et al. [56.7] present a parameterizable benchmark generator for bin packing instances based on the well-known Weibull distribution. Using the shape and scale parameters of the Weibull distribution, the authors generate benchmarks that contain a variety of item size distributions. They report that for all bin capacities, the number of bins required in an optimal solution increases as the Weibull shape parameter increases. Using this feature, scalability is enabled.

## 56.2 Features of Optimization Problems

### 56.2.1 Problem Classes and Instances

Nowadays, it is common practice in optimization to choose a *fixed* set of problem instances in advance and to apply classical **ANOVA** or regression analysis. In many experimental studies a few problem instances  $\pi_i$  ( $i = 1, 2, \dots, q$ ) are used and the results of some runs of the algorithms  $\alpha_j$  ( $j = 1, 2, \dots, h$ ) on these instances are collected. The instances can be treated as *blocks* and all algorithms are run on each single instance. Results are grouped per instance  $\pi_i$ . Analyses of these experiments shed some light on the performance of the algorithms on those specific instances. However, the interest of the researcher should not be just the performance of the algorithms on those specific instances chosen, but rather on the generalization of the results to the entire class  $\Pi$ . Generalizations about the algorithm's performance on new problem instances are difficult or impossible in this setting.

Based on ideas from Chiarandini and Goegebeur [56.3], to overcome this difficulty, we propose the following approach: a small set of problem in-

stances  $\{\pi_i \in \Pi | i = 1, 2, \dots, q\}$  is chosen at random from a large set, or class  $\Pi$ , of possible instances of the problem. Problem instances are considered as factor levels. However, this factor is of a different nature from the fixed algorithmic factors in the classical **ANOVA** setting. Indeed, the levels are chosen at random and the interest is not in these specific levels but in the problem class  $\Pi$  from which they are sampled. Therefore, the levels and the factor are *random*. Consequently, our results are not based on a limited, fixed number of problem instances. They are randomly drawn from an infinite set, which enables generalization.

### 56.2.2 Feature Extraction and Instance Generation

A problem class  $\Pi$  can be generated in different manners. We will consider *artificial* and *natural* problem class generators. Artificially generated problems allow feature generation based on some predefined characteristics. They are basically theory driven, i.e., the researcher defines certain features such as linearity or

multi modality. Based on these features, a model (formula) is constructed. By integrating parameters into this formula, many problem instances can be generated by parameter variation. We will exemplify this approach in the following paragraph. The second way, which will generate natural problem classes, uses a three-stage approach. First, the real-world system and its components are described. Then, features are extracted from a real-world system. Based on this feature set, a model is defined. Adding parameters to this model, new problem instances can be generated. There is also a third way to generate test instances: if we are lucky, many data are available. In this case, we can sample a limited number of problem instances from the larger set of real-world data. The statistical analysis is similar for these three cases.

### Artificial Test Functions

Several problem instance generators have been proposed over the last years. For example, *Gallagher* and *Yuan* present a landscape test generator, which can be used to set up problem instances for continuous, bound-constrained optimization problems [56.6]. The *Max-set of Gaussian landscape generator* (**MSG**) uses the maximum of  $m$  weighted Gaussian functions

$$G(x) = \max_{i \in 1, 2, \dots, m} (w_i g_i(x)),$$

where  $g : \mathbb{R}^n \rightarrow \mathbb{R}$  denotes an  $n$ -dimensional Gaussian function

$$g(x) = \left( \frac{\exp\left(-\frac{1}{2}(x - \mu)\Sigma^{-1}(x - \mu)^T\right)}{(2\pi)^{n/2}|\Sigma|^{1/2}} \right)^{1/n},$$

$\mu$  is an  $n$ -dimensional vector of means, and  $\Sigma$  is an  $(n \times n)$  covariance matrix. The mean of each Gaussian corresponds to an optimum on the landscape and the location of all optima is known. The global optimum is the one with the largest value. We will use the **MSG** problem instance generator in Sect. 56.5 to demonstrate our approach.

### Natural Problem Classes

This section exemplifies the three fundamental steps for generating real-world problem instances, namely:

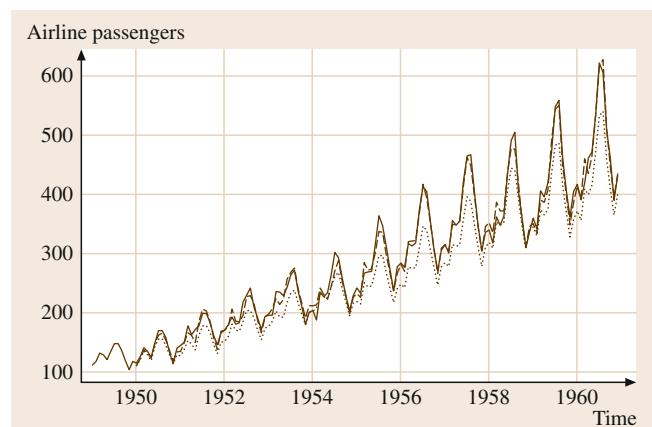

1. Describing the real-world system and its data
2. Feature extraction and model construction
3. Instance generation.

We will illustrate this procedure by using the classic Box and Jenkins airline data [56.8]. These data contain

the monthly totals of international airline passengers from 1949 to 1961. The feature extraction is based on methods from time-series analysis. Because of its simplicity the Holt–Winters method is popular in many application domains. It is able to adapt to changes in trends and seasonal patterns. The Holt–Winters prediction function requires the estimation of three parameters, i. e.,  $\alpha$ ,  $\beta$  and  $\gamma$ , which can be estimated from original time-series data. Their optimal values are determined by minimizing the squared one-step prediction error. To generate new problem instances, these parameters can be slightly modified. Based on these modified values, the model is re-fitted. Finally, we can extract the new time series. One typical result from this instance generation is shown in Fig. 56.1. *Bartz-Beielstein* [56.9] describes this procedure in detail.

To illustrate the wide applicability of this approach, we will list further real-work problem domains, which are subject of our current research:

- *Smart metering*: The development of accurate forecasting methods for electrical energy consumption profiles is an important task. We consider time series collected from a manufacturing process. Each time series contains quarter-hourly samples of the energy consumption of a bakery. A detailed data description can be found in [56.10].
- *Water industry*: *Canary* is a software developed by the *United States Environmental Protection Agency (US EPA)* and Sandia National Laboratories. Its purpose is to detect events in the context of wa-

**Fig. 56.1** Holt–Winters problem instance generator. The *solid line* represents the real data, the *dotted line* predictions from the Holt–Winters model and the *fine dotted line* modified predictions, respectively

ter contamination. An event is in this context defined as a certain time period where a contaminant significantly deteriorates the water quality. Distinguishing events from (i) background changes, (ii) maintenance and modification due to operation, and (iii) outliers is an essential task, which was implemented in the Canary software. Therefore, deviations are compared to regular patterns and short term changes. The corresponding data contains multi-variate time-series data. It is a selection from a larger dataset shipped with the open source event-detection software CANARY developed by [US EPA](#) and Sandia National Laboratories [56.11].

- **Finance:** The data are real-world data from intraday *foreign exchange (FX)* trading. The **FX** market is a financial market for trading currencies to enable international trade and investment. It is the largest and most liquid financial market in the world. Currencies can be traded via a wide variety of different financial instruments, ranging from simple spot trades over to highly complex derivatives.

We use three foreign exchange (currency rate) time series collected from Bloomberg. Each time series contains hourly samples of the change in currency exchange rate [56.12].

One typical goal in forecasting is the minimization of the forecast errors or the differences between real (observed) values, say  $y_i$ , and predicted values, say  $\hat{y}_i$ . This goal can be considered as an optimization problem.

As stated in Sect. 56.2.2, the statistical analysis is similar for artificial and natural problem classes. Our goal can be stated as follows: For a given problem class  $\Pi$ , which can be artificial or natural, we try to determine if an optimization algorithm  $\alpha$  or several algorithm instances  $\alpha_i$  show similar behavior on randomly selected problem instances  $\pi_i \in \Pi$ . This question will be formulated as a statistical hypothesis. Based on the related statistical framework, we can determine confidence intervals for the performance of the algorithm on unseen problem instances.

## 56.3 Algorithm Features

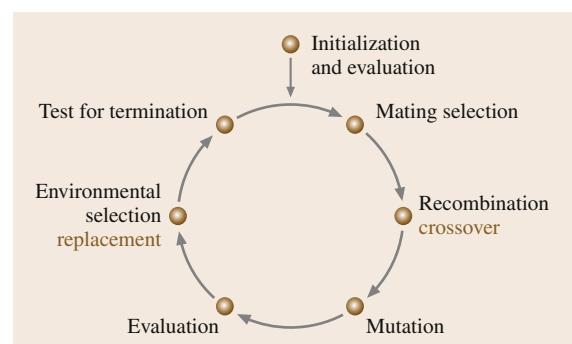

### 56.3.1 Factors and Levels

*Evolutionary algorithms (EA)* belong to the large class of bio-inspired search heuristics. They combine specific components, which may be *qualitative*, like the recombination operator or *quantitative*, like the population size. Our interest is in understanding the contribution of these components. In statistical terms, these components are called *factors*. The interest is in the effects of the specific *levels* chosen for these factors. Hence, we say that the levels and, consequently, the factors are *fixed*. Although modern search techniques like sequential parameter optimization or Pareto genetic programming [56.13] allow multi-objective performance measures (solution quality versus variability or description length), we restrict ourselves to analyzing the effect of these factors on a univariate measure of performance. We will use the quality of the solutions returned by the algorithm at termination as the performance measure.

### 56.3.2 Example: Evolution Strategy

*Evolution strategies (ES)* are prominent representatives of evolutionary algorithms, which includes genetic algorithms and genetic programming as well [56.15].

They can be classified as generic population-based metaheuristic optimization algorithms for global optimization that in some sense mimics the natural evolution. Evolution strategies are applied to hard real-valued optimization problems. Mutation is performed by adding a normally distributed random value to each vector component. The standard deviation of these random values is modified by self-adaptation. Evolution

**Fig. 56.2** The evolutionary cycle, basic working scheme of all **ES** and **EA**. Terms common for describing evolution strategies are used, alternative terms are added below in brown

**Table 56.1** Settings of exogenous parameters of an **ES**. Recombination operators are labeled as follows: 1 = no, 2 = dominant, 3 = intermediate, 4 = intermediate as in [56.14]. Mutation uses the following encoding: 1 = no mutation, 2 = self adaptive mutation

| Parameter | Symbol            | Name                                                             | Range            | Value |
|-----------|-------------------|------------------------------------------------------------------|------------------|-------|

| sel       | $\kappa$          | Maximum age                                                      | $\mathbb{R}_+$   | 1.0   |
| mutation  |                   | Mutation                                                         | $\{1, 2\}$       | 2     |
| sreco     | $r_\sigma$        | Recombination operator for strategy variables                    | $\{1, 2, 3, 4\}$ | 3     |
| oreco     | $r_x$             | Recombination operator for object variables                      | $\{1, 2, 3, 4\}$ | 2     |

strategies can use a population of several solutions. Each solution is considered as individual and consists of object and strategy variables. Object variables represent the position in the search space, whereas strategy variables store the step sizes, i.e., the standard deviations for the mutation. We analyze the **ES** basic variant, which was proposed in [56.14].

Mutation means neighborhood-based movement in search space, which includes the exploration of the *outer space* currently not covered by a population, whereas recombination rearranges existing information and so focuses on the *inner space*. Selection is meant to introduce a bias towards better fitness values. A concrete **ES** may contain specific mutation, recombination, or selection operators, or call them only with a certain probability, but the control flow is usually left

unchanged. Each of the consecutive cycles is termed a *generation*. The control flow is shown in Fig. 56.2.

Concerning the representation, it should be noted that most empiric studies are based on canonical forms as binary strings or real-valued vectors, whereas many real-world applications require specialized, problem-dependent ones. Table 56.1 summarizes important **ES** parameters. This chapter presents two case studies. The first case study is based on a fixed **ES** parameter setting, whereas the second case study modifies the recombination operator for object variables. We are convinced that the applicability of the methods presented in this chapter goes far beyond the simplified case studies. Our main contribution is a framework, which allows conclusions that are not limited to a small number of problem instances but to problem classes.

## 56.4 Objective Functions

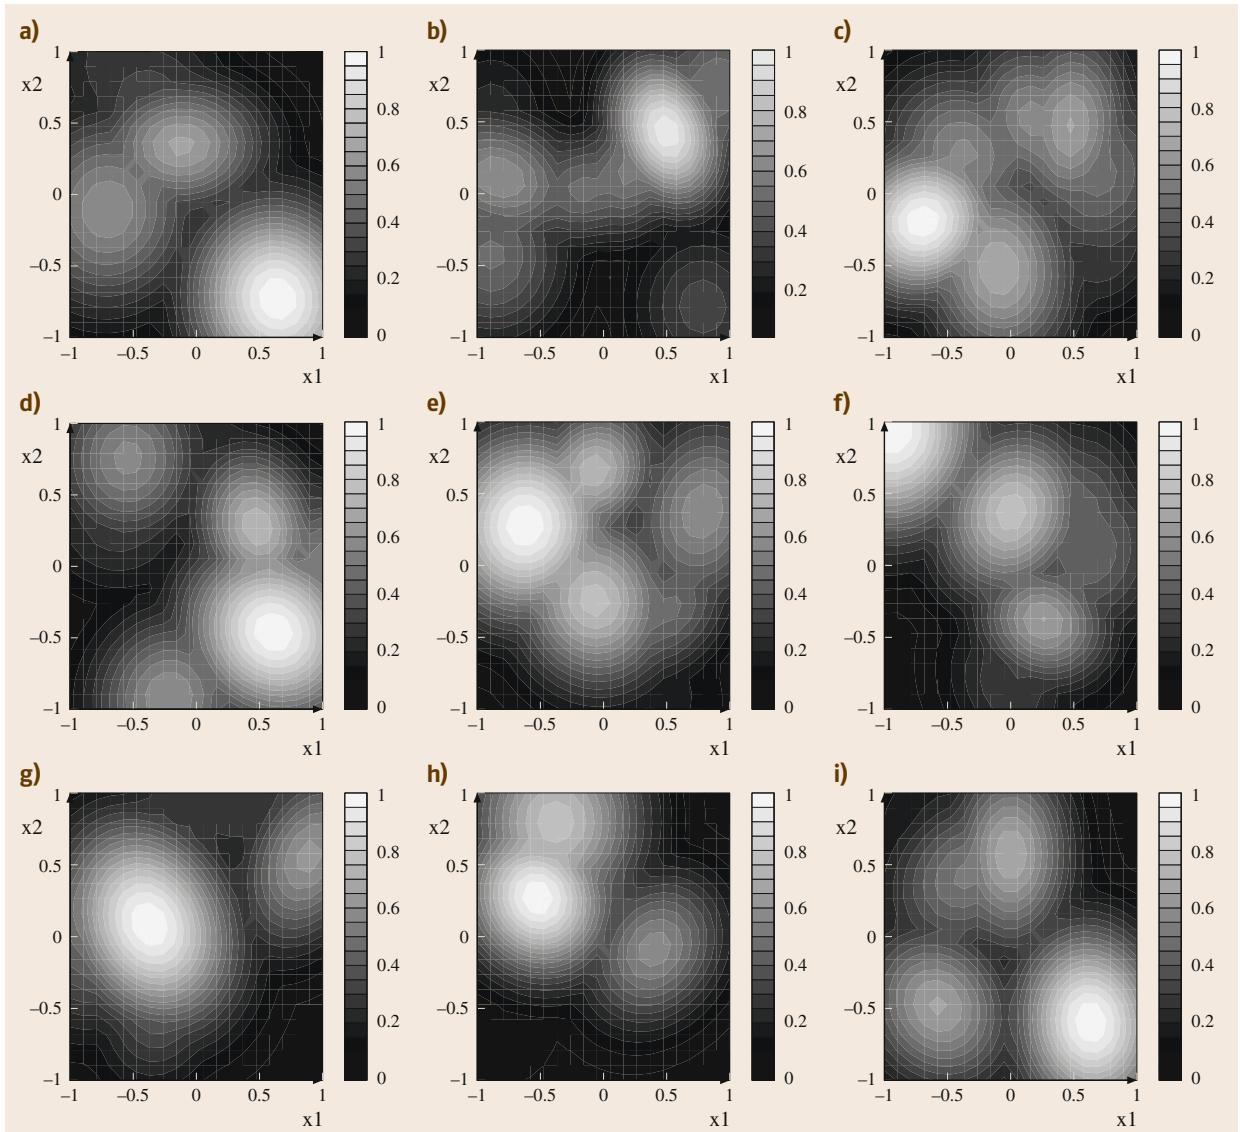

We will use the following optimization framework: an **ES** is applied as a minimizer on the test function  $f(x)$ . Formally speaking, let  $S$  denote some set, e.g.,  $S \subseteq \mathbb{R}^n$ . We are seeking for values  $f^*$  and  $x^*$ , such that  $\min_{x \in S} f(x)$  with  $f^* = \min_{x \in S} f(x)$  and  $x^* = \arg \min f(x)$ . This approach can be extended in many ways. For example, if  $S$  denotes times-series data, then an optimization algorithm can be applied to minimize the empirical mean squared prediction error.

Test problem instances will be drawn from Gallagher's and Yuan's **MSG** test function generator. The following parameters can be used to specify the **MSG** generator:

- The number of Gaussian components  $m$ .
- The mean vector  $\mu$  of each component.
- The covariance matrix  $\Sigma$  of each component.
- The weight of each component  $w_i$ .
- A maximum threshold  $t \in [0; 1]$  can be specified for local optima and the fitness value of the global optimum  $G^*$ . Local optima are randomly generated within  $[0; t \times G^*]$ .

The following tuple can be used to specify an **MSG** generator

$$\Pi := ([-c, c]^n, n, m, D_\mu, \{D_\Sigma\}, \{t, G^*\}) , \quad (56.1)$$

**Fig. 56.3a–i** Nine test problem instances from  $\Pi_{\text{MSG}}$ , generated with the [MSG](#) landscape generator as specified in (56.2). These figures exemplify how numbers and locations of the randomly generated optima can vary. Usually, the optima are evenly distributed in the search space. In some settings, there are a few dominating optima as can be seen in part (g)

where  $c \in \mathbb{R}$  defines the boundary constraints of the search space,  $n$  the search space dimensionality,  $m$  the number of Gaussian components,  $D_\mu$  the distribution used to generate the mean vectors of components,  $D_\Sigma$  the distribution or procedures used to generate covariances of components,  $t \in [0; 1]$  the threshold for local optima, and  $G^*$  the function value of the global optimum.

Based on (56.1), we have specified the following [MSG](#) landscape generator for our experiments

$$\begin{aligned} \Pi_{\text{MSG}} := & \left( [-1; 1]^2, 2, 10, \mathcal{U}[-1; 1], \right. \\ & \left. \{\mathcal{U}[0.05; 0.15], \mathcal{U}[-\pi/4, \pi/4]\}, \{0.8, 1\} \right). \end{aligned} \quad (56.2)$$

With this setting, the mean vector of each component is generated randomly within  $[-1, 1]^2$ . The covariance

matrix of each component is generated with the procedure  $D_{\Sigma}$  in three steps:

1. A diagonal matrix  $\mathbf{S}$  with eigenvalues is generated.
2. An orthogonal matrix  $\mathbf{T}$  is generated through  $n(n - 1)/2$  rotations with random angles between  $[-\pi/4, \pi/4]$ .
3. The covariance matrix is generated as  $\mathbf{T}^T \mathbf{S} \mathbf{T}$ .

The weight  $w_i$  of the component corresponding to the global optimum is set to 1 while other weights are randomly generated within  $[0; 0.8]$ . The nine problem instances,  $\pi_i \in \Pi_{MSG}$ , ( $i = 1, \dots, 9$ )

from Fig. 56.3 were generated with this parametrization.

Note that we are using the distance to the optimum as an objective function in our experiments. Our objective function reads  $G^* - f(x)$ , because we are considering minimization problems. Other measures of interest might be the *gap percent of optimality*

$$\frac{(G^* - f(x))}{G^*} \times 100,$$

or computation time, etc., see, e.g., [56.16].

## 56.5 Case Studies

Bartz-Beielstein [56.9] introduced the acronyms:

- **SASP**: one single algorithm and one single problem instance
- **SAMP**: one single algorithm and multiple problems instances
- **MASP**: multiple algorithms and one single problem instance
- **MAMS**: multiple algorithms and multiple problem instances

for classifying optimization designs [56.17].

### 56.5.1 Single Problem Designs: **SASP** and **MASP**

In **SASP** we analyze the performance of an *optimization algorithm*  $\alpha$  on a single problem instance  $\pi$ . An optimization problem has a set of input data which instantiate the problem. This might be a function in continuous optimization or the location and distances between cities in a traveling salesman problem. In the following, we will use  $Y$  to denote the random performance measure obtained by  $r$  runs of algorithm  $\alpha$  on problem instance  $\pi$ . Because many optimization algorithms such as evolutionary algorithms are randomized, their performance  $Y$  on one instance is a random variable. It might be described by a probability density/mass function  $p(y|\pi)$ . Running the algorithm with different random seeds on one problem instance, we collect sample data  $y_1, \dots, y_r$ , which are *independent and identically distributed* (i.i.d.).

There are situations, in which **SASP** is the method of first choice. Real-world problems, which have to be solved only once in a very limited time, are good ex-

amples for using **SASP** optimizations. **MASP** shares several characteristics with **SASP**. Because of their limited capacities for generalization, **SASP** and **MASP** will not be investigated further in this study.

### 56.5.2 SAMP: Single Algorithm, Multiple Problems

#### Fixed-Effects Models

This setup is commonly used for testing an algorithm on a given (fixed) set of problem instances. Standard assumptions from *analysis of variance* (**ANOVA**) lead us to propose the following *fixed-effects model* [56.2]

$$Y_{ij} = \mu + \tau_i + \varepsilon_{ij}, \quad (56.3)$$

where  $\mu$  is an overall mean,  $\tau_i$  is a parameter unique to the  $i$ -th treatment (problem instance factor), and  $\varepsilon_{ij}$  is a random error term for replication  $j$  on problem instance  $i$ . Usually, the model errors  $\varepsilon_{ij}$  are assumed to be normally and independently distributed with mean zero and variance  $\sigma^2$ . If problem instance factors are considered fixed, i. e., non random, the stochastic behavior of the response variable originates from the algorithm. This implies the experimental results

$$Y_{ij} \approx N(\mu + \tau_i, \sigma^2), \quad i = 1, \dots, q, j = 1, \dots, r, \quad (56.4)$$

and that the  $Y_{ij}$  are mutually independent. Results from statistical analyses remain valid only on the specific instances. Furthermore, **SAMP** with a fixed set of problem instances is subject to criticism, e.g., that algorithms are trained for this specific set up test instances (over fitting).

In order to make the results of the analysis independent of the specific instances and dependent instead

on the class of instances from which the specific instances are drawn, Chiarandini and Goedgebeur propose randomized and mixed models for the experimental analysis of optimization algorithms as an extension of (56.3) [56.3]. In contrast to model (56.3), these models allow generalizations of results to the whole class of instances.

### Randomized Models

In the following, we consider a population or *class* of instances  $\Pi$ . The class  $\Pi$  consists of a large, possibly an infinite, number of problem instances  $\pi_i, i = 1, 2, 3, \dots$ . Let  $p(\pi)$  denote the probability of sampling instance  $\pi$ . The performance  $Y$  of the algorithm  $\alpha$  on the class  $\Pi$  is described by the probability function

$$p(y) = \sum_{\pi \in \Pi} p(y|\pi)p(\pi). \quad (56.5)$$

If we run an algorithm  $\alpha$   $r$  times on instance  $\pi$ , then we receive  $r$  replicates of  $\alpha$ 's performance, denoted by  $Y_1, \dots, Y_r$ . These  $r$  observations are *i.i.d.*, i.e.,

$$p(y_1, \dots, y_r|\pi) = \prod_{j=1}^r p(y_j|\pi). \quad (56.6)$$

So far, we have considered  $r$  replicates of the performance measure  $Y$  on *one* problem instance  $\pi$ . Now we consider *several*, randomly sampled problem instances. Over all the instances the joint probability distribution of the observed performance measures is obtained by marginalizing over all instances

$$p(y_1, \dots, y_r) = \sum_{\pi \in \Pi} p(y_1, \dots, y_r|\pi)p(\pi). \quad (56.7)$$

Extending the model (56.7) to the case where one algorithm with several parameter settings or several algorithms are analyzed leads to mixed models, which will be discussed in Sect. 56.5.3.

### Example SAMP: ES on $\Pi_1$ (Random-Effects Design)

The simplest random-effects experiment is performed as follows. For  $i = 1, \dots, q$  a problem instance  $\pi_i$  is drawn randomly from the class of problem instances  $\Pi$ . On each of the sampled  $\pi_i$ , the algorithm  $\alpha$  is run  $r$  times using different seeds for  $\alpha$ . Due to  $\alpha$ 's stochastic nature, we obtain, *conditionally on the sampled instance*,  $r$  replications of the performance measure that are *i.i.d.*

Let  $Y_{ij}$  ( $i = 1, \dots, q; j = 1, \dots, r$ ) denote the random performance measure obtained in the  $j$ -th replication of  $\alpha$  on  $\pi_i$ . We are interested in drawing conclusions about  $\alpha$ 's performance on a larger set of problem instances from  $\Pi$  and not just on those  $q$  problem instances included in the experiment. A systematic approach to accomplish this task comprehends the following steps:

- **SAMP-1** algorithm and problem instances
- **SAMP-2 ANOVA** and restricted maximum likelihood estimator (**REML**) model building
- **SAMP-3** validation of the model assumptions
- **SAMP-4** hypothesis testing
- **SAMP-5** Confidence intervals and prediction.

**SAMP-1 Algorithm and Problem Instances.** The goal of this case study is to analyze if one algorithm shows a similar performance on a class of problem instances, say  $\Pi_{MSG}$ . A random-effects design will be used to model the results. We illustrate the decomposition of the variance of the response values in (i) the variance due to problem instance and (ii) the variance due to the algorithm and derive results, which are based on hypotheses testing as introduced in (56.12).

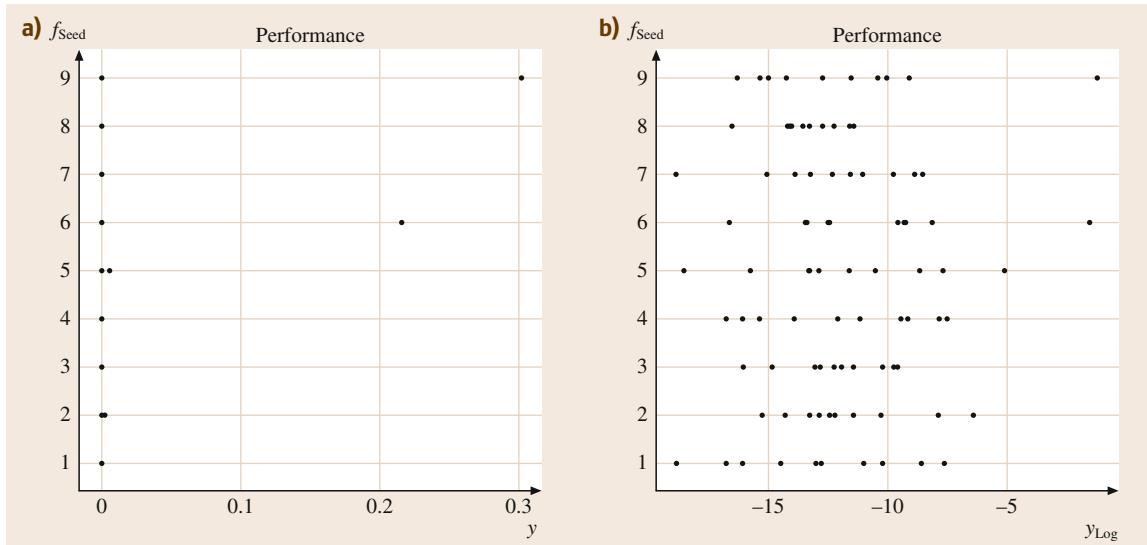

We consider one algorithm, an **ES**, which is run  $r = 10$  times on a set of randomly generated problem instances. The **ES** is parameterized with the default setting from Table 56.1. These parameters are kept constant during the experiment. Nine instances are drawn from the set of problem instances  $\Pi_{MSG}$ . Problem instances were generated with the **MSG** landscape generator as specified in (56.2). The corresponding problem instances are shown in Fig. 56.3.

The null hypothesis reads *There is no instance effect*. Since we are considering the **SAMP** case, our experiment is based on one **ES** instance only. There are 90 observations, because 10 repeats were performed on 9 problem instances. Figure 56.4 shows the performance of the **ES** on these nine instances. The variable **fSeed** is used to denote the problem instance number  $\pi_i$ .

### SAMP-2 ANOVA and REML Model Building.

**ANOVA Model Building.** The following analysis is based on the linear statistical model

$$Y_{ij} = \mu + \tau_i + \varepsilon_{ij} \begin{cases} i = 1, \dots, q, \\ j = 1, \dots, r, \end{cases} \quad (56.8)$$

**Fig. 56.4a,b** Performance of the ES on nine test problem instances. (a) Problem instances plotted versus algorithm performance. (b) Problem instances plotted against logarithmic performance. Smaller values are better

where  $\mu$  is an overall mean and  $\varepsilon_{ij}$  is a random error term for replication  $j$  on instance  $i$ . Note that in contrast to the fixed-effects model from (56.3),  $\tau_i$  is a random variable representing the effect of instance  $i$ . The stochastic behavior of the response variable originates from both the instance and the algorithm. This is reflected in (56.8), where both  $\tau_i$  and  $\varepsilon_{ij}$  are random variables. The model (56.8) is the so-called *random-effects model*, cf. [56.2] or [56.3].

We assume that  $\tau_1, \dots, \tau_q$  are i.i.d.  $\mathcal{N}(0, \sigma_\tau^2)$  and  $\varepsilon_{ij}, i = 1, \dots, q, j = 1, \dots, r$ , are i.i.d.  $\mathcal{N}(0, \sigma^2)$ . If  $\tau_i$  is independent of  $\varepsilon_{ij}$  and has variance  $V(\tau_i) = \sigma_\tau^2$ , the variance of any observation is  $V(Y_{ij}) = \sigma^2 + \sigma_\tau^2$ . Similar to the partition in classical ANOVA, the variability in the observations can be partitioned into a component that measures the variation between treatments and a component that measures the variation within treatments. Based on the fundamental ANOVA identity  $SS_{\text{total}} = SS_{\text{treat}} + SS_{\text{err}}$ , we define

$$MS_{\text{treat}} = \frac{SS_{\text{treat}}}{q-1} = \frac{r \sum_{i=1}^q (\bar{Y}_i - \bar{Y}_{..})^2}{q-1},$$

and

$$MS_{\text{err}} = \frac{SS_{\text{err}}}{q(r-1)} = \frac{\sum_{i=1}^q \sum_{j=1}^r (Y_{ij} - \bar{Y}_{i..})^2}{q(r-1)}.$$

It can be shown that

$$E(MS_{\text{treat}}) = \sigma^2 + r\sigma_\tau^2 \quad \text{and} \quad E(MS_{\text{err}}) = \sigma^2, \quad (56.9)$$

cf. [56.2]. Therefore, the estimators of the variance components are

$$\hat{\sigma}^2 = MS_{\text{err}}, \quad (56.10)$$

$$\hat{\sigma}_\tau^2 = \frac{MS_{\text{treat}} - MS_{\text{err}}}{r}. \quad (56.11)$$

The corresponding ANOVA table is shown in Table 56.2. Based on ANOVA calculations, with (56.10) we obtain an estimator of the first variance component  $\hat{\sigma}^2 = -0.4848257$ , and from (56.11), we obtain

**Table 56.2** ANOVA table for a one-factor fixed and random effects models

| Source of variation | Sum of squares      | Degrees of freedom | Mean square         | EMS fixed                                        | EMS random                  |
|---------------------|---------------------|--------------------|---------------------|--------------------------------------------------|-----------------------------|
| Treatment           | $SS_{\text{treat}}$ | $q-1$              | $MS_{\text{treat}}$ | $\sigma^2 + r \frac{\sum_{i=1}^q \tau_i^2}{q-1}$ | $\sigma^2 + r\sigma_\tau^2$ |
| Error               | $SS_{\text{err}}$   | $q(r-1)$           | $MS_{\text{err}}$   | $\sigma^2$                                       | $\sigma^2$                  |
| Total               | $SS_{\text{total}}$ | $qr-1$             |                     |                                                  |                             |

the second component  $\hat{\sigma}_\tau^2 = 11.32854$ . The model variance can be determined as  $\hat{\sigma}^2 + \hat{\sigma}_\tau^2 = 10.84372$ . The mean  $\mu = -12.05554$  from (56.8) can be extracted. Finally, the  $p$  value in the ANOVA table is calculated as 0.7979083.

Note that we have obtained a negative variance. Since negative variances are not feasible, we can proceed by setting their values to zero and proceed with these modified values. A more elegant way is presented in the following.

**Restricted Maximum Likelihood.** In some cases, the standard ANOVA, which was used in our example, produces a negative estimate of a variance component. This can be seen in (56.11): if  $MS_{\text{err}} > MS_{\text{treat}}$ , negative values occur. By definition, variance components are positive. Methods that always yield positive variance components have been developed. Here, we will use *restricted maximum likelihood estimators* (REML). The ANOVA method of variance component estimation, which is a method of moments procedure, and REML estimation may lead to different results. Output from an R-based analysis with the function `lme` from the package `lme4` reads as follows (`fSeed` denotes the problem instance) [56.18]:

```
Linear mixed model fit by REML
Formula: yLog ~ 1 + (1 | fSeed)
Data: samp.df
AIC   BIC logLik deviance REMLdev
475.6 483.1 -234.8    469.3    469.6
Random effects:
Groups   Name        Variance Std.Dev.
fSeed    (Intercept) 0.000    0.0000
```

```
Residual           10.893 3.3004
Number of obs: 90, groups: fSeed, 9
```

#### Fixed effects:

|             | Estimate | Std. Error | t value |
|-------------|----------|------------|---------|
| (Intercept) | -12.0555 | 0.3479     | -34.65  |

Compared to the ANOVA setting, different values for  $\hat{\sigma}^2$ ,  $\hat{\sigma}_\tau^2$ , and  $\mu$  were obtained. However, the REML-based analysis also shows that the variability in the response observations can be attributed to the variability of the algorithm.

**SAMP-3 Validation of the Model Assumptions.** Before performing hypothesis testing based on the models introduced in SAMP-2, the validity of the model assumptions has to be investigated. If the model is adequate, the residuals should exhibit no structure. Residuals are plotted against fitted values to check the assumption of homoscedasticity and quantile-quantile (Q-Q) plots are used to check if residuals meet the normality assumption. Quantile-quantile plots of the residuals are shown in Fig. 56.5 for the raw and the log-transformed responses. These plots provide a good way to compare the distribution of a sample with a distribution. Large deviations from the line indicate non-normality of the sample data. These Q-Q plots indicate that a log transformation of the response might be useful in our setting.

**SAMP-4 Hypothesis Testing.** Testing hypotheses about individual treatments (instances) is useless be-

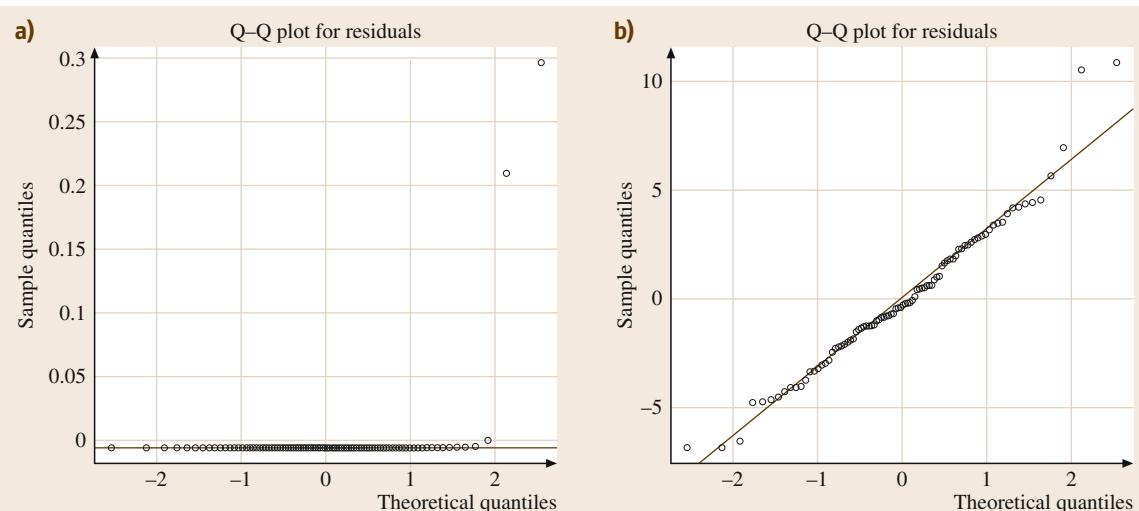

Fig. 56.5a,b (a) Q-Q plot of the residuals for raw data. (b) Q-Q plot for the log-transformed responses

cause the problem instances  $\pi_i$  are here considered as samples from some larger population of instances  $\Pi$ . We test hypotheses about the variance component  $\sigma_\tau^2$ , i.e., the null hypothesis

$$H_0 : \sigma_\tau^2 = 0 \text{ versus } H_1 : \sigma_\tau^2 > 0. \quad (56.12)$$

Under  $H_0$ , the algorithm performance is identical on all problem instances (*all treatments are identical*), i.e.,  $r\sigma_\tau^2$  is very small. Based on (56.9), we conclude that  $E(\text{MS}_{\text{treat}}) = \sigma^2 + r\sigma_\tau^2$  and  $E(\text{MS}_{\text{err}}) = \sigma^2$  are similar. Under the alternative, variability exists between treatments. Standard analysis shows that  $\text{SS}_{\text{err}}/\sigma^2$  is distributed as chi-square with  $q(r-1)$  degrees of freedom. Let  $F_{u,v}$  denote the  $F$  distribution with  $u$  numerator and  $v$  denominator degrees of freedom. Under  $H_0$ , the ratio

$$F_0 = \frac{\text{SS}_{\text{treat}}/q - 1}{\text{SS}_{\text{err}}/q(r-1)} = \frac{\text{MS}_{\text{treat}}}{\text{MS}_{\text{err}}}$$

is distributed as  $F_{q-1,q(r-1)}$ . To test hypotheses in (56.8), we require that  $\tau_1, \dots, \tau_q$  are **i.i.d.**  $\mathcal{N}(0, \sigma_\tau^2)$ ,  $\varepsilon_{ij}$ ,  $i = 1, \dots, q$ ,  $j = 1, \dots, r$ , are **i.i.d.**  $\mathcal{N}(0, \sigma^2)$ , and all  $\tau_i$  and  $\varepsilon_{ij}$  are independent of each other. These considerations lead to the decision rule to reject  $H_0$  at the significance level  $\alpha$  if

$$f_0 > F(1 - \alpha; q - 1, q(r - 1)), \quad (56.13)$$

where  $f_0$  is the realization of  $F_0$  from the data observed. An intuitive motivation for the form of statistic  $F_0$  can be obtained from the expected mean squares. Under  $H_0$  both  $\text{MS}_{\text{treat}}$  and  $\text{MS}_{\text{err}}$  estimate  $\sigma^2$  in an unbiased way, and  $F_0$  can be expected to be close to one. On the other hand, large values of  $F_0$  give evidence against  $H_0$ .

Regarding the **SAMP** case, we obtain the following values: Based on (56.9) and (56.13), we can determine the  $F$  statistic and the  $p$  value. We get  $\text{MS}_{\text{treat}} = \text{MS}_{\text{err}} = 10.89275$  and  $f_0 = 1$ , which results in a large  $p$  value: 0.4426363. The null hypothesis  $H_0 : \sigma_\tau^2 = 0$  from (56.12) cannot be rejected, i.e., we conclude that there is no instance effect. A similar conclusion was obtained from the **ANOVA** method of variance component estimation as introduced in Table 56.2.

**SAMP-5 Confidence Intervals and Prediction.** An unbiased estimator of the overall mean  $\mu$  is

$$\hat{\mu} = \bar{y}_{..} = \sum_{i=1}^q \sum_{j=1}^r \frac{y_{ij}}{(qr)}.$$

Its variance is given by

$$V(\bar{y}_{..}) = V\left(\sum_{i=1}^q \sum_{j=1}^r \frac{y_{ij}}{(qr)}\right) = \frac{r\sigma_\tau^2 + \sigma^2}{qr}.$$

With (56.9) and (56.10), we obtain an estimator of the variance of the overall mean  $\mu$  as

$$\hat{V}(\bar{y}_{..}) = \frac{\text{MS}_{\text{treat}}}{qr}.$$

Since

$$\frac{\bar{Y}_{..} - \mu}{\sqrt{\frac{\text{MS}_{\text{treat}}}{qr}}} \approx t_{q(r-1)},$$

the confidence limits for  $\mu$  can be derived as

$$\bar{y}_{..} \pm t_{1-\alpha/2;q(r-1)} \sqrt{\frac{\text{MS}_{\text{treat}}}{qr}}. \quad (56.14)$$

We conclude the **SAMP** case study with prediction of the algorithm's performance on a new instance from the same class. Based on (56.14), we obtain the following 95% confidence interval:  $[2.6773 \times 10^{-6}; 1.262 \times 10^{-5}]$ . Again, confidence intervals from the **REML** and **ANOVA** methods are very similar. Summarizing, we can conclude that the **ES** performs similarly on instances from  $\Pi_{\text{MSG}}$ , which were generated with (56.2).

### 56.5.3 MAMP: Multiple Algorithms, Multiple Problems

In the **MAMP** case study, fixed effects are included in the conditional structure of (56.6), which leads to a mixed model. Instead of one fixed algorithm as in the **SAMP** case, we consider either several algorithms or algorithms with several parameters. Both situations can be treated while considering algorithms as levels of a fixed factor, whereas problem instances are drawn randomly from the population of instances  $\Pi_{\text{MSG}}$ :

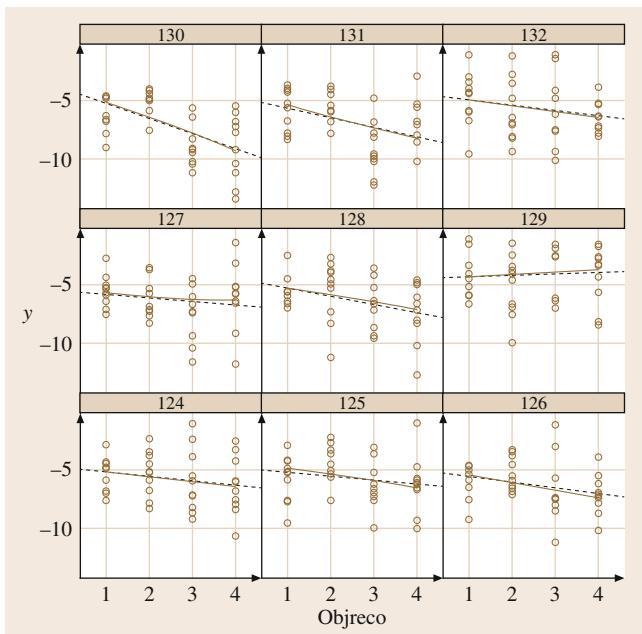

- **MAMP-1** algorithm and problem instances
- **MAMP-2 ANOVA** and **REML** model building
- **MAMP-3** validation of the model assumptions
- **MAMP-4** hypothesis testing:
  1. Random effects
  2. Fixed effects
- **MAMP-5** confidence intervals and prediction.

### MAMP-1 Algorithm and Problem Instances

We aim at comparing the performance of the **ES** with different recombination operators over an instance class. More precisely, we have four **ES** instances using recombination operators  $\{1, 2, 3, 4\}$  and nine instances randomly sampled from the class  $\Pi_{\text{MSG}}$  as illustrated in Fig. 56.3. Each run is repeated ten times. In this study  $4 \times 9 \times 10 = 360$  data were used. We are interested in the following questions:

- Is there an instance effect?
- Do the mean performances of the **ES** with different recombination operators differ?
- Do the instance–algorithm interactions contribute to the variability of the response?

A first visual inspection, which plots the performance of the algorithm within each problem instance, is shown in Fig. 56.6. In eight of the nine instances the linear regression line has a negative slope and the intercepts do not differ very much. This indicates that there is no significant interaction between the fixed and the random factors.

**Fig. 56.6** Four algorithms (**ES** with modified recombination operators) on nine test problem instances. Each *panel* represents one problem instance and problem instances are labeled from 124 to 130. Performance is plotted against the level of the recombination operator

### MAMP-2 ANOVA and REML Model Building

The variability in the performance measure can be decomposed according to the following *mixed-effects ANOVA model*

$$Y_{ijk} = \mu + \alpha_j + \tau_i + \gamma_{ij} + \varepsilon_{ijk}, \quad (56.15)$$

where  $\mu$  is an overall performance level common to all observations,  $\alpha_j$  is a fixed effect due to the algorithm  $j$ ,  $\tau_i$  is a random effect associated with instance  $i$ ,  $\gamma_{ij}$  is a random interaction between instance  $i$  and algorithm  $j$ , and  $\varepsilon_{ijk}$  is a random error for replication  $k$  of algorithm  $j$  on instance  $i$ . We assume that the  $\alpha_j$ 's are fixed effects such that  $\sum_{j=1}^h \alpha_j = 0$  and that the random elements  $\tau_i$  are i.i.d.  $\mathcal{N}(0, \sigma_\tau^2)$ ,  $\gamma_{ij}$  are i.i.d.  $\mathcal{N}(0, \sigma_\gamma^2)$ ,  $\varepsilon_{ijk}$  are i.i.d.  $\mathcal{N}(0, \sigma^2)$  and  $\tau_i$ ,  $\gamma_{ij}$  and  $\varepsilon_{ijk}$  are mutually independent random variables. Similarly to (56.6) the conditional distribution of the performance measure given the instance and the instance–algorithm interaction is given by

$$Y_{ijk} | \tau_i, \gamma_{ij} \approx \mathcal{N}(\mu + \alpha_j + \tau_i + \gamma_{ij}, \sigma^2), \quad (56.16)$$

with  $i = 1, \dots, q$ ,  $j = 1, \dots, h$ , and  $k = 1, \dots, r$ . The marginal model reads (after integrating out the random effects  $\tau_i$  and  $\gamma_{ij}$ ):

$$Y_{ijk} \approx \mathcal{N}(\mu + \alpha_j, \sigma^2 + \sigma_\tau^2 + \sigma_\gamma^2). \quad (56.17)$$

Based on these statistical assumptions, hypothesis tests can be performed about fixed and random factor effects. Using the mixed model (56.16), we are interested in testing whether there is a difference between the factor level means  $\mu + \alpha_j$  ( $j = 1, \dots, h$ ). The hypotheses for testing the fixed effects can be formulated as

$$H_0: \alpha_i = 0 \quad \forall i \quad \text{against} \quad H_1: \exists \alpha_j \neq 0. \quad (56.18)$$

Regarding random effects, tests about particular levels are useless. This is similar to the random-effects model (56.8). Again, we perform tests on the variance components  $\sigma_\tau^2$  and  $\sigma_\gamma^2$  instead. These can be formulated as follows

$$\begin{aligned} H_0: \sigma_\tau^2 &= 0, & \text{and} & \quad H_0: \sigma_\gamma^2 = 0, \\ H_1: \sigma_\tau^2 &> 0, & \text{and} & \quad H_1: \sigma_\gamma^2 > 0, \end{aligned} \quad (56.19)$$

respectively. If all treatment (problem instances) combinations have the same number of observations, i.e., if the design is balanced, the test statistics for these hypotheses are ratios of mean squares that are chosen such

**Table 56.3** Expected mean squares and consequent appropriate test statistics for a mixed two-factor model with  $h$  fixed factors,  $q$  random factors, and  $r$  repeats (after [56.3])

| Effects       | Mean squares | Df           | Expected mean squares                                             | Test statistics |
|---------------|--------------|--------------|-------------------------------------------------------------------|-----------------|
| Fixed factor  | MSA          | $h - 1$      | $\sigma^2 + r\sigma_y^2 + rq \frac{\sum_{j=1}^h \alpha_j^2}{h-1}$ | MSA/MSAB        |
| Random factor | MSB          | $q - 1$      | $\sigma^2 + r\sigma_y^2 + rho_\tau^2$                             | MSB/MSAB        |
| Interaction   | MSAB         | $(h-1)(q-1)$ | $\sigma^2 + r\sigma_y^2$                                          | MSAB/MSE        |
| Error         | MSE          | $hq(r-1)$    | $\sigma^2$                                                        |                 |

**Table 56.4** ANOVA for the MAMP case

| Mean squares | Factors       | Df  | Sum Sq  | Mean Sq | F value | Pr(>F) |
|--------------|---------------|-----|---------|---------|---------|--------|
| MSA          | objreco       | 3   | 154.59  | 51.53   | 11.05   | 0.0000 |
| MSB          | fSeed         | 8   | 251.79  | 31.47   | 6.75    | 0.0000 |
| MSAB         | objreco:fSeed | 24  | 185.60  | 7.73    | 1.66    | 0.0288 |
| MSE          | Residuals     | 324 | 1511.27 | 4.66    |         |        |

that the expected mean squares of the numerator differs from the expected mean squares of the denominator only by the variance components of the random factor under test. Chiarandini and Goegebeur [56.3] present the resulting analysis of variance, which is shown in Table 56.3.

### ANOVA Model Building

The ANOVA table for the experiments from the MAMP case study is shown in Table 56.4. Equating the observed mean squares in the lines of the ANOVA table to their expected values and solving for the variance components leads to the following equations [56.2]

$$\hat{\sigma}_\tau^2 = \frac{MSB - MSAB}{hr} = 0.593502,$$

$$\hat{\sigma}_y^2 = \frac{MSAB - MSE}{r} = 0.306907,$$

$$\hat{\sigma}^2 = MSE = 4.664423.$$

Next, we will compare these results to the REML-based analysis of the mixed model.

### REML Model Building

We have specified sum contrasts instead of the default treatment contrasts used in `lmer()`. Again, `fSeed` represents the problem instance, whereas the algorithm instance  $\alpha_j, j = 1, \dots, 4$ , is represented by `objreco`.

```
Linear mixed model fit by REML
Formula: yLog ~ objreco + (1 | fSeed)
          + (1 | fSeed:objreco)
```

Random effects:

| Groups        | Name        | Variance | Std.Dev. |
|---------------|-------------|----------|----------|
| fSeed:objreco | (Intercept) | 0.30691  | 0.55399  |
| fSeed         | (Intercept) | 0.59351  | 0.77039  |

Residual 4.66442 2.15973  
Number of obs: 360,  
groups: fSeed:objreco, 36; fSeed, 9

Fixed effects:

|             | Estimate | Std. Error | t value |
|-------------|----------|------------|---------|
| (Intercept) | -6.0222  | 0.2956     | -20.370 |
| objreco1    | 0.6176   | 0.2539     | 2.433   |
| objreco2    | 0.6918   | 0.2539     | 2.725   |
| objreco3    | -0.6671  | 0.2539     | -2.628  |

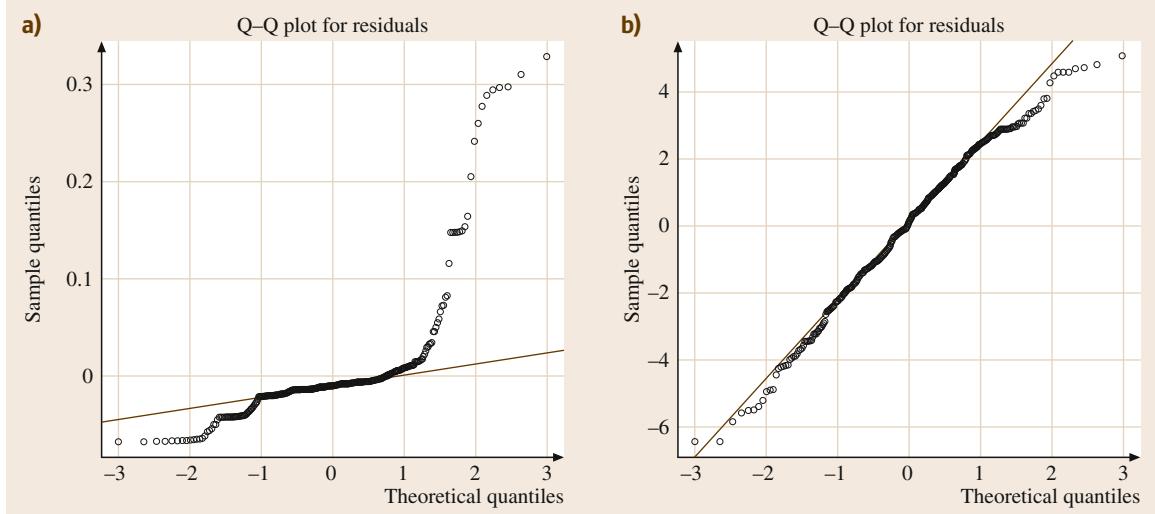

As can be seen from the Random effects section of the REML model output, the estimated variances for the problem instance and the instance-interaction random effects are  $\hat{\sigma}_\tau^2 = 0.59351$  and  $\hat{\sigma}_y^2 = 0.30691$ , respectively. The Random effects section presents the estimates of the fixed effects model parameters, i.e., `objreco`.

### MAMP-3 Validation of the Model Assumptions

Again, a check of the diagnostic plots (Fig. 56.7) reveals that a log transformation of the response improves the model adequacy.

### MAMP-4a Hypothesis Testing: Random Effects

We will consider random effects first. Regarding problem instances, test about levels are meaningless. Hence, we perform tests about the variance components  $\sigma_\tau^2$  and  $\sigma_y^2$ , which were presented in (56.19). First, we test the null hypothesis, which states that the components of the random effects are zero. Based on the ANOVA from Table 56.3, we obtain the values for the MAMP case that are shown in Table 56.4. The values reveal that there are main factor effects (fixed and random), but no significant interaction effects.

**Fig. 56.7a,b** (a) Q-Q plot of the residuals for raw data. (b) Q-Q plot for the log-transformed responses

Alternatively, we can compute the likelihood ratios of models with and without the factors under observation.

```
Data: mamp.df
Models:
mamp.lmer2: yLog ~ objreco + (1 | fSeed)
mamp.lmer3: yLog ~ objreco + (1 | fSeed)
           + (1 | fseed:objreco)
      Df   AIC   BIC logLik
mamp.lmer2 6 1616.7 1640.0 -802.35
mamp.lmer3 7 1616.6 1643.8 -801.31
      Chisq Chi Df Pr(>Chisq)
      2.0929     1    0.148
```

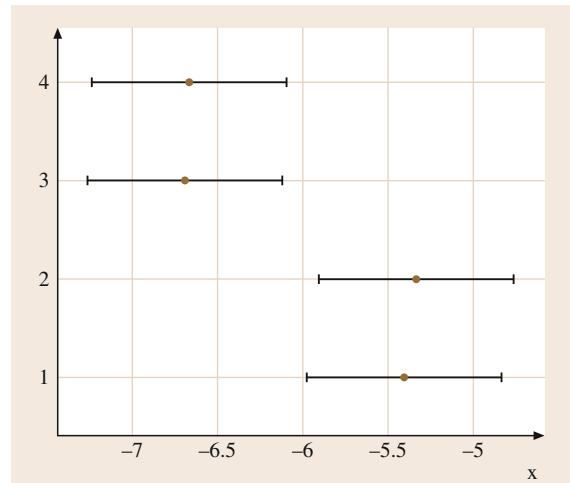

These tests indicate that there are also no significant instance-algorithm interactions. Additional likelihood-ratio tests show that the fixed factor and random factor effects are significant.

#### MAMP-4b Hypothesis Testing: Fixed Factor Effects

Regarding fixed factors, we are interested in testing for differences in the factor level means  $\mu + \alpha_i$ . These tests were formulated in (56.18), i.e., we are testing  $H_0$ : all  $\alpha_i$  are equal to 0 versus  $H_1$ : at least one  $\alpha_j \neq 0$ . Here, we use the test statistic from [56.2, p. 523] for testing that the means of the fixed factor effects are equal. The appropriate test statistic for testing that the means of the fixed factor effects are equal, i.e.,  $H_0$  is true, is

$$F_0 = \frac{\text{MSA}}{\text{MSAB}} = \frac{154.59/3}{185.6/24} = 6.663\,362,$$

with values taken from Table 56.4. The reference distribution is  $F_{n-1, (n-1)(q-1)}$ . We calculate the  $p$  value for the test on the fixed-effect term. The  $p$  value obtained is 0.002, hence the results collected indicate that the factor recombination (objreco) has a statistically significant impact on the performance of the algorithm. Using sum of contrasts implies that  $\sum \alpha_j = 0$ . The point estimates for the mean algorithm performance with the  $j$ -th fixed factor setting can be obtained by  $\mu_j = \mu + \alpha_j$ . The fixed factor effects can be estimated

**Fig. 56.8** Paired comparison plots. Results from four ES instances with different recombination operators are shown in this plot

in the mixed model as

$$\hat{\mu} = \bar{y} \dots \\ \hat{\alpha}_j = \bar{y}_{\cdot j} - \bar{y} \dots ,$$

which results in the following estimates:  $\hat{\alpha}_1 = 0.6175519$ ,  $\hat{\alpha}_2 = 0.6918047$ ,  $\hat{\alpha}_3 = -0.6671266$ , and  $\hat{\alpha}_4 = -0.6423659$ .

The same estimates were obtained with the **REML** analysis as can be seen from the **REML** model output in Sect 56.5.3. The corresponding fixed effects are shown in the Fixed effects section of the **REML** output. For example, we obtain the following value: `objreco1 =  $\hat{\alpha}_1 = 0.6176$` .

### MAMP-5 Confidence Intervals and Prediction

We generate paired comparisons plots, which are based on confidence intervals. The wrapper function `intervals()` from Chiarandini and Goegebeur [56.3] was used for visualizing these confidence intervals as shown in Fig. 56.8. When intervals overlap we conclude that there is no significant difference. Here, we can conclude that the recombination operators (1) and (2) show a similar performance, whereas performances between (3) and (2) are different.

*Intermediate* recombination of the object variables, i.e., (3) and (4), results in a significant improvement of the performance.

## 56.6 Summary and Outlook

In order to answer question (Q-1), we propose an approach to generate natural problem classes, which are based on real-world data. If no such data are available, artificial problem generators such as **MSG** can be used. Since our approach uses a model, say  $M$ , to generate new problem instances, one conceptual problem arises: this approach is not applicable, if the final goal is the determination of a model for the data, because  $M$  is per definition the best model in this case, and the search for good models will result in  $M$ . However, there is a simple solution to this problem. In this case, the feature extraction and model generation should be skipped and the original data should be modified by adding some noise or performing transformations on the data. Nevertheless, if applicable, the model-based approach is preferred, because it sheds some light on the underlying problem structure.

The model-based approach can be used to generate infinitely many test-problem instances. Instead of using a fixed number of problem instances, we propose:

1. Using randomly generated problem instances
2. Treating the problem instance as a random factor.

Algorithms with different parameterizations are tested on this set of randomly generated problem instances. This experimental setup requires modified statistics, so-called random-effects models or mixed models. This approach may lead to objective evaluations and comparisons. If normality assumptions are

met, confidence intervals can be determined, which *forecast* the behavior of an algorithm on unseen problem instances. Furthermore, results can be generalized in real-world settings. This gives an answer to question (Q-2).

In order to demonstrate the applicability of our approach, the performance of an evolution strategy was analyzed. The first **SAMP** example illustrates that the selection of the problem instance from the problem class  $\Pi_{\text{MSG}}$  has no significant impact on the performance of the optimization algorithm. Furthermore, confidence intervals, which can be used to predict the performance of the algorithm on a problem class, were determined. The **MAMP** case exemplifies how to analyze the effect of different algorithm parameter settings on the performance. Four variants of the recombination operator and nine problem instances were used. The analysis reveals that the choice of the recombination operator has a significant effect on the algorithm's performance: the performance of the algorithm differs with different recombination operators. Intermediate recombination of the object variables results in an performance improvement. We demonstrated that the problem instances contribute significantly to the variability in the response and that there is no significant instance-algorithm interaction.

The software that was used in this study will be integrated into the R package **SPOT** (sequential parameter optimization toolbox) [56.19].

# Computation

## 57. Computational Intelligence in Industrial Applications

**Ekaterina Vladislavleva, Guido Smits, Mark Kotanchek**

In this chapter, we review the progress and the impact of computational intelligence for industrial applications sampled from the last 10 years of our personal careers and areas of research (all authors of this chapter do computational modeling for a living). This chapter is structured as follows. Section 57.2 introduces a classification of data-driven predictive analytics problems into three groups based on the goals and the information content of the data. Section 57.3 briefly covers most frequently used methods for predictive modeling and compares them in the context of available a priori knowledge and required execution time. Section 57.4 focuses on the importance of good workflows for successful predictive analytics projects. Section 57.5 provides several examples of such workflows. Section 57.6 concludes the chapter.

### 57.1 Intelligence and Computation

Developments in computational intelligence (**CI**) are driven by real-world applications. Over the years a lot of **CI** has become ubiquitous to the average user and is deeply interwoven into the way modern design, research and development is done.

In our view, **CI** is human intelligence assisted and (dramatically) enhanced by computational modeling. Intelligence is the capability to predict, and, in theory, there are two directions to get to prediction through computing – data-driven modeling and first principle modeling. In reality though, since even fundamental models and theories have to be validated by data, everything is data driven. For this reason, from now on we will focus on data-driven computational modeling, and say that it exists to enhance predictive capabilities

of the human or business. While prediction is the ultimate goal and computational modeling is the means to achieve this goal, we will use concepts of predictive analytics and (data-driven) computational modeling as if they were the same.

Computational modeling methods allow us to generate various hypotheses about a specific problem based on observations in an objective way. The mental models that the scientists develop during this process help them to filter through these hypotheses and come up with new experiments that either support or falsify some of the previous hypotheses or lead to new ones. This process supports the scientific method and significantly accelerates technological development and innovation.

There are many examples of new computational methods empowering problem solving in the areas of material science, energy management, plant optimization, sensory evaluation science, broadband technology, social science (economic modeling), infectious disease prevention, etc. And while success in many cases is undeniable, two main challenges still remain.

First, there is an education gap to bridge before modern **CI** techniques can reach their full potential, are widely accepted, and become as natural as performing experiments in the lab. While many engineering educational programs are embracing these techniques and help raise awareness of the useful methods in data-driven modeling and computational statistics, the majority of programs in pure sciences tend to ignore them for the most part. There is still a considerable (psychological, cognitive, educational) barrier for experimental scientists – biologists, chemists, physicists, computer scientists – to fully exploit the potential of **CI**. People will happily save an hour of computing time by spend-

ing an additional week in the lab, while in some cases it makes much more sense to spend a week of computing time to spare one experiment in the lab (consider, e.g., an expensive car *crash-test*). We appeal to educational programs to nurture the interest in computation among graduates and facilitate the joint projects of academia with industry targeted at the use and further development of computational intelligence methods for real-world problems.

Second, there is a development gap in the production of scalable off-the-shelf **CI** algorithms. The parallelization bottleneck seems to affect most **CI** methods when they are executed on massively parallel architectures. The fact that computational advances in hardware (exa-scale computing) happen at a much faster pace than advances in the design of scalable **CI** algorithms raises the question: *Up to which moment can we get more intelligence, i.e., more predictive capability, with more computational power?*

## 57.2 Computational Modeling for Predictive Analytics

While many barriers remain in improving the incorporation of **CI** in classical education, in solving the new (previously unthinkable) challenges, and in further innovating **CI** technology, the current time is a perfect moment to make this happen.

First of all, the realization for the indispensability of **CI** across all industries and all sciences grows as does the number of required **CI** practitioners (computational statisticians, data scientists, modelers). The report of *Manyika et al.* on Big Data [57.1] predicts a potential gap of 50–60% (300 000 people) in demand relative to the supply of well-educated analytical talent in the USA by 2018. The *data science* and *big data* movement have grown in the last decade to become a buzz-word omnipresent in scientific magazines, technology reviews, and business offerings.

While we are happy that the attention of the average user is being focused on the importance and impact of computational modeling, we are also concerned with the fact that too many details are omitted and almost everything (business strategies, **CI** methods, targets for predictive analytics, etc.) gets thrown onto one pile.

While Big Data is occupying the minds of future engineers, data scientists, and business majors as a *next big thing to watch* and a synonym of predictive analytics, we want to balance the story some more and provide a full picture of what we think constitutes predictive an-

alytics by computational modeling. While business and industry is striving to become data driven these days, it seeks **CI** strategies to compete, innovate, and capture value. Success and impact of **CI** will be generated only if the right strategies are used in the right place.

Success of **CI** in industry will be awarded to methods that create impact measured in attaining the new level of understanding and knowledge, in units of dollars. In Fig. 57.1 we sketch a relation between the degree of intelligence and the level of competitive advantage from [57.2]. Further on, we will use the terms predictive analytics and computational modeling (for predictive analytics to sustain human intelligence) as if they were the same.

We distinguish three pillars of computational modeling for predictive analytics: business analytics applied to big data (millions to billions of records, dozens to hundreds of variables), process analytics applied to medium-sized data (tens of thousands of records, hundreds of variables), and research analytics applied to precious data (tens to thousands of records, dozens to hundreds to thousands of variables) (Fig. 57.2).

### 57.2.1 Business Analytics

Business analytics is the part of predictive analytics associated with big data. In recent years, other sci-

ences also created big data problems, so the field could be called big data analytics. The distinguishing feature of business analytics is the fact that it is used to inspect big data streams to provide a quick and simple analysis with immediate value reliably and consistently. Because of the size, big data already offers tremendous challenges in stages preceding analytics – in storage, retrieval, and visualization. These imply that the predictive goals can only be modest, except when big computing facilities and specialized data bases are available (like it happens in environmental and biological research, Internet search, smart grids, etc.). Main goals here are:

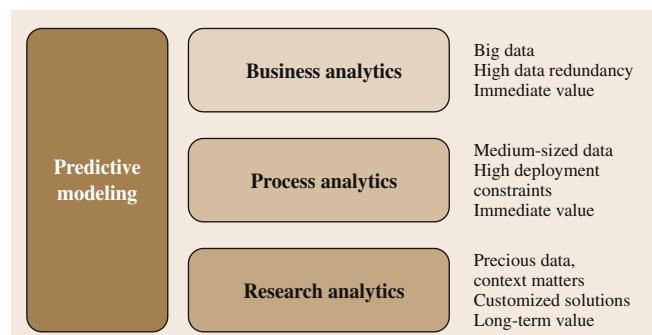

- Visualization (e.g., dashboards).
- Recommendation (e.g., studying customer habits and preferences to recommend a new suitable product item). Recommendation uses network analysis to select relevant or similar items.
- Identification of (simple) trends to enhance customer experience and increase surplus. Trends are typically found using time series analysis.
- Binary classification to distinguish out-of-the-ordinary data points from the prototypes following the trends (credit risk analysis, fraud detection, spam identification).

Because of the memory limitations, the challenge in business analytics is to quickly give an answer to simple questions with the main focus on algorithms for in- and out-of-memory computation and visualization. Industries benefitting most from business analytics are retail, banking, insurance, health-care, telecommunications, and social networks.

For example, at large multinational manufacturing companies, business analytics predominantly revolves around the multivariate forecasting of supply and demand. The expected prices and volumes of feedstocks and raw materials as well as the expected demand for various products are important to minimize risk and optimize production as well as the supply chain. Classical statistical forecasting techniques are the main workhorse for this area and the main challenges consist of being able to gather the required data, dealing with possibly large numbers of candidate inputs and outputs for the models and properly dealing with the hierarchies that exist, e.g., products-markets-industry resulting in an explosion in the number of models that have to be built and maintained.

**Fig. 57.1** Davenport and Harris [57.2] have wonderfully adapted the graphics from SAS software. The graph above eloquently explains why to use predictive modeling to excel, compete, and capture value

**Fig. 57.2** Predictive modeling has three components: Business analytics, predictive analytics, and research analytics

## 57.2.2 Process Analytics

Process analytics exploits medium-size data to generate time-sensitive prediction of an industrial process (e.g., manufacturing, process monitoring, remote sensing, etc.) with immediate value.

Process analytics models must be very robust, simple (mostly linear), and concise to be deployed in real industrial processes.

This well understood and probably most conservative area of predictive analytics has experienced a big change in the last years. A couple of decades ago, process optimization and control groups had more people and less pressure. Nowadays, pressure for integrating production workflows has increased together with the

need to meet tighter quality specifications, much tighter emission thresholds, requirements to reduce production, operation, and energy costs, and to maximize throughput. The sensor's side has changed – sensors have become much more sophisticated and much more abundant. The human interference has also decreased due to (sometimes exaggerated) drive to automation, and cost reduction.

All these factors have dramatically increased the demand for reliable optimization and control. In general, process analytics models must be very robust, simple (mostly linear) and concise to be deployed in real industrial processes. The main challenge for this industry is to integrate more sophisticated models and adopt new computational methods for process analytics to adapt to the changing world of new requirements while maintaining robustness over a wide process range. At the time when this chapter was written data-driven modeling was still considered exotic for the field of process analytics, and model deployment is still heavily constrained.

The main goals in process analytics are process forecasting and process optimization and control.

The challenge in process forecasting is to build models that hit the tradeoffs between model interpretability and their long-term (real-time) predictive power. The technological challenge of successful CI methods is the capability to identify driving features in a large set of correlated features. For example, think of a problem of predicting the quality of a manufactured plastic using the smallest subset of available factors controlling the production process – pressures, temperatures, flows. Robust feature selection is as important as good prediction accuracy – models that are too bulky will never be accepted by process engineers.

The main challenge in process control is the multiobjective nature of control specifications and subsequent optimization problems. Consider an example of manufacturing and wholesaling thin sheets of metal. The thickness of the sheet is an important quality characteristic that should not fall below a predefined minimum, or the product will be considered off-spec. If due to the processing condition the thickness variability is high (sheets are several meters wide and tens of meters long, rolled at high speeds, high temperatures), penalty for off-spec material is high, and costs for raw steel are also high – the manufacturer faces a delicate problem of making the sheet thicker than the allowed minimum to keep the clients happy but not too thick to keep the production costs down. These competing

objectives usually require a multiobjective approach to process optimization.

Process analytics relies on a rich data set coming from the many sensors in a typical plant. Mature platforms exist that store this, often high-frequency, sensor data in databases and plant information systems. The primary intent for this data is to run the various plant control and quality control systems but archived data are often available for predictive modeling as well. The use of models that predict the aging and lifetime of catalysts and the associated changes in optimal settings for the plant are good examples.

Another example is the building of the so-called soft sensors that link difficult measurements, such as, e.g., grab samples that need to be brought to the lab for analysis with results only becoming available after some time to some of the easier high-frequency measurements, such as, e.g., temperatures, flows, and pressures. These models then serve as substitutes for the difficult measurements at a high frequency and can be calibrated if needed when the slow measurements become available. There are also many opportunities to use the demand and supply forecasting models from the business analytics side to optimize production and product mix that is most optimal for a given scenario. As an extreme example, it may be cheaper to shutdown a plant for a while vs continued production when demand is forecasted to be very weak. The level and amount of coupling that is possible between demand-supply forecasts and actual production can vary significantly and depends on many factors, but it is clear that much more is possible in this area.

Examples of industries employing process analytics are manufacturing, chemical engineering, energy, environmental science.

### 57.2.3 Research Analytics

Research analytics is used to accelerate the development of new products and systems. This task is fundamentally different from all the ones mentioned previously as it is usually applied to small, complex, and precious data, is heavily dependent on problem context and provides long-term value without immediate rewards. (By *small* we mean any data set where the number of record is comparable or even smaller than the number of features. In this way, gene expression data with thousands of variables taken over dozens of individuals is small.)

Research analytics provides very customized solutions and requires a close collaboration between analysts/modelers and subject matter experts.

Research analytics is by nature much less generic and becomes very dependent on the specific product that is being developed. In research, once you have predictive analytics, then there is only a small step to make from optimization of existing products to the design of new ones. One example of a research analytics success story is the development of an application to predict the exact color of a plastic part based on the composition of the colorants and the specific grade a plastic being used, see [57.3]. Robust color prediction models led to the capability of actually designing colorant compositions in silico directly from customer specifications. The models also provided the specifications that were necessary to even let the customer produce that part himself.

How far one is able to take this depends on the fidelity of the models as well as the quality of the data that is available. Another example of research analytics at work is the design of new coatings and catalysts based on high throughput experimentation where all

the available data is being used to build models on the fly. These models are than used to design the next experiments such that the information gain is maximum. The requirements for the modeling process are quite high because everything is embedded in a high-throughput workflow but the benefits are also huge. Significant speedups in the total design time as well as the performance of new products can be achieved this way.

We stress that because research analytics is an enhancement to human intelligence for the development of new products and systems, the benefits of its application scale proportionally with the size of the problem and the impact of that particular product or system. For big enough problems the benefits quickly get into the hundreds of thousands to millions of dollars.

Research analytics can help drive innovation in all industry segments, particularly in materials science, formulation design, pharmaceuticals, engineering, simulation-based optimization in research, bio-engineering, healthcare, telecommunications, etc. In the coming 10 years, we will continue to see the trend of innovation enabled to a large extent by predictive modeling.

## 57.3 Methods

Over many years of exercising process and research analytics, we built up a practice of using predictive modeling as the integration technology for real-world problem solving. In the last 8–10 years, predictive modeling for computational intelligence has evolved from the solution of last resort to the main stream approach to industrial problem solving (prediction, control, and optimization). It is technology that glues together fundamental modeling and domain expertise, high-performance computing and computer science, empirical modeling and mathematics – a heaven for an inquiring mind and interdisciplinary enthusiast.

Predictive modeling is a bridge that connects theory and facts (data) to enable insight and system understanding. The theory for poorly understood problems is often based on simplifying assumptions, on which the fundamental models are built. The facts, or empirical evidence, are often affected by high uncertainty and a limited observability of the system's behavior.

Predictive modeling applied iteratively to a growing set of facts tests the theory against the data and *extrapolates* models build on the data to confirm or adjust the theory until the theory and facts start to agree.

The validation always lies in the hands of a subject matter expert who in the case of success accepts both the theory and the designed predictive models as plausible and interesting. While the real validation comes when models are deployed and keep generating value, without the first step of intriguing the subject matter expert the project does not have a chance to succeed.

To clear any obstacles toward the acceptance of models by the domain expert the models should be:

1. Interpretable
2. Parsimonious
3. Accurate
4. Extrapolative
5. Trustable, and
6. Robust.

In an industrial setting, the capability of having a trustable prediction of the output within and outside the training range is as important as interpretability and the possibility of integrating information from first principles, low maintenance and development costs with no (or negligible) operator interference, robustness with re-

spect to the variability in data, and the ability to detect novelties in data to attune itself toward changes in system's behavior.

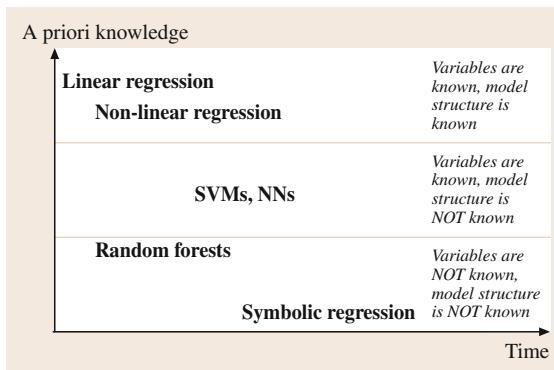

There is no single technique producing models that are guaranteed to fulfill all of the requirements above, but rather there is a continuum of methods (and hybrids) offering different tradeoffs in these competing objectives.

Commonly used predictive modeling techniques include linear regression, and nonlinear regression [57.4], boosting, regression random forests [57.5], radial-basis functions [57.6], neural networks [57.7], support vector machines (**SVM**) [57.8, 9], and symbolic regression [57.10, 11] (see more in [57.12]).

In Fig. 57.3, we place some of the most common methods for predictive modeling for process and research analytics in the objective space of development time versus the level of a priori knowledge about the problem. When identifying which methods to use other objectives (like interpretability and extrapolative capability) must also be taken into account. The time axis is depicted on a log scale, and the exact development time depends on implementation and a particular algorithm flavor.

Support vector machines and ensemble-based neural networks lose to linear, nonlinear, and regularized regression in interpretability, but have advantages for problems where little a priori information is known about the system, and no assumptions on model structures can be made (see Fig. 57.3).

Regression random forests, and symbolic regression [57.13–15] have further advantages for problems where not only model structures but also the variable drivers (significant factors) are unknown.

**Fig. 57.3** Predictive modeling methods as competing tradeoffs in development time versus the level of a priori knowledge about the problem

Random forests proved to be robust and very efficient for predicting the response within the training range and for identifying the most significant variables, but because they do not possess extrapolative properties they can only be used in problems where no extrapolation is necessary. Recent studies [57.16] indicate that variable selection information obtained by random forests can lose meaning if correlated variables are present in the data and affect the response differently.

In business analytics, when the speed of model development is the main goal, linear regression and regularized learning are the only remaining options. (Recent developments for predictive modeling for big data are also focusing on the feature generation problem, where the set of original data variables gets expanded to a much larger set of new features – transformations of the original variables, for which regularized linear regression is applied. Much like in support vector regression).

In process analytics when the driving input factors are known – ensemble-based neural networks, support vector regression, and ensemble-based symbolic regression are the modeling alternatives.

If very little is known about the process or system, experiments are demonstrating correlations among input variables, and concise interpretable models are required – symbolic regression is the only resort, which comes at a price of a higher development time (Fig. 57.3).

We stress the importance of using ensembles of predictive models irrespective of which modeling method is used. Ensemble disagreement used as a trustability measure defines the confidence of prediction and is crucial for reliable extrapolation. (It cannot be stressed enough that all prediction in a space of dimensionality above 3 is mostly extrapolation, even when evaluated inside the training range.)

We deal mostly with process and research analytics. In our experience, the aspect of trustability via ensembles of global transparent models, coupled with the massive algorithmic efficiency gains and the ability to easily handle real-world data with spurious and correlated inputs has led to symbolic regression largely replacing neural networks and support vector machines in our industrial modeling. Our experience also is that symbolic regression models tend to extrapolate well as well as provide warning of that extrapolation.

The reason for symbolic regression being successful for process and research analytics is the fact that all real-world modeling problems we have seen up to now contained only a dozen of relevant inputs (never more

than 25 variables, in most cases less than 10) which were truly significantly related to the response. Because symbolic regression searches for plausible models in a space of all possible structures from the given set of potential inputs, and allowed functional transforms, the computational complexity increases nonlinearly with the dimensionality of the true design space. For this reason, symbolic regression effortlessly identifies dozens of driving variables among tens to hundreds of candidates (albeit using hours of multicore computing time). But it should not be used for problems where hundreds of inputs are significantly related to the response and

should be filtered out of thousands of candidates. We claim though that no methods are available to solve the latter kind of problems because the necessary amount of data capturing true input–output relationships will never be collected.

Although tremendous progress has been made over the past decade in terms of the efficiency and quality of symbolic regression model development, we also have made corresponding advances from a holistic perspective encompassing the overall modeling workflows from data collection through model deployment.

## 57.4 Workflows

Although there is no universal solution for predictive modeling and no size fits all, especially for research analytics, nothing is as important for a successful solution as a good modeling workflow.

We would like to make a case for the utmost importance of workflows and the need to nurture and actively proliferate them through all CI projects. In the next section, we give an example on how a successful workflow developed in a project from flavor science could be seamlessly applied to a project in video quality prediction. And because predictive modeling for CI will soon be used in nearly all industry segments and research domains, we believe that it is the responsibility of CI practitioners to facilitate innovation through proliferation and popularization of (interpretable) workflows allowing straightforward application in new domains.

The most general approach to practical predictive modeling is depicted in Fig. 57.3.

We view this generic framework as an iterative feedback loop between three stages of problem solving (just as it usually happens in real-life applications):

1. Data generation, analysis and adaptation
2. Model development, and
3. Problem analysis and reduction.

An important observation is made in the *Toward 2020 Science* report edited by Emmott and Rison [57.17]:

*What is surprising is that science largely looks at data and models separately, and as a result, we miss the principal challenge – the articulation of modelling and experimentation. Put simply, models both consume experimental data, in the form of the con-*

*text or parameters with which they are supplied, and yield data in the form of the interpretations that are the product of analysis or execution. Models themselves embed assumptions about phenomena that are subject of experimentation. The effectiveness of modeling as a future scientific tool and the value of data as a scientific resource are tied into precisely how modelling and experimentation will be brought together.*

This is exactly the challenge of predictive modeling workflows – a holistic approach to bring together data, models, and problem analysis into one generic framework. Ultimately, we want to automate this iterative feedback loop over data analysis and generation, model development, and problem reduction as much as possible, not in order to eliminate the expert, but in order to free as much thinking time for the expert as possible.

This philosophical shift away from human replacement in the modeling workflow toward human augmentation has been very important in the last decade. A successful workflow must offer suites which mine the developed models to identify driving factors, variable combinations, and key variable transforms that lead to insight as well as robust prediction.

### 57.4.1 Data Collection and Adaptation

Very often, especially in big companies, and especially for process analytics, CI practitioners do not have access to data creation and experiment planning. This gap is a typical example of a situation, where multivariate data is given and there is no possibility to gather better sampled data.

In other situations, there is a possibility to plan the experiments, and gather new observations of the response for desired combinations of input variables, but the assumption always is that these experiments are very expensive, i. e., require long computation, simulation, or experimentation time. Such a situation is most common in research analytics and meta modeling for the design and analysis of simulation experiments.

The questions to ask at the data collection and adaptation stage are: How to design experiments within the available timing and cost budget to optimally cover the design space (possibly containing spurious variables)? How can available data and developed models guide design-space exploration in the next iterations? Is available data well sampled? Is it balanced? What is the information content of performed experiments? Is there redundancy in the data and how to minimize it?

## 57.4.2 Model Development

In model development, the focus is on automatic creation of collections of diverse data-driven models that infer hidden dependencies on given data and provide insight into the problem, process, or system in question.

# 57.5 Examples

## 57.5.1 Hybrid Intelligent Systems for Process Analytics

A good example of a unified workflow for process analytics is the hybrid intelligent systems framework popularized at the Core R&D department of the Dow Chemical Company in the late 1990s.

The methodology was developed to improve soft sensor performance (performance of predictive models), to shorten its development time, and minimize maintenance. It employed different intelligent system components – genetic programming, support vector machines, and analytic neural networks [57.18].

The process analytics in this framework consists of three steps following data collection:

1. Data preprocessing and compression. Support vector regression using the  $\epsilon$ -insensitive margin is used to identify and remove data outliers and compress data to a representative set of prototypes (support vectors). The result is a clean and compressed data set.

Irrespective, of which modeling engines are used at this stage, the questions on how to best generate, evaluate, select, and validate models given particular data features (size and dimensionality) are of great importance. Model quality, in general, i. e., generalization, interpretability, efficiency, trustworthiness, and robustness is the main focus for model analysis leading to the next stage.

## 57.4.3 Problem Analysis and Reduction

The stage of problem analysis and reduction supposes that developed models are carefully scrutinized, filtered, and validated, to infer preliminary conclusions on problem difficulty. The focus is on driving inputs, assessment of variable contribution, linkages among variables, dimensionality analysis, and construction of trustable model ensembles. The latter if defined well will contribute to intelligent data collection in the style of active learning.

With a goal to augment human intelligence by computation, we emphasize the critical need for a human, an inquiring mind who will test the theory, the facts (data) and their interpretations (models) against each other to iteratively develop a convincing story where all elements fit and agree.

2. Preliminary variable selection using ensemble-based stacked analytic neural networks [57.19]. The result of this step is a ranking of input variables and quantification of variable contribution based on iterative input elimination and re-training.
3. Convolution parameter estimation to identify relevant time-lags of significant inputs using appropriate convolution functions.
4. Development of transparent predictive models using symbolic regression via genetic programming and final variable selection using symbolic regression models.
5. Model selection and analytical function validation.
6. Online implementation.
7. Soft sensor maintenance to guarantee robustness of process prediction.

Examples of the use of this workflow for reactor modeling can be found in [57.18].

We all practiced the hybrid intelligent systems workflow in the past, but the massive algorithmic effi-

ciency gains in ensemble-based symbolic regression via genetic programming of the last decade [57.14, 20] have led us to simplify the workflow and largely eliminate steps one and two to replace them by direct application of symbolic regression.

### 57.5.2 Symbolic-Regression Workflow for Process Analytics

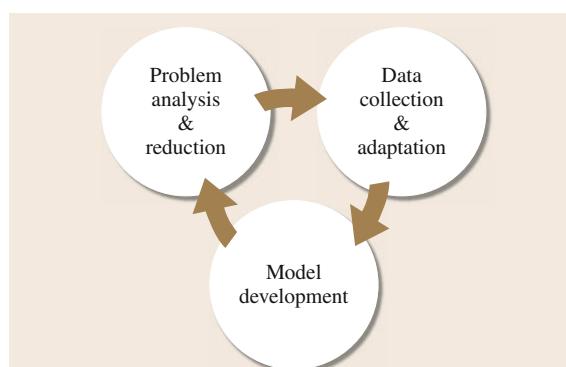

The major modeling engine breakthrough was the incorporation of a multiobjective viewpoint; this introduced orders of magnitude improvements in model development speed while simultaneously allowing the analyst to choose the proper balance between complexity and accuracy post facto. In essence, the data could now define the appropriate model structure and driving inputs, which became the main reason for symbolic regression's success for predictive modeling.

Other conceptual advances ordinal genetic programming, interval arithmetic, Lamarckian evolution and secondary optimization objectives, such as age, model dimensionality, nonlinearity, etc., have brought us to the current situation where we can largely inject data into a (properly designed) symbolic regression engine and interesting and useful models will emerge.

The symbolic regression workflow has become as depicted in Fig. 57.4, but with model development done using Pareto-aware symbolic regression [57.14].

#### Distillation Tower Example

The dataset comes from an industrial problem on modeling gas chromatography measurements of the composition of a distillation tower and is available online at <http://www.symbolicregression.com>.

**Fig. 57.4** Generic iterative model-based problem solving workflow (after [57.15])

A chemical reaction typically generates a variety of chemicals along with the one (or several) of interest. One method of isolating the mixture coming from the reactor into various purified components is to use a distillation column. The (hot gaseous) input stream is fed into the bottom and on the way to the top goes through a series of trays having successively cooler temperatures. The temperature at the top is the coolest. Along the way, different components will condense at different temperatures and be isolated (with some statistical distribution on the actual components). With vapors rising and liquids falling through the column, purified fractions (different chemical compounds) can be retrieved from the various trays. The distillation column is very important for the chemical industry because it allows continuous operation as opposed to a batch process and is relatively efficient.

This distillation column problem contains nearly 7000 records and 23 potential input variables – mixture of flows, pressures, and temperatures – in addition to the quality metric and material balance. The response variable is the concentration of a purified component at the top of the distillation tower. This quality variable needs to be modeled as a function of relevant inputs only. The range of the measured quality metric is very broad and covers most of the expected operating conditions in the distillation column.

To design the test data, we sorted the samples by their response values and selected every third and seventh samples for the validation set and every fourth and eighth samples for the test set. The remaining points formed the training set.

Many input variables in the data are heavily correlated. Because symbolic regression can deal with correlated variables, we used all 23 inputs in the first round of modeling to perform initial variable importance analysis.

The workflow that follows exploratory data analysis is described below:

1. *Initial modeling:* We allocated 2 hours of computing time on a quad-core machine to perform 24 20-minute independent runs of symbolic regression by genetic programming using Evolved-Analytics' DataModeler [57.14]. All symbolic regression runs used basic arithmetic operators augmented by a negation and a square as primitives. All models were stored on disk, and all other settings set to default settings of the symbolic regression function of [57.14]. In total, more than 3000 symbolic

- regression models were generated during 24 independent runs.
2. *Variable importance analysis:* For all models presence-based importances were computed. Figure 57.5 demonstrates that only a handful of variables is identified as drivers ([57.14] suggests to use importance threshold of 20%).
  3. *Variable combination analysis:* All developed models were analyzed for dimensionality and most frequent variable combinations. In Fig. 57.6, one can see model subsets niched according to constituting variable combinations. The bottom graph suggests that variables colTemp1, colTemp3, and colTemp5 might be sufficient for describing the response, since they cover the knee of the Pareto front in complexity vs. accuracy space.
  4. *Variable contribution analysis:* Models were simplified by identifying and eliminating the least contributing variable. Variable combination analysis was repeated for simplified models and resulted in identifying colTemp1 and colTemp3 as new candidates for a sufficient subspace.
  5. *New runs performed on a subset of input variables identified as drivers:* The new batch of independent symbolic regression runs was applied to the same data but only using colTemp1 and colTemp3 as the candidate input variables. As expected, models generated in this experiment demonstrated that the same complexity-accuracy tradeoffs can be achieved in only two-dimensional rather than 23-dimensional input space.

6. *Ensemble generation using developed models and a validation set:* Final model ensemble was generated automatically using developed symbolic regression models and validation data set. It was augmented by quadratic and cubic models on two variable drivers.
7. *Ensemble prediction validation using test data:* Ensemble prediction and ensemble disagreement were finally evaluated on the test data. Initial requirements for prediction accuracy to not exceed 5–7% of standard deviation were met by all ensemble models. Ensemble prediction is graphed in Fig. 57.7.

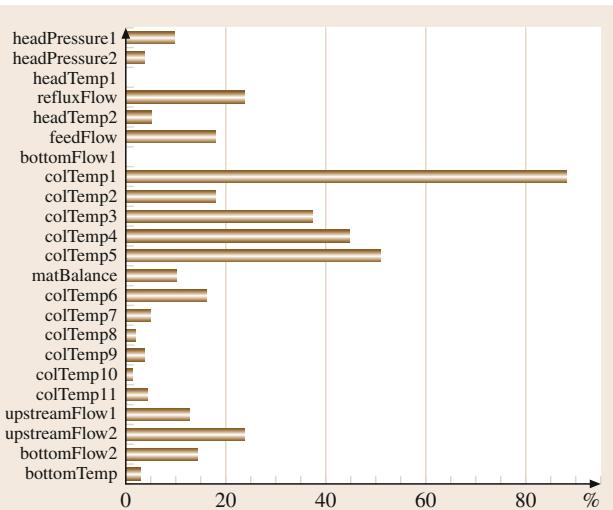

This example demonstrates the use of a good model development workflow. An ensemble similar to the one described here has been deployed for controlling a gas chromatography measurement in a real distillation column.

### 57.5.3 Sensory Evaluation Workflow for Research Analytics

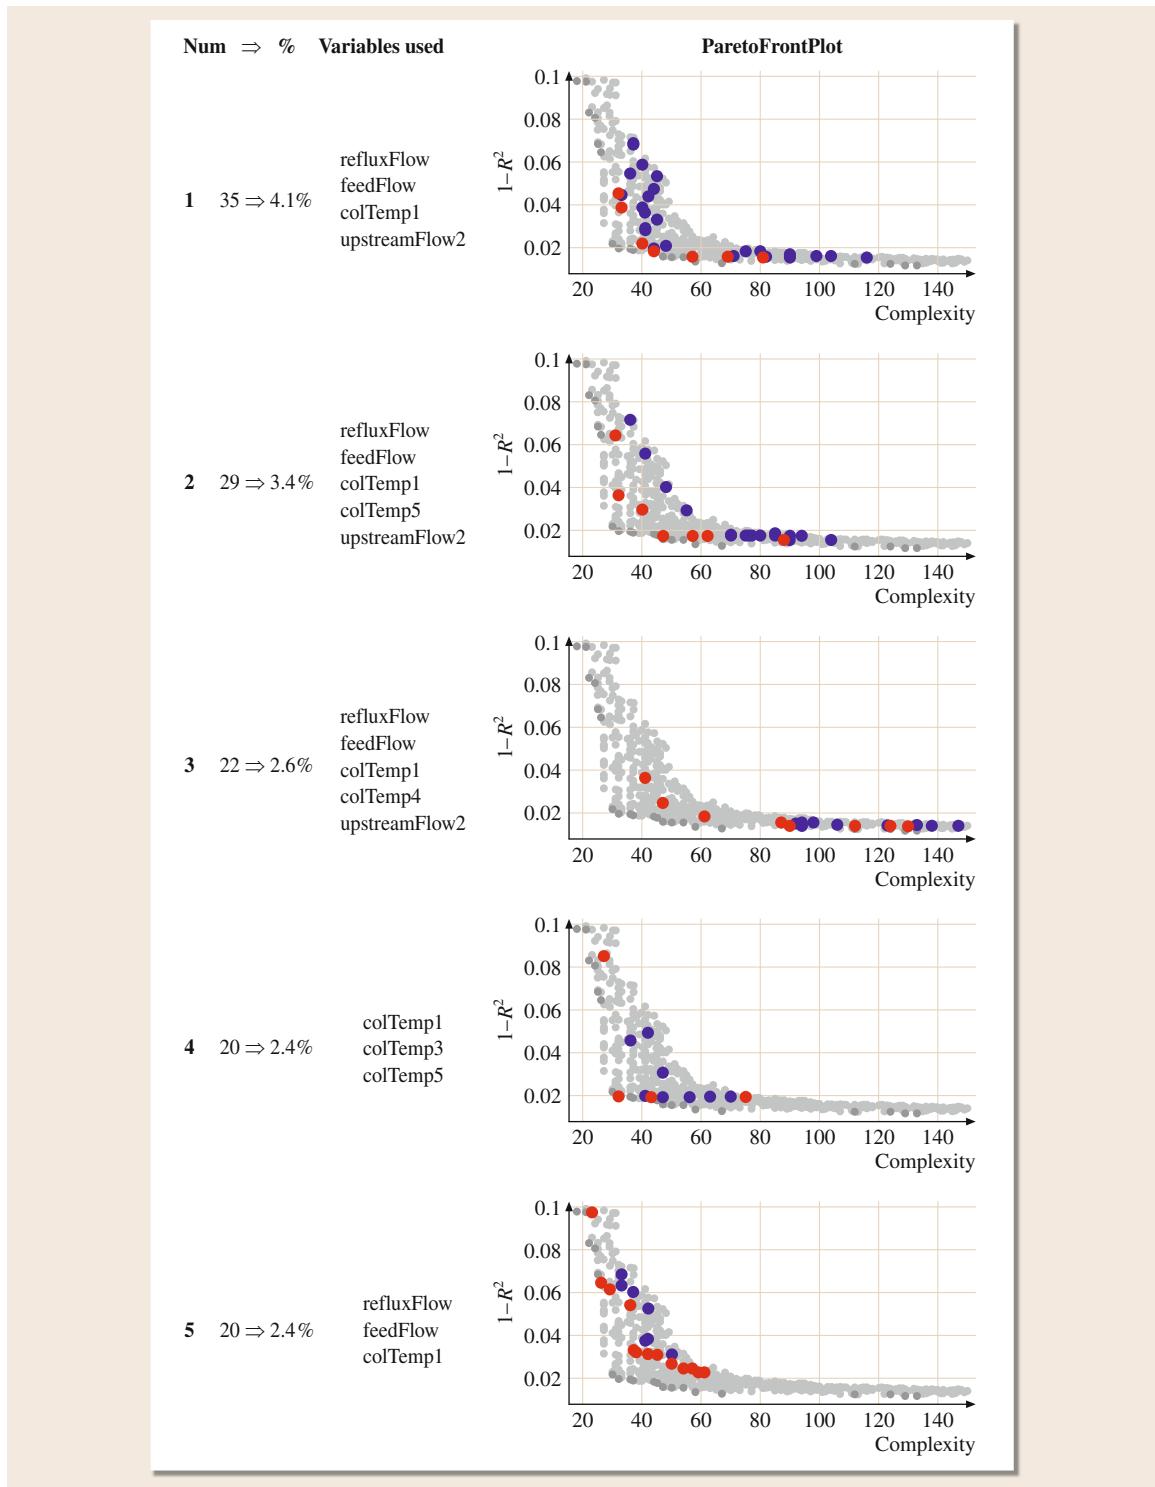

A flavor design case study is an example of a more specialized workflow [57.21]. In sensory evaluation, scientifically designed experiments are used to define a small set of mixtures that can be presented aromatically to evaluators to identify the ingredients that drive hedonic response (positively or negatively) of a target panel of consumers. Each panelist is asked how much they like the flavor, ranging from like extremely to dislike extremely with 9 distinctions. Details of the study can be found in [57.21]. Our focus here is the workflow that allowed to evaluate the consistency of liking preferences in the target population and gain insight into how to design or identify flavors that most consumers would consistently like.

The data for this project was provided by the Givaudan Flavors Corp. It falls into a category of precious data. It consists of sensory evaluation scores of 36 mixed flavors containing seven ingredients evaluated by 69 human panelists. In other words, data has seven input variables (flavor ingredients), 36 records (flavors), and 69 response measurements per record (Fig. 57.8).

Because of the high variability of response values per flavor, panelist responses were modeled individually. Because transparent and diverse input response models were required to approximate this challeng-

**Fig. 57.5** Variable presence in developed symbolic regression models

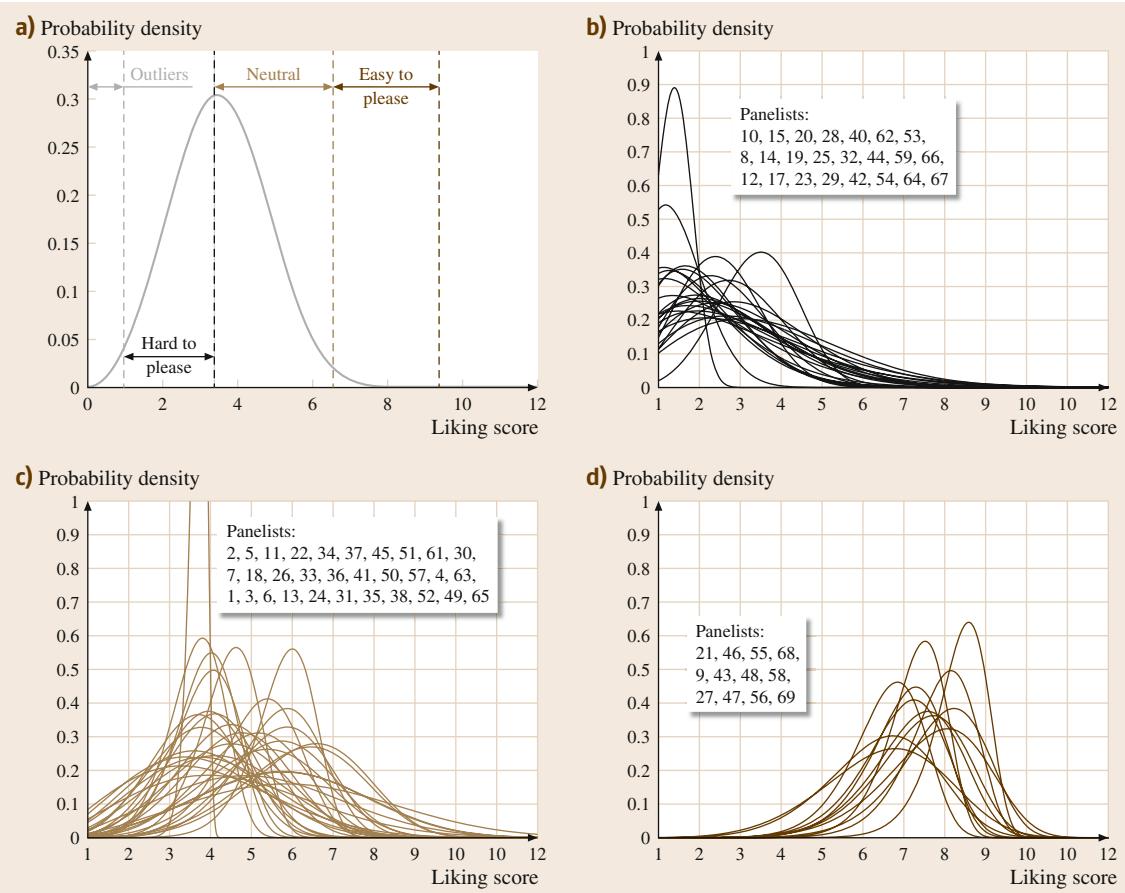

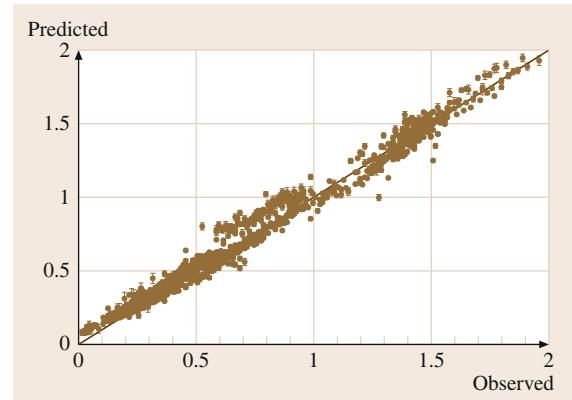

**Fig. 57.6** Complexity–accuracy tradeoffs for most frequent variable combinations in the distillation column example

**Fig. 57.7** Prediction of the final ensemble of symbolic regression models on test data. All models seem to agree on unseen test data set. This should not be surprising, because the training, validation, and the test set were designed to cover the full range of operating conditions ►

ing data set, modeling was done using ensemble-based symbolic regression.

For each panelist, a standard workflow was applied to identify driving ingredients which changes in panelist's liking [57.22].

When developed, model ensembles predicting individual responses could be bootstrapped to a richer set of virtual mixtures (tens of thousands of flavors instead of the available 36). The bootstrapped responses

**Fig. 57.8a-d** Example of panel segmentation by propensity to like from [57.22]: (a) Decision regions for evaluating cumulative distribution for liking score density model (b) hard to please panelist (c) neutral panelists, (d) easy to please panelists

were used to cluster the target population into three segments: easy to please – (cyber)individuals who consistently give high ratings to most flavors, hard to please – individuals that consistently use a low range of scores for all flavors, and neutral panelists whose preferential range is centered around the medium score – *neither like, nor dislike*. Such segmentation of the target population by people's propensity to like products turned out to be very useful in several other applications beyond flavor design. It focuses product development by giving insight into the fundamental variability in the preferences of the target audience.

The standard workflow for variable importance estimation applied to model ensembles forecasting the scores of individual panelists also allowed to segment the target population by ingredients that drive liking in the same direction. Such segmentation of the consumer market combined with the cost analysis for new product design offers visualization and analysis of beneficial tradeoffs for product specialization.

The third outcome of this study was the development of a model-guided optimization workflow

for designing optimal virtual mixtures. Multi-objective optimization using swarm intelligence was used to find tradeoffs in the flavor design space that simultaneously maximize the average liking score and minimize variance in the liking across virtual panelists.

Such model-guided optimization workflow combined with the standard ensemble-based modeling workflow presents a strong motivation for the development of a targeted data collection system for designing new products.

We should point out that despite a very custom design and specialized domain of sensory evaluation in food science, the workflow could successfully be applied in the very different domain of video quality prediction. Ensemble-based symbolic regression was used to model the perceived quality of perturbed video frames and results were used to predict customer satisfaction and segment the representative population of video viewers by propensity to notice perturbations and sensitivity to particular perturbations [57.23].

## 57.6 Conclusions

In this chapter, we discussed how computational intelligence leads to predictive analytics to produce business impact. We identified three main areas of predictive analytics: business analytics that deals mainly with visualization and forecasting, process analytics which aims to improve optimization and control of manufacturing processes, and research analytics which aims at speeding up and improving product and process design. All three areas have the potential to save and earn many millions of dollars but deal with very different data sources, context, information content, amount of available domain knowledge, and time and prediction requirements for value generation. Driven by different motivations, the areas are subsequently employing different predictive modeling methods.

We presented several predictive modeling methods in the context of different prediction requirements, solution development, and deployment constraints. We emphasized that there is no single method that fits all problems, but rather there is a continuum of methods, and each problem dictates selection of a method by specific time requirements and the amount of available *a priori* subject-matter knowledge (Fig. 57.3).

We stressed the importance of good and stable predictive modeling workflows for success in **CI** projects and provided several examples of such workflows for process and research analytics, illustrating that research analytics projects require highly customized approaches.

We point out that successful **CI** projects are amplifiers, that necessarily keep the human in the loop and vastly enhance her/his capabilities. Because of this, integrating **CI** in the various process and business workflows is essential!

It is clear that our ability to generate data as well as our ability to analyze it and produce actionable knowledge are quickly expanding. The challenge remains on how to develop scalable **CI** algorithms that keep up with the ever rising tide of data, given that computational advances in hardware (massive parallelization, exa-scale computing) are developing at a much faster pace than the **CI** algorithms.

A question that still puzzles us is: *Can we get more intelligence with more computational power, and where (and whether) it stops?* Undoubtedly, the right answer lies in the development of new algorithms that can tackle the new challenges – advanced material design,

problems in bio-informatics, complex-system modeling in social sciences, and social networks. We expect the largest impact of predictive modeling to happen in the areas of research and process analytics – in design of new products and new processes. Examples of design problems that can be assisted by data-driven CI methods for research analytics are the development of advanced materials – photovoltaic cells, alternative fuels, bio-degradable replacements for paints and plastics, composite materials, sustainable food sources. From the process analytics side, we would like to see CI methods used for optimization of water purification, emission control in combustion processes, simulation-

based optimization of social events on a world scale (terror attacks, revolutions, pandemics spread), efficiency optimization of manufacturing cycles, garbage minimization, and recycling.

It cannot be stressed enough that the dynamics around CI is changing – instead of CI being an optional addition to the arsenal of problem solving tools and methods, CI is becoming indispensable to deal and make progress with this new breed of real-world problems. The only way for CI practitioners to bring CI to prime time is to develop scalable algorithms, proliferate good workflows, and implement them in great applications.

# 58. Solving Phase Equilibrium Problems by Means of Avoidance-Based Multiobjectivization

Mike Preuss, Simon Wessing, Günter Rudolph, Gabriele Sadowski

Phase-equilibrium problems are good examples for real-world engineering optimization problems with a certain characteristic. Despite their low dimensionality, finding the desired optima is difficult as their basins of attraction are small and surrounded by the much larger basin of the global optimum, which unfortunately resembles a physically impossible and therefore unwanted solution. We tackle such problems by means of a multiobjectivization-assisted multimodal optimization algorithm which explicitly uses problem knowledge concerning where the sought solutions are not in order to find the desired ones. The method is successfully applied to three phase-equilibrium problems and shall be suitable also for tackling difficult multimodal optimization problems from other domains.

## 58.1 Coping with Real-World Optimization Problems

A multitude of methods from within and beyond *evolutionary computation* (EC) has been applied to real-valued multimodal optimization problems. These are generally considered the harder, the more basins of attraction they contain, and the less smooth the fitness landscape is. Additionally, a search space that extends over a large number of dimensions is said to complicate search for the desired global or good local optima [58.1].

However, in a real-world setting, even a low-dimensional problem may turn out to be quite difficult. This can stem from different factors, one of which would be a very small extent of the basins that contain the sought optima. Figure 58.1 visualizes the fitness landscape of an optimization problem that possesses this property. The application background will be detailed in Sect. 58.2, but for now it suffices to know

that there are only two variables  $a$  and  $b$ , and that the desired minima (function values do not depend on variable order and are thus symmetric to the main diagonal) are located near  $(0.650, 0.001)$  and  $(0.001, 0.650)$ , respectively. It is easy to see that the appropriate basins are small; in the figure, they are hardly recognizable at all.

Another complicating factor would be uncertainty about the relative target function value of the sought optima. If it is not a priori known whether we are looking for a global or only a certain local optimum, there is no way around enumerating all existing optima and choosing the *right* solution out of these afterward. Such difficulties may occur in cases where it is not possible to integrate the whole available application specific knowledge into the established target function, i. e., if its value must be obtained by simulation and the exist-

**Fig. 58.1a,b** Visualizations of the two-dimensional example problem. In the bottom panel, the search space is transformed by a square root. The desired optima are marked with white dots. Note that the diagonal consists of globally optimal but undesired (trivial) solutions

ing simulation tool is not able to represent all important features of the real system.

Obviously, there are several workarounds to overcome the difficulties imposed by this problem:

- Applying a transformation to the search space, so that the local optima at the lower boundaries occupy more space. This is shown in Fig. 58.1.
- Only initializing the optimization algorithm with solutions on the boundaries of the search space. In this case, we sometimes start from very near to the local optima, and thus have a higher chance to find them.
- Exploiting the symmetry of the landscape by a special representation. This can be done by enforcing

$a \geq b$  and would help, e.g., recombination operators of evolutionary algorithms (EAs).

However, all these approaches are dependent on the location of the desired optima. Any algorithm exploiting this expert knowledge would necessarily show a worse performance on problems without these special features, as predicted by the *no free lunch* theorem [58.2]. Instead, a more general method, which uses information on where the desired optima is *not*, will be discussed and evaluated in this chapter.

Many different EAs may be used to tackle this global or multimodal optimization problem because they are able to detect several optima simultaneously or subsequently. The latter may be achieved by multi-start approaches as sequential niching [58.3], whereas the former is established by means of diversity maintenance. That is, candidate solutions of the search populations are prevented from converging to the same region by implicitly or explicitly keeping them apart [58.4]. Prominent examples are crowding [58.5] and fitness sharing [58.6], and their successors. More recent approaches include, but are not limited to UEGO [58.7], clearing [58.8], species conservation [58.9], clustering-based niching [58.10], and cellular EA (CEA) [58.11]. Although there is no commonly accepted formal definition of what a niching method is [58.12], most of these algorithms may be subsumed under the term *niching EA*. They all use the distance between candidate solutions (diversity) as an implicit criterion which shall be maximized.

However, nothing prevents us from utilizing a diversity criterion directly. A step into this direction has been taken in the shifting balance GA [58.13]. But although it employs a separate diversity evaluation via subpopulation distance computation, it finally resorts to a single objective by weighting the distance and target function values.

In [58.14], we established a more radical approach and employ diversity in search space as an additional objective and treat the resulting combined problem by an *evolutionary multiobjective algorithm* (EMOA). The expected benefit is twofold:

- It enables placing solution candidates in basins that would otherwise go unnoticed due to their small size.
- We obtain a good overview of the available *interesting* search space regions in a single run.

As we presume that this approach is not only applicable to the thermodynamic problems treated in

this work but also to real-valued engineering problems with similar properties, it is also followed and further extended here. Other related multiobjectivization ap-

proaches are discussed in Sect. 58.3 after introducing the problem context.

## 58.2 The Phase-Equilibrium Calculation Problem

The knowledge of phase equilibria is required for the design and optimization of separation processes which are essential parts of typical chemical plants. The aim of a *phase-equilibrium calculation* is to quantitatively relate the variables (in particular, temperature  $T$ , pressure  $p$ , and mole fraction  $x$ ) which describe the state of equilibrium of two or more homogenous phases [58.15].

In any problem concerning the equilibrium distributions of  $k$  components between two phases, one must always begin with the equality of the chemical potential  $\mu$  as

$$\forall i \in \{1, \dots, k\} : \mu'_i = \mu''_i . \quad (58.1)$$

To establish the relation of  $\mu'_i$  (We use the domain-specific notation with upper index denoting different phases and lower index standing for separate substances.) to  $T$ ,  $p$ , and  $x'_i$ , it is convenient to introduce a certain auxiliary function such as the fugacity coefficient  $\varphi'_i(T, p, x'_i)$ , which can be calculated by a thermodynamic model. Then, (58.1) can be rewritten as

$$\forall i \in \{1, \dots, k\} : x'_i \cdot \varphi'_i = x''_i \cdot \varphi''_i . \quad (58.2)$$

Typically, the calculation is performed at constant temperature and pressure, and the remaining concentrations  $x'_i$  and  $x''_i$ , respectively, are to be found. The fugacity coefficient  $\varphi_i$  of component  $i$  in the mixture is calculated as

$$\ln \varphi_i = \frac{\mu_i^{\text{res}}}{RT} - \ln Z , \quad (58.3)$$

with  $Z$  being the compressibility factor, defined as

$$Z \equiv \frac{pv}{RT} , \quad (58.4)$$

where  $v$  is the molar volume, and  $R$  is the gas constant. The residual chemical potential  $\mu_i^{\text{res}}$  is given by

$$\begin{aligned} \mu_i^{\text{res}} &= a^{\text{res}} + RT(Z-1) \\ &+ \frac{\partial a^{\text{res}}}{\partial x_i} - \sum x_\ell \left( \frac{\partial a^{\text{res}}}{\partial x_\ell} \right) , \end{aligned} \quad (58.5)$$

where  $(\partial a^{\text{res}} / \partial x_i)$  is a partial derivative of the residual Helmholtz energy with respect to the mole fraction stated in the denominator, while all other mole fractions are considered constant.

The residual Helmholtz energy according to the perturbed chain statistical associating fluid theory (**PC-SAFT**) is considered as the sum of different contributions resulting from repulsion (hard chain), van der Waals attraction (dispersion), and hydrogen bonding (association)

$$a^{\text{res}} = a^{\text{hc}} + a^{\text{disp}} + a^{\text{assoc}} . \quad (58.6)$$

The detailed equations for each contribution can be found in [58.16] and [58.17].

Solving phase-equilibrium problems according to (58.2) may lead to trivial solutions, i.e.,  $x'_i = x''_i$ , which are mathematically correct but have no physical meaning (except at the so-called critical demixing point). To avoid obtaining them, the initial guesses for the minimization procedure may not be too far away from the correct solutions, provided that the correct solutions are known.

In the case of polymer solutions, initialization is very critical, because the concentration of the polymer in the solvent-rich phase can be in the magnitude of  $10^{-20}$ , which is a numerical challenge for simulation programs [58.18]. Another difficulty arises as the number of components in the mixture increases. All these challenges point out the need for a robust algorithm to solve the phase-equilibrium calculation for an arbitrary number of components and phases, and which is also applicable to polymer solutions.

Figure 58.1 actually shows a phase-equilibrium problem, namely a simple two-component mixture of water and pentanol. This type of liquid–liquid equilibrium (**LLE**) data are necessary for the design and optimization of liquid–liquid extractors and decanters. The two variables correspond to the concentrations of water in the water-rich phase (for the larger of the two) and in the pentanol-rich phase (for the smaller one). Under the assumption that  $a > b$ , and that  $w$  stands for water and  $p$  for pentanol, we have  $a = x'_w$ , and  $b = x''_w$ .

The remaining mole fractions  $x'_p$  and  $x''_p$  can be obtained indirectly as  $x'_p = 1 - x'_w$  and  $x''_p = 1 - x''_w$ , because for every phase, the following equality holds:

$$\sum_{i=1}^k x'_i = \sum_{i=1}^k x''_i = 1. \quad (58.7)$$

For this two-component problem, two equations of type (58.2) have to be satisfied, resulting in two error values  $e_w = |x'_w \varphi'_w - x''_w \varphi''_w|$  and  $e_p = |x'_p \varphi'_p - x''_p \varphi''_p|$ . A feasible solution to the problem shall exhibit errors below  $10^{-10}$  due to practical requirements. In the following,  $e_w$  and  $e_p$  are aggregated into a single target function value by using the sum of squares, which is to be minimized (note the vector notation)

$$f_1(\mathbf{x}', \mathbf{x}'') = e_w^2 + e_p^2. \quad (58.8)$$

**Table 58.1** The sought optima at different temperatures

| Mole fraction | 40 °C      | 60 °C      | 90 °C      |
|---------------|------------|------------|------------|
| $x'_w$        | 0.74698    | 0.7097     | 0.65084    |
| $x''_w$       | 0.00020913 | 0.00038142 | 0.00082809 |

In Fig. 58.1, (58.8) is modeled at a temperature of 90 °C, for which the sought optimum is located near the coordinates (0.650, 0.001). As system properties change with temperature and pressure, the pursued optimum also moves through the search space. Table 58.1 depicts approximate solutions for different temperatures and constant pressure of 1.0132 bar. The trivial solutions are the only feature representative for all phase-equilibrium problems. Thus, this is the only information that shall be exploited in the following.

### 58.3 Multiobjectivization-Assisted Multimodal Optimization: MOAMO

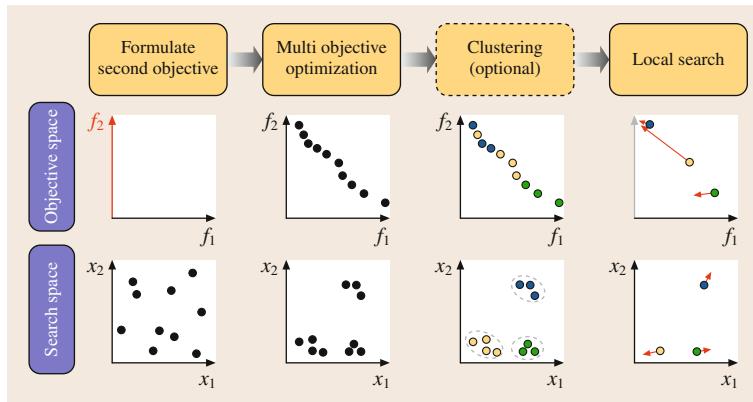

As seen in Sect. 58.1, the optimization problem at hand is inherently multimodal. That is, local optimization schemes are only successful if started from a region near the desired nontrivial solution. To make things worse, the basin of attraction of the undesired trivial solutions may largely dominate the search space as found for the very simple LLE problem (two phases, two components: water/pentanol). Hitting the basin of attraction of the desired solution can be very difficult, and if failing on this, the final outcome of quasi-Newton or similar algorithms will be a trivial solution.

Stochastic optimization methods like EAs and other metaheuristics employ a more globally oriented optimization scheme. Several attempts using these methods have been tried on equilibrium detection problems in recent years, namely genetic algorithms (GA) and simulated annealing in [58.19] or differential evolution (DE) and tabu search (TS) in [58.20]. The algorithms have been mostly used in their canonical form with some parameters tuning and a concluding local optimization step by means of a quasi-Newton method. Alternative approaches applied artificial neural networks for learning and predicting phase equilibria as in [58.21], the authors of which evolve the neural networks by means of genetic programming (GP), and [58.22], where the authors employ a real-coded GA to optimize initial weights and biases of the neural network before it is further refined using a quasi-Newton method. Where

enough training data is available, the binodal curves of equilibria can be learned and predicted for the missing areas.

Some recent metaheuristic attempts concentrate on the global (multimodal) nature of the optimization problem to find equilibrium points for rather difficult systems where global optima are located in relatively small basins. [58.23] use tabu search, [58.24] a random tunneling method, and [58.25] a DE hybrid with TS components. While we agree that *looking elsewhere* for even better solutions is mandatory for a multimodal problem, it may be even more rewarding to obtain a good overview over large portions of the search space before climbing down into the individual optima. This has been attempted by using a refined version of the algorithm of [58.26] which has been applied to phase stability problems by [58.27]. The base algorithm GLOBAL has been developed further in [58.28]. As the latter methods start from a random sample, it may however happen that either the initial sample is too small so that important optima are missed, or it is relatively large and thus costly.

The optimization concept suggested in this work therefore relies on an evolutionary multiobjective algorithm (EMOA) approach in order to generate a spectrum of possible near-optimal solutions before applying a local search method on these. We term it *multiobjectivization-assisted multimodal optimization* (MOAMO). The method was successfully applied

**Fig. 58.2** The general concept of MOAMO and its influence on search and objective space

onto the two-phase 2-component water/pentanol system in [58.14]. Here, we demonstrate that it is viable for more complicated equilibrium problems with more phases and components. Although not yet tried on polymer problems, this ultimate goal seems to be in reach as very small basins of attraction can be attained reliably.

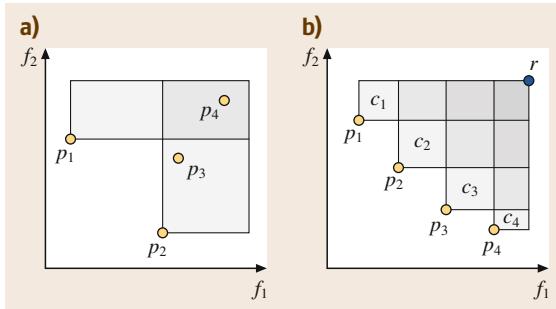

Figure 58.2 shows the main concept of the MOAMO approach. The key idea is to use a population-based multiobjective algorithm as a preprocessing step for generating search points in the different basins of attraction of the tackled problem, the basin of the non-trivial optimum being among them. To do this, the practitioner first has to formulate an additional objective function. This second objective is then employed to obtain good coverage of the search space despite the high attraction of certain areas. We label this type of multiobjectivization *avoidance-based* because application knowledge about where the sought optimum is *not* helps to transform the single-objective optimization problem into a multiobjective one that is easier to solve. More precisely, it enables detecting several different basins, among them many that would most likely have gone unnoticed with the single-objective approach alone.

For this specific application, the distance to the trivial solution (equal concentrations) is taken into account. From then on, the system can work autonomously. In the next step, the multiobjective optimization is carried out. The obtained search points then are fed one by one into a local optimization method, until a satisfying nontrivial solution is found. For this local search, only the original objective is relevant. We employed the algorithm of [58.29] and the covariance matrix adaptation evolution strategy (CMA-ES) of [58.30] for

this last step. The experimental results suggest that especially the latter seems well suited for the task. However, one may resort to another method here (e.g., quasi-Newton or similar standard optimization algorithms as described in [58.31]) if it is deemed more appropriate. To avoid superfluous local optimization steps on candidate solutions that are close to each other, this phase may be prepended with a clustering step so that one tries a representative of each *group* of solutions first and then proceeds in a round robin fashion.

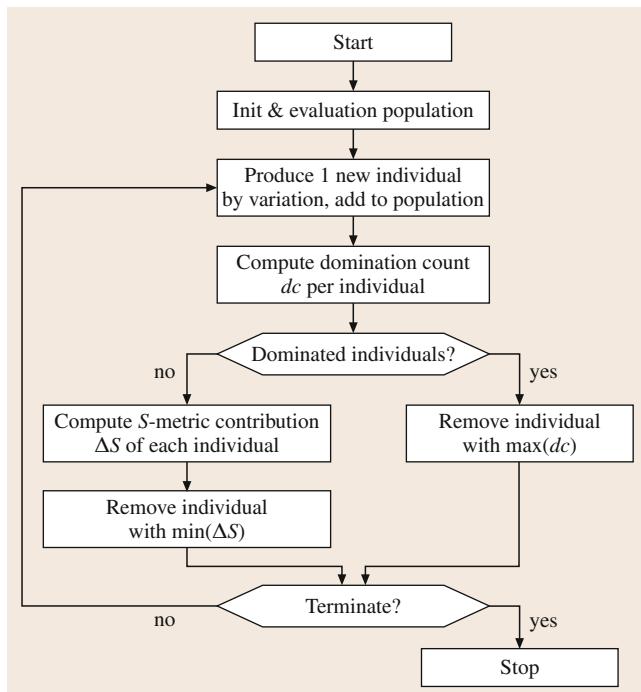

The idea of simplifying a difficult single-objective problem by a multiobjective approach has some precursors in evolutionary computation and has been coined as multiobjectivization by [58.32]. The approach can be divided into two general categories, namely multiobjectivization by adding objectives and multiobjectivization by the decomposition of a scalar objective function.

For the latter one, it can be proven that the approach can only decrease the number of local optima [58.33]. It was for example successfully applied to protein structure prediction problems in [58.34, 35]. MOAMO belongs to the category of multiobjectivization by adding objectives. No theoretic guarantees of benefits can be given [58.36] for this approach, but nonetheless it has already been tried in several different ways [58.37–40]. However, these applications somewhat remain in the tradition of evolutionary multiobjective algorithms that already contain diversity preserving mechanisms. The second objectives suggested all refer to the current population or single individuals thereof and do not take characteristics of the actual problem into account. MOAMO strongly differs as instead of a *population-relative*, it employs an *absolute*

**Fig. 58.3** (a) Pareto dominance for minimization:  $p_1$  and  $p_2$  are non-dominated,  $p_3$  is dominated by  $p_2$ , and  $p_4$  is dominated by  $p_1$  and  $p_2$ . (b) A non-dominated front between objectives  $f_1$  and  $f_2$ , consisting of points  $p_1$  to  $p_4$ .  $c_1$  to  $c_4$  denote the hypervolume contribution of each point (the space not covered by any other point) against the reference point  $r$

distance objective, namely the distance to the known trivial solutions. The **MOAMO** approach is therefore especially well suited to phase equilibrium problems,

**Fig. 58.4** Working scheme of the **SMS-EMOA**. Termination is done according to predefined conditions, e.g., a certain budget of fitness evaluations

as the fugacity equations do not allow to directly conclude where the sought solution is, but at least they provide information on where it is not. It has been demonstrated in [58.14] that by using the multiobjective **EA** as preprocessing step, the important basin can be located with a much smaller amount of function evaluations than would be needed by sampling the search space randomly, even if the basin is very small.

In the following, basic **EMOA** concepts are summarized and the particular multiobjective optimization algorithm employed in our experiments is introduced, namely the **SMS-EMOA** by [58.41] and [58.42].

### 58.3.1 Basics of Multiobjective Optimization

Multi-objective optimization fundamentally relies on Pareto dominance. A point in the objective space of two or more objective functions is dominated, if there is at least one other that is not worse in all objectives and better in at least one (Fig. 58.3a). As the optimization progresses, the population approaches the Pareto front which resembles the set of optimal compromises and consists of non-dominated points only.

Several criteria exist to judge the quality of whole populations within the algorithm run (as means to determine the next search steps) and thereafter to assess optimization success. One of the most popular is the hypervolume, the amount of objective space covered by the population with regard to a reference point as documented in the right panel of Fig. 58.3.

The  $S$ -metric selection evolutionary multiobjective algorithm (**SMS-EMOA**) is a further development of the popular **NSGA2** (nondominated sorting genetic algorithm 2) by [58.43]. Figure 58.4 displays its major steps. Starting from a usually randomly placed population, a loop begins with deriving one new individual (search point) and adding it to the population. The domination count of each individual is computed by counting how many other individuals dominate it. If such dominated individuals exist, the one with the largest domination count is deleted. Otherwise, the hypervolume contribution of each individual is determined (Fig. 58.3b), and the individual with the smallest contribution is deleted. If the current state does not fulfill the termination criterion (e.g., a predefined budget of function evaluations) the loop starts over. After terminating, the remaining population is the result set.

## 58.4 Solving General Phase-Equilibrium Problems

We present the results of phase-equilibrium calculations for the three-component system water/methanol/**MMA** as well as for the three-phase systems water/**MMA** and water/furfural. The corresponding optimization problems have four, three, and three decision variables.

**PC-SAFT** uses statistical mechanics for its simulation of thermodynamic systems and thus requires a calibration of some pure-component parameters and one binary parameter. The aim of this calibration is to achieve a consistency between the calculated phase equilibria and results of physical experiments. Carrying out this task manually for a single substance takes up several days of work for a chemical engineer, although the data of the physical experiments are already available in the literature [58.44]. These data contain series of measurements of temperature, density, and pressure for the vapor and the liquid phase of each substance. Among the several parameters that model the molecular properties, there are five per substance that have to be estimated. These are the number of sphere segments  $m$ , the segment diameter  $\sigma$ , the segment energy parameter  $\epsilon/k$ , an association energy  $\epsilon^{\text{A}i\text{Bi}}/k$ , and the effective association volume  $\kappa^{\text{A}i\text{Bi}}$ . Two different association sites are assigned to all the considered substances. If the substance is non-self-associating, then association energy as well as association volume are set to zero. Besides the five (three) parameters per substance, the

model requires one parameter  $k_{ij}$  that is characteristic for each binary mixture. The respective values for all these parameters were taken from [58.45, 46] and are summarized in Tables 58.2 and 58.3. The applicability of **PC-SAFT** to model the mentioned systems in good agreement with experimental data has been proved in [58.46].

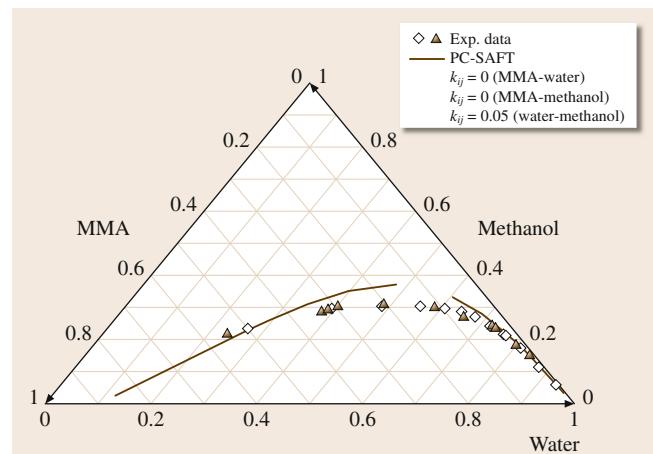

The following experiments show that the **MOAMO** approach provides a reliable and fast tool for the detection of equilibrium points which are difficult to find with standard optimization tools as a gradient or quasi-Newton search.

### 58.4.1 Ternary Liquid-Liquid Equilibrium: Water/Methanol/**MMA**

In Fig. 58.5, the ternary phase diagram of water/methanol/**MMA** at 50 °C and 1.013 bar with two liquid phases is shown. The calculation of the tie-lines was performed for different fixed concentrations of **MMA** in one liquid phase ( $x'_{\text{MMA}}$ ), see Table 58.4, at constant temperature and pressure.

#### Pre-Experimental Planning

The first objective (58.9) is generated from the error values output by **PC-SAFT**. These refer to the departure from the equilibrium state between every two phases of

**Table 58.2** **PC-SAFT** pure-component parameters for considered components

| Substance                          | $m$    | $\sigma$ | $\epsilon/k$ | $\epsilon^{\text{A}i\text{Bi}}/k$ | $\kappa^{\text{A}i\text{Bi}}$ |

| Water/methanol       | -0.05    |
| Water/furfural       | -0.006   |
| <b>MMA</b> /methanol | 0        |

**Fig. 58.5** Phase diagram of water/methanol/**MMA** system at 50 °C and 1.013 bar. The symbols are experimental data from [58.47] and [58.48]. The line is the calculation result of **PC-SAFT** with **MOAMO**-approach

one component as given by (58.1).

$$f_1(\mathbf{x}', \mathbf{x}'') = \sum_{i=1}^3 |x'_i \varphi'_i - x''_i \varphi''_i|. \quad (58.9)$$

Different formulations of the second objective for the **SMS-EMOA** were tried and several of them work well. Therefore, a generalization of the distance criterion for the two-component two-phase case in Sect. 58.1 was chosen. It measures the Euclidean norm of a vector of concentration differences (slightly shifted to allow for minimization) and is easily extendable for more components

$$\begin{aligned} f_2(\mathbf{x}', \mathbf{x}'') &= \sqrt{2} - \|\mathbf{x}' - \mathbf{x}''\|_2 \\ &= \sqrt{2} - \sqrt{\sum_{i=1}^3 (x'_i - x''_i)^2}. \end{aligned} \quad (58.10)$$

### Experimental Task

The task for **MOAMO** in this experiment is to reliably reach the sought optimum for all indicated **MMA** concentrations, that is the number of individuals converging to the optimum in the local search phase shall be considerably larger than 1 on average. Furthermore, the **MOAMO**-based approach shall find the optimum considerably faster than a naïve multistart local search procedure.

### Setup

For each of the concentrations indicated in Table 58.4, **MOAMO** is run five times with 30 individuals in the

**Table 58.4** MOAMO with 30 individuals, remaining population put into local optimization and rate of success and convergence to trivial solution, averaged over five runs. Where the sum of optimum and trivial is below 30, some local searches did not converge. The last column gives the empirical success probabilities for random start points of the local search

| $x'_{\text{MMA}}$ | Optimum | Trivial | Success rate (%) |
|-------------------|---------|---------|------------------|
| 0.05              | 25.2    | 3.8     | 45.0             |
| 0.15              | 0.0     | 30.0    | 2.7              |
| 0.25              | 5.8     | 24.0    | 3.6              |
| 0.35              | 19.6    | 10.2    | 3.9              |
| 0.45              | 25.8    | 4.0     | 3.5              |
| 0.55              | 29.4    | 0.6     | 2.9              |
| 0.65              | 28.8    | 0.0     | 3.1              |
| 0.75              | 29.0    | 0.6     | 3.1              |
| 0.85              | 23.2    | 0.6     | 2.3              |

multiobjective first step. Each search point contained in the last population is then optimized by a local search procedure (**CMA-ES** is employed for this second step). For each local search, it is recorded if either the undesired trivial solution or the sought optimum is obtained or if the search did not converge. Other than population size and run length (30 and 5000), the **SMS-EMOA** parameters are chosen as in [58.41].

In order to perform a comparison, the local search procedure (**CMA-ES**) is started 1000 times for each **MMA** concentration from a randomized start point and the rate of success for converging to the sought optimum is recorded. The **CMA-ES** terminates if progress or adapted stepsizes decrease below  $10^{-12}$  as usual.

### Observations

Table 58.4 comprises the results for the **MOAMO** approach and in comparison the success rates for the random start local search procedure. Run lengths of the **CMA-ES** are not given in detail, but mostly range between 2600 and 5000 evaluations.

For the **MMA** concentrations from 0.25 to 0.85, both methods are consistent: **MOAMO** obtains the sought optimum from at least 60% of the last population's search points, while the success rates of the random start local search vary between 2 and 4%. However, 0.05 and 0.15 are special cases: In the first case, the problem is obviously not that hard as the random start local search also detects the sought optimum often, and in the second case, the **MOAMO** approach completely fails.

### Discussion

The most striking result of the experiment is that hardness of the problem for the two compared approaches seems uncorrelated. An **MMA** concentration of 0.05 is much more easily solved by the random start local search than any other, but the success rates for **MOAMO** do not reflect this. For 0.15, the opposite happens as the problem poses average difficulties for the random start local search procedure, but is very hard for **MOAMO**. We conjecture that this is an exception as we are almost at the critical point here, where concentrations in both phases differ less and less. Presumably, trivial solution and sought optimum are too equal to separate them in the **SMS-EMOA** phase via the distance objective. However, we can be satisfied with the results for the other concentrations, where the **MOAMO** approach reliably detects the sought optimum and is much faster than the random start local search procedure, even if the effort for the first (multiobjective)

phase is considered (which is on the order of one or two local searches).

### 58.4.2 Three Phase Equilibria: Water/MMA and Water/Furfural

We now turn to an application of the **MOAMO** approach on 2 component/3 phase systems in order to detect the heteroazeotrope point (a 3-phase equilibrium). The first objective is again obtained from the phase equilibrium equations and differs from the one chosen for the 3 component/2 phase system (58.9) in the number of relevant phase equations. Due to transitivity, four error values remain here. Additionally, a quadratic form is chosen here instead of the absolute value form used in the previous case, under the assumption that the quadratic form simplifies the local optimization task (Quasi-Newton as well as evolutionary optimization methods usually perform better in this case).

$$f_1(\mathbf{x}', \mathbf{x}'', \mathbf{x}''') = \sum_{i=1}^2 [(x'_i \varphi'_i - x''_i \varphi''_i)^2 + (x'_i \varphi'_i - x'''_i \varphi'''_i)^2] . \quad (58.11)$$

As for the previous system, it is necessary to determine a suitable second (distance) criterion for the multiobjective first step. However, for three phases, the approach

taken in [58.14] has to be generalized in a different way than done for three components. Interestingly, our preliminary test showed that it is sufficient to consider only one component and its three phases to create a distance criterion. We may use mutual phase concentration differences of phases 1 and 2, 2 and 3, and 1 and 3 to aggregate an objective function. (Note that Euclidean distances have been employed in the previous section, however our tests show that for the multiobjective **MOAMO** step, the choice of the distance norm itself is not very important and Manhattan distances as used here are also sufficient.)

$$f_2(\mathbf{x}', \mathbf{x}'', \mathbf{x}''') = 2 - \sum_{i=1}^2 (|x'_i - x''_i| + |x''_i - x'''_i| + |x'_i - x'''_i|) . \quad (58.12)$$

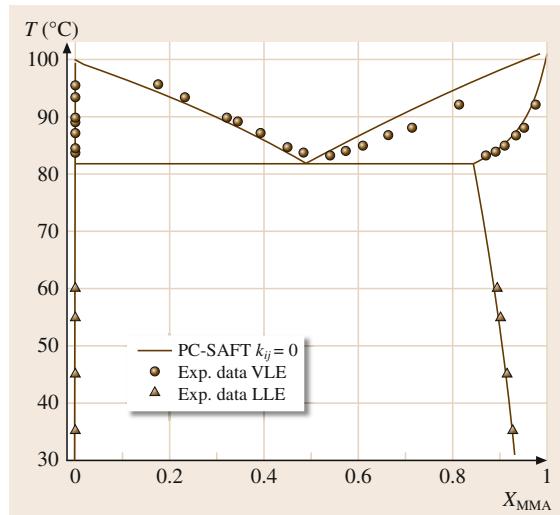

Alternatively, the phase concentration differences can also be stated as three separate criteria, resulting in a four-objective problem for the **SMS-EMOA**

$$\begin{aligned} f_2(\mathbf{x}', \mathbf{x}'', \mathbf{x}''') &= 1 - \sum_{i=1}^2 |x'_i - x''_i| \\ f_3(\mathbf{x}', \mathbf{x}'', \mathbf{x}''') &= 1 - \sum_{i=1}^2 |x''_i - x'''_i| \\ f_4(\mathbf{x}', \mathbf{x}'', \mathbf{x}''') &= 1 - \sum_{i=1}^2 |x'_i - x'''_i| . \end{aligned} \quad (58.13)$$

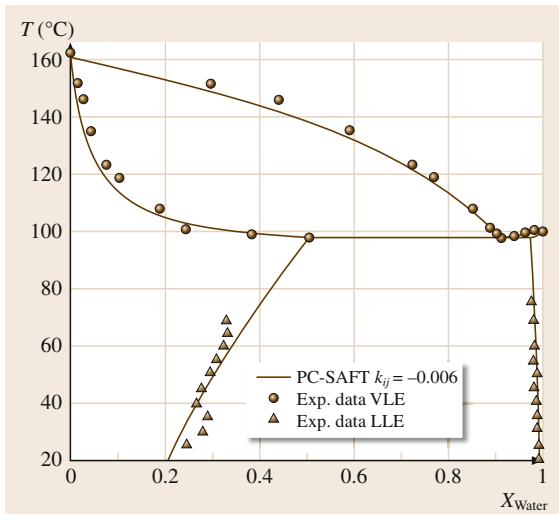

The following experiment will show whether the aggregated formulation or the separate criteria are more advisable.

The binary system water/MMA in Fig. 58.6 exhibits a heteroazeotrope behavior at 1 bar. According to the phase rule, only one variable can be fixed to determine the heteroazeotrope, as in this case the pressure. The temperature of the heteroazeotrope was found at 81.93 °C and the concentrations of MMA in the three phases were  $x'_{\text{MMA}} = 0.841826$ ,  $x''_{\text{MMA}} = 0.488033$ , and  $x'''_{\text{MMA}} = 0.002577$ .

The identification of the heteroazeotrope point for water/furfural at 1 bar was more complicated than the previous system due to the fact that two sought water concentrations are close to each other ( $x'_{\text{water}} = 0.911822$  and  $x''_{\text{water}} = 0.973374$ ), see Fig. 58.7. The third water concentration was found at  $x'''_{\text{water}} = 0.507017$  and the heteroazeotrope temperature was determined at 97.64 °C.

**Fig. 58.7** Phase diagram of water/furfural system at 1 bar. The symbols are experimental data from [58.51]. Lines are calculation results of PC-SAFT with MOAMO-approach

### Pre-Experimental Planning

Taking over the SMS-EMOA parameters (population size and run length) from the previous experiment led to an unreliable behavior for the two systems tested here. Seemingly, they are more difficult to solve than the given three-component/two-phase system. Therefore, population size is doubled to 60 individuals and run length is accordingly slightly increased to 6000 evaluations.

### Experimental Task

As the last paragraph indicated that the problems in this section are even more difficult than the that of Sect. 58.4.1, there is no point in testing against random start local search again. Instead, it shall be determined if the aggregated (58.12) or the separate criteria approach (58.13) is more suitable for solving the problems with MOAMO. To enable a decision between the two, a significant difference in success rates is required.

### Setup

For each of the two systems (water/MMA and water/furfural) and each of the problem formulations (aggregated/separate), 30 MOAMO runs are performed and the number of successes is recorded. A run is successful if at least one of the local search steps obtains the sought optimum the number of successful local searches is not recorded. As before, we employ the combination of SMS-EMOA and CMA-ES. The

**Table 58.5** Success rates for detecting the heteroazeotrope point via MOAMO approach under different formulation of the distance criterion

| System         | Distance criterion | Success rate (%) |
|----------------|--------------------|------------------|
| Water/MMA      | Aggregated         | 100.0            |
|                | Separate           | 50.0             |
| Water/furfural | Aggregated         | 93.3             |
|                | Separate           | 36.7             |

resulting values for the first objective function (computed from the error values output by PC-SAFT) shall be below  $10^{-15}$  in this case, requiring to modify the CMA-ES internal stopping criteria accordingly. Its initial step size is set to 0.01. The SMS-EMOA parameters are set as in the previous experiment except population size and run length which are modified as documented above.

### Observations

The number of successful runs is given in Table 58.5. The aggregated approach seems to consistently perform better than the one with separate criteria, and success rates hint to the fact that the second system poses more difficulty than the first one.

### Discussion

Fortunately, the much simpler (aggregated) approach is also the more reliable for both systems. The much larger objective space in the first phase (four instead of two objective functions) obviously outweighs the benefits of a *correct mapping* by far. Furthermore, for higher numbers of phases, the number of objectives would grow faster than linear, so that in conclusion, the aggregated approach is much more suitable than the one with separate objective functions.

### 58.4.3 Obtaining the Phase Diagrams

Once the heteroazeotrope point is detected, a phase diagram of the system may be obtained by systematic exploration of the two-phase equilibria at different temperatures. We simply increase or decrease the temperature (which is a free variable for two-phase systems) by  $1^\circ\text{C}$  and take the solution for the last temperature step as initial point for a local search (executed by the CMA-ES) on every binodal curve. Figures 58.6 and 58.7 have been generated by means of this method. (Note that this is different from the common approach of detecting several two-phase equilibria by means of a quasi-Newton method first and then to conclude on the heteroazeotrope point from these.)

## 58.5 Conclusions and Outlook

In this chapter, a multistage method named **MOAMO** (multiobjectivization-assisted multimodal optimization) was presented. It is especially designed for difficult multimodal direct search problems as arising in phase equilibrium detection. However, the method is very well applicable whenever some problem knowledge is available concerning where the global optimum is *not*. The experimental analysis, performed on three different systems with either three components and two phases or two components and three phases, has shown that the approach is reliable and fast. It outperforms random multistart local search by a large margin under nearly all tested conditions. Two important properties of the approach need to be emphasized:

- Unlike many attempts to solve phase-equilibrium problems by means of evolutionary or related algorithms, **MOAMO** utilizes known features of the problem to direct the search and thereby avoids spending too much effort in repeatedly approaching

trivial solutions. However, it does not make any assumptions about the *location* of the sought optima and is thus still a generic approach.

- Unlike in some other multiobjectivization approaches, the second objective is population independent. Moving a single individual does not change the objective function values of any other. This prevents unwanted feedback loops. The optimization focuses on the problem and not on the current population.

Our results indicate the **MOAMO** approach as remarkably independent of the actual formulation of the second objective. Performance increases or decreases only gradually for alternative objectives, the overall concept remains intact. However, obtaining better guidelines for setting up a matching second objective is an area for future research, as is the comparison with more different algorithms and the adoption for other problems, not necessarily restricted to phase equilibrium detection.

# 59. Modeling and Optimization of Machining Problems

Dirk Biermann, Petra Kersting, Tobias Wagner, Andreas Zabel

Part E | 59

In this chapter, applications of computational intelligence methods in the field of production engineering are presented and discussed. Although a special focus is set to applications in machining, most of the approaches can be easily transferred to respective tasks in other fields of production engineering, e.g., forming and coating. The complete process chain of machining operations is considered: The design of the machine, the tool, and the workpiece, the computation of the tool paths, the model selection and parameter optimization of the empirical or simulation-based surrogate model, the actual optimization of the process parameters, the monitoring of important properties during the process, as well as the posterior multicriteria decision analysis. For all these steps, computational intelligence techniques provide established tools. Evolutionary and genetic algorithms are commonly utilized for the internal optimization tasks. Modeling problems can be solved using artificial neural networks. Fuzzy logic represents an intuitive way to formalize expert knowledge in automated decision systems.

In production engineering and particularly in the field of machining, improvements in materials, coatings, tools, and machines continuously provide potentials for improving the processes. In order to exploit these potentials, however, optimal setups of the changing processes have to be found. Since modern production processes involve many complex subsystems, as well as preceding and subsequent steps, all these systems and steps have to be adapted for achieving the optimal result.

In this chapter, it is shown that computational intelligence (**CI**) provides methods to assist in achieving this ambitious aim. A particular focus is on the applications of evolutionary computation (**EC**) in machining, but also artificial neural networks (**NN**) and fuzzy logic are considered. A comprehensive overview is presented by

considering several subsystems, as well as the preceding and subsequent steps in the operating sequence. In this aspect, the chapters contribute to common surveys in the literature [59.1–5], which are often only focused on the modeling and optimization of the actual process.

In order to assist interested engineers in choosing a suitable method for their problem, the solutions offered by **CI** are structured according to the specific subproblems to be solved in a machining problem. To keep the big picture still apparent, these subproblems are integrated into the complete operating sequence in the following section. They are then discussed according to their chronological order in the sequence. The chapter is concluded with summarizing remarks on **CI** applications in the field of production engineering.

## 59.1 Elements of a Machining Process

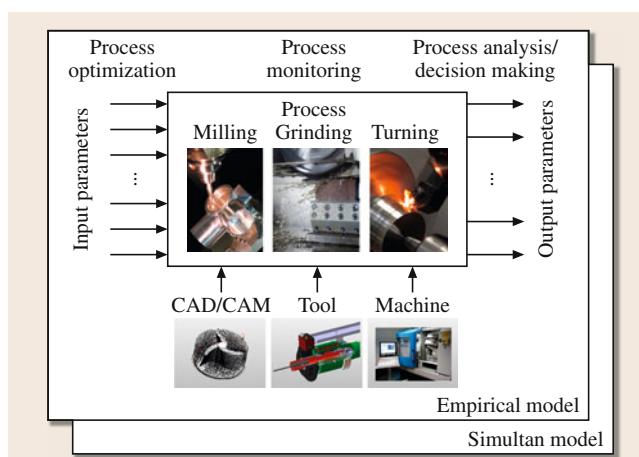

An overview of the elements and steps to be considered when optimizing a machining process is shown in Fig. 59.1. In the focus of the considerations is the actual process. The results of this process, however, significantly depend on its elements, in particular on the mechanical properties and the dynamic characteristics of the machine, geometry, and the properties of the tools, as well as the layout of the workpiece which determines the required machining operations. All these elements can be individually optimized to improve the results of the process. For the latter, often complex numerical control (**NC**) paths for the machines have to be generated using computer-assisted manufacturing (**CAM**) software. To accomplish this, a model of the final workpiece geometry is required. If no such model is available, e.g., after manual modifications of a prototype, **CI**-based methods can assist in computing an optimized workpiece model for the **CAM** software. However, even if a model is available, the **NC** paths computed by the **CAM** software can be far from optimal due to the complexity of the process, e.g., in five-axis milling operations. In this case, the subsequent optimization of the position-dependent parameters of the **NC** code, such as the inclination angles  $\alpha$  and  $\beta$ , and the feed rate  $f$  [59.6], can significantly increase the efficiency of the process.

When all the components of the actual process are selected and fixed therewith, the optimization of the adjustable process parameters can begin. Thereby, **CI**-

based techniques are usually based on a self-organizing process. In order to let the self-organization take effect, a high number of experiments is required. Since a real-world experiment involves high costs, it can become necessary to use a surrogate model on which the method is applied. In this case, however, additional problems have to be solved. It has to be selected which kind of model (empirical, analytical, physical, numerical) is applied and which type or realization of this kind of model is implemented, e.g., an empirical model can be computed using artificial neural networks, Gaussian processes, or regression techniques. As soon as a model is chosen, the parameters of this model (internal coefficients, material constants, etc.) have to be adapted with respect to the given application. This often represents an additional nonlinear optimization problem which can be solved using techniques of **EC**.

Moreover, the robustness of the process can be increased by a monitoring-based process control. To accomplish this, dynamic characteristics of the process, such as acoustic emission signals and force measurements, are analyzed online and control operations are initiated as soon as these characteristics show suspicious patterns. In this kind of application, however, it is necessary to automatically detect what indeed is a suspicious pattern. Fuzzy logic and **NNs** have proven to be capable of performing these tasks.

A lot of information can be obtained in order to analyze the process and its results. This information can either be achieved by measurements during and after the process or by performing simulation studies. They usually build the basis for the calculation of the actual objectives. In this context, machining processes have to be optimized with respect to several conflicting aims, e.g., a simultaneous minimization of tool wear and maximization of the material removal rate. Even if multiobjective optimization techniques are used, a lot of details can be lost in this formulation step. Often the first version of the objectives does not result in the desired results. Additional objectives have to be defined or preferences have to be integrated. In order to allow a deeper understanding of the process to be obtained and a refinement of the objectives to be made, an intuitive visualization and exploration of the detail information is required. For this task, again **CI**-based techniques can be used.

**Fig. 59.1** Overview of the elements and steps of an arbitrary machining process

## 59.2 Design Optimization

The optimal design of a machine, tool, or workpiece is a great challenge in the field of production engineering. The optimization task is often conducted as an iterative manual process which is based on expert knowledge and which can be very cost and time consuming. *Roy et al.* [59.7] gave an extensive overview of the recent advances in automated and interactive design optimization. They presented a classification of the optimization problems and discussed the most important optimization approaches and techniques. In the following subsections, examples of successful applications of **CI** for the optimization of machine, tool, and workpiece designs are provided.

### 59.2.1 Optimal Design of Machines

Designing machines necessitates the consideration of multiple objectives, such as geometric accuracy and costs. *Liu and Liang* [59.8], for instance, presented an approach combining a modified Chebyshev programming method for the scalarization of these objectives and a particle swarm optimization algorithm for evolving the machine designs. They were dealing with reconfigurable machine tools, so not only the process accuracy and investment costs of the machine layouts, but also the configurability was considered. Significant changes in the shape of the product could thus be easily adapted. *Mekid and Khalid* [59.9] discussed an optimization method based on a multiobjective genetic algorithm for the design of three-axis micromilling machines. They took user requirements (for example the workspace volume), axis positions, and geometric errors of the machine into account. For the latter, they used a mathematical error model of the three-axis milling machines.

### 59.2.2 Tool Optimization

Designing machining tools is a very difficult optimization task since not only complex geometries, but also different machining criteria have to be taken into account [59.10]. *Abele and Fujara*, for example, presented a simulation approach for optimizing the drill geometry based on a genetic algorithm [59.11]. They considered not only the structural stiffness of the tool during their optimization run, but also took the coolant flow resistance and the chip evacuation capability into ac-

count. They also defined the machinability, especially the grindability of the chip flute, as constraint. In order to take all these criteria into account, different simulation approaches have to be used (Sect. 59.4). *Abele and Fujara* used, for example, the finite element method in order to analyze the structural stiffness. The cutting forces were computed using a semiempirical cutting force model. Additionally, a model of the grinding wheel had to be determined in order to evaluate the grindability of the optimized drill geometry. Another application was presented by *Jared et al.* [59.12] who integrated **GA** into the computer-aided design software CATIA. In one of their case studies, the volume and the tip deflection of a cutting tool were minimized by automatically parameterizing length and angles between segments of a **2-D** (two-dimensional) profile which were then extruded to the actual tool.

### 59.2.3 Workpiece Layout Optimization

The layout of products can usually be described as multiobjective optimization problem. For example, the design of aerospace structures always faces a trade-off between the stiffness and the weight of the products [59.13]. The layout of a cooling system, e.g., for a turbine blade [59.13] is a tradeoff between the machining quality, the cooling effect, and the production costs. *Weinert et al.* [59.14–17] developed a simulation system for optimizing the layout of mold temperature control systems in order to minimize the production cycle times and costs, and to maximize the product quality. They developed an efficient simulation system in order to evaluate the effect and homogeneity of the tempering of the design layout and to estimate the manufacturing costs [59.18]. Using fast but sufficiently accurate evaluation methods, a computer-aided optimization of the temperature control system based on multiobjective optimization methods, like **NSGA-II** [59.19] and **SMS-EMOA** [59.20], became possible [59.21–24]. Nevertheless, this optimization task is very complex and the engineer's experience is still necessary. Due to this, *Biermann et al.* [59.25] combined the computer-aided optimization system with the possibility of user interaction so that a visual real-time manipulation of target functions is possible. *Dürr and Jurkies* [59.26] presented a fuzzy expert system in order to use the expert knowledge in a computer-assisted way.

## 59.3 Computer-Aided Design and Manufacturing

In the modern construction process, computer-aided design (**CAD**) software is used for all design tasks – for example for the model of the workpiece. This model is the basis for the generation of the **NC** paths by **CAM** software. However, if only a physical prototype exists or manual modifications of the original model have been performed, methods to compute a respective model are required. To accomplish this, the original object is scanned and a point-based representation is obtained. From this point data, a new **CAD** model has to be calculated or the original model has to be adapted. This process is called *surface reconstruction* or *reverse engineering*.

When a model of the workpiece is available, **NC** paths can be generated based on **CAM** software for most machining processes. For complex five-axis milling processes, however, the results of standard **CAM** software are not always optimal with respect to the requirements of the specific machine and process. In this case, **CI**-based techniques can be used to improve the **NC** paths generated by the **CAM** software.

### 59.3.1 Surface Reconstruction

The optimization of the visual quality of triangulations with respect to different quality criteria was successfully performed using evolutionary algorithms by *Weinert et al.* [59.27]. Based on an initial triangulation, as provided by the software of the scanning system, edges were flipped in order to minimize the total length of all edges, the surface area, the sum of angles between normals, and the total absolute curvature. It was found that the latter is best suited for generating visually smooth surfaces.

Small tolerances in the representation of the original object, however, result in a huge number of required scan points. Current scanners are able to provide this dense and precise set of scan points, but the resulting triangulations become very large and difficult to handle. Approximating triangulations tackle this problem. The number of control points for the triangles is independent of the size of the point set and usually considerably smaller than the number of scan points. *Weinert et al.* [59.28] documented the capabilities of a standard evolution strategy to optimize the control point positions of approximating triangulations. In order to avoid an uncontrolled expansion of the triangulation, balancing strategies based on mass–spring systems were integrated.

Unfortunately, even approximating triangulations produce a nonsmooth surface and are therefore not convenient for the later computation of **NC** paths. *Nonuniform rational B-splines (NURBS)* [59.29] are another popular mathematical model for free-form surfaces in **CAD** software. The most important advantages of **NURBS** over triangulations are their smoothness, their compact definition, the possibility for an intuitive local manipulation, as well as the ability to combine **NURBS** patches to larger structures. *Mehnen et al.* [59.30, 31] applied an evolution strategy to the coordinates of the **NURBS**'s control points in order to minimize the distance between the scan points and their projection to the **NURBS**. *Wagner et al.* [59.32] did the same using a real-valued genetic algorithm. They also proposed another distance indicator that is based on a sampling of the **NURBS** and that is much cheaper to evaluate. The use of the sampling-based distance measure in combination with a equation-solver-based hybrid real-valued genetic algorithm significantly reduced the runtime of the optimization. This approach was further enhanced [59.16] to a two-step approach, in which the single-objectively optimized solution is used as initial individual for a multiobjective optimization. As additional objective, the smoothness of the **NURBS** was considered. This objective was also considered by *Jared et al.* [59.12] in their **GA**-based optimization of **NURBS** in CATIA.

In addition, *Weinert et al.* [59.33] combined **NURBS** with constructive solid geometries [59.34] in a hybrid evolutionary algorithm/genetic programming approach. By these means, the constructional logic behind the workpiece could also be approximated.

### 59.3.2 Optimization of NC Paths

The five-axis milling process offers the possibilities to tilt the milling tool and, thus, to use shorter and therewith stiffer tools. This allows complex free-form surfaces to be machined in one workpiece clamping, and the engagement conditions to be adapted [59.35]. An improvement of the machining results and a reduction of the machining time can be achieved. However, in contrast to the three-axis process, the generation of the **NC** paths particularly for the machining of free-form surfaces is much more complex [59.6].

*Weinert and Stautner* [59.36] presented an algorithm for converting three- into five-axis milling paths

in which the position of the tool tip is kept from the three-axis NC program. An optimization approach based on an evolutionary strategy was used to improve the tool movement [59.37]. To accomplish this, they developed a fast simulation system of the five-axis milling process based on a discrete dexel model of the workpiece (Sect. 59.4) [59.38].

The NC paths generated for a five-axis milling process are often not smooth enough since the kinematic behavior of the specific milling machine is not taken into account. Zabel et al. developed a simulation approach which is placed in the process chain between the CAM system and the real-milling process [59.39]. The five-axis tool movement is optimized taking the tool axis configuration and the dynamic behavior of the milling machine into account. For this purpose, methods of evolutionary computation and wavelet the-

ory were combined [59.35]. In 2007, Mehnen et al. integrated a multiobjective optimization algorithm into this simulation system which combined the variation of a modern single-objective approach with the selection mechanism of a classical multiobjective optimization algorithm in order to optimize the tool movement [59.40].

One challenging task during the optimization of the five-axis milling process is the avoidance of collisions between the milling tool and the workpiece. Kersting and Zabel [59.6] developed an efficient simulation approach, which maps the high-dimensional restriction area on a two-dimensional matrix structure. They showed that the use of a multipopulation multiobjective evolutionary algorithm in the restriction-free area improved the corresponding Pareto fronts [59.41].

## 59.4 Modeling and Simulation of the Machining Process

The optimization of real-world applications using CI-based or classical optimization approaches requires that a performance value or vector can be obtained for all possible settings of the input parameters, whereby the performance values are usually calculated based on measurements during or after the actual process. In order to achieve a near-optimal result, however, far more than 100 different parameter vectors have to be evaluated – even for low-dimensional problems. This amount of real experiments is often impossible due to the costs related to them. As a possible solution, the use of empirical or physical (simulation) models can significantly reduce the number of required experiments since most of the evaluations can be performed on the model. For both kinds of approaches, CI techniques have already been successfully used. Some examples are presented in the following subsections.

### 59.4.1 Empirical Modeling

For the use of empirical models, real or simulated experiments are still required in order to build up a data base for the training of the model. In contrast to the direct optimization of the process, however, these experiments are performed as a block of moderate size in the beginning of the optimization. Afterward, the model allows new parameter settings to be predicted based on the information obtained from training data. The determination of near-optimal solutions can be performed on the model.

The number of empirical models is exhaustive [59.42]. Nevertheless, NNs often showed their capability to empirically model responses from machining processes. For instance, the material removal rate of an abrasive jet drilling process was successfully predicted by using an NN with back error propagation [59.43]. As input parameters, varying gas pressure, nozzle inside diameter, abrasive flow rate, size of the medium particle, and standoff distance were considered. Accordingly, the ablating depth obtained for specific values of the peak power, pulsing frequency, and overlapping in a laser drilling process could be predicted using NN [59.44]. Casalino et al. [59.45] showed that NN achieve higher prediction accuracies than regression techniques in predicting surface roughness and resultant forces for varying cutting speed, feed rate, and radial depth in milling. In the same line, NN were used for the prediction of the specific cutting constants resulting from different cutting speeds, feeds, inclination angles  $\alpha$  and  $\beta$ , cutting depths, and cutting widths [59.46]. With respect to tool wear, the wheel life of a cylindrical grinding wheel was modeled using a feedforward backpropagation NN. A direct prediction of the tool wear was also accomplished using NN [59.47, 48]. Moreover, the thermal expansion of the Y-axis ball screw was predicted based on temperature measurements at different points of the machine structure [59.49].

In addition, CI-based techniques can also indirectly be used for empirical modeling. As soon as complex

empirical models, such as Gaussian processes, support vector or other kernel machines, are used, the determination of the optimal model parameters is an individual nonlinear optimization problem. Evolutionary algorithms, in particular the covariance matrix adaptation evolution strategy (**CMA-ES**) [59.50], showed to be suitable for solving these problems [59.51, 52].

#### 59.4.2 Physical Modeling for Simulation

In cases where sufficient knowledge about the physical laws of the process is available, simulation models based on equations representing these physical laws are likely to be superior to the very general formulations of the empirical models. Nevertheless, also these models have parameters that are related to the properties of the material, tool, and machine. Since these parameters can often not be measured, their values are usually set by minimizing the error between the predictions of the simulation and a training set of observations from real-world experiments. As consequence, **EC** is a valuable tool for calibrating simulation models which was shown to be superior to classical data fitting tools [59.53].

In an exemplary application, the dynamic behavior of manufacturing systems was characterized by its frequency response function. This function can be modeled by a superposition of decoupled damped harmonic

oscillators, whereby each oscillator has three parameters (mass, natural frequency, and damping) [59.54]. In order to minimize the deviation between the measured frequency response function and one of the oscillators, an interactive approach based on evolutionary algorithms was successfully implemented [59.54].

An open issue in the simulation of machining processes is the modeling of the extremely high strain rates which can only rarely be covered by classical material models and tensile tests. As a possible solution, **EC** can be used as a submodule of a simulation in order to predict the deformation and flow characteristics for high strain rates. For instance, Weinert et al. used symbolic regression by means of a genetic programming system to evolve mathematical formulae that describe the trajectories of single particles of steel based on recordings of a high-speed camera during the turning process [59.55, 56]. Teti et al. [59.57] employed **NN** to reconstruct the stress-strain curve of the workpiece material from experimental data of tensile tests. They found out that the learned **NN** is capable of predicting workpiece material properties in a wide range of temperature and strain rate values. A hybrid simulation model based on physical equations and the empirical stress-strain prediction was finally proposed. Two recent overviews of hybrid models for simulation which also incorporate **CI** techniques were provided by Jawahir et al. [59.58, 59].

### 59.5 Optimization of the Process Parameters

In this section, possible applications of **EC** methods for the optimization of the actual process parameters are discussed. Since a recent survey book for the model-based optimization of process parameters exist [59.1], only a short summary of possible applications is provided. In contrast to this survey, the following presentation does not distinguish between different processes, as the aspects related to the use of **EC** are independent of the actual process, e.g., milling, turning, or grinding.

As already discussed in the previous section, it is mandatory to approximate the process quality indicators by means of analytical, empirical, or physical models. In the literature, no direct application of **EC** optimization techniques to machining processes was reported until now. Instead, polynomial or process-related equations were usually fitted to experimental data [59.60–78]. Neural networks [59.63, 79–83], other empirical models [59.51, 62, 84], and simulation mod-

els [59.85, 86] were also popular to accomplish this task.

For the actual optimization, two important decisions on the formulation of the problem have to be taken in order to choose the **EC** method. These decisions are concerned with the representation of the input parameters and the objectives. In most cases, continuously defined input parameters, such as feed and cutting speed, are to be optimized. This relates to techniques such as evolution strategies, particle swarm optimization, and real-valued genetic algorithms (**GAs**). If also discrete parameters, such as the cooling concept or tool material, are considered, special evolution strategies [59.65, 87] or binary **GAs** may better be suited. With respect to the objectives, it has to be decided whether a single optimal solution or a set of tradeoffs is desired. In the former case, almost all **EC** techniques can directly be used. Due to the complexity of

production engineering problems, however, a suitable scalarization of the different objectives has to be found in order to achieve reasonable results. In the latter case of searching for an approximation of the trade-off structure, it is important that the algorithm is capable of coping with multiple objectives which have to be considered in parallel [59.51, 72, 74, 78, 79, 84, 86].

In the literature, the use of continuous input variables and single-objective formulations is established. The most popular **EC** methods are particle swarm optimization (**PSO**) [59.63, 68, 75, 76, 81–83, 85, 88] and standard **GA** or evolutionary algorithm (**EA**) [59.60, 62, 64, 67, 69, 77, 80]. The use of specifically designed heuristics [59.71, 75, 89] is rather uncommon. Nevertheless, the formulation of the problem and the design of the algorithm should aim at incorporating as much knowledge as possible into the optimization [59.16].

Unfortunately, the generality of **CI**-based techniques often results in problem formulations which are not completely sophisticated. An important factor of-

ten neglected when optimizing production engineering problems is the uncertainty about the external process variables, e.g., properties of the tool or material. Although modern algorithms are capable of incorporating them into the optimization [59.90], only a few applications actually take these uncertainties into account [59.70]. More specifically, two sources of uncertainty can be considered [59.91]: perturbations in the input variables, e.g., due to online control, and environmental uncertainties, such as outdoor temperature, humidity, and the already mentioned external process variables. A detailed overview of such factors can be found in the literature [59.92]. A comprehensive survey of possible problem formulations and respective optimization approaches was presented by *Beyer and Sendhoff* [59.91]. In production-engineering applications, however, classical statistical methods are usually used to cope with these problems. The potential of **CI**-based techniques has not yet been exploited.

## 59.6 Process Monitoring

The analysis of different process variables – like for example the cutting forces, acoustic emission, or temperatures – allows conclusions about the process-dependent state of the machining processes and its components (tools, machines, workpieces, etc.) to be drawn and provides the possibility for an adaptive process control [59.93]. The idea of process monitoring is to measure, visualize, and analyze the values of these variables during the machining process. *Teti et al.* [59.93] gave an extensive overview of *advanced monitoring of machining operations* describing sensor

systems for machining, signal processing, monitoring scopes, and the decision-making support systems. In order to evaluate the measured values, cognitive computing methods – for example genetic algorithms, fuzzy logic, or **NN**s – can be used. In contrast to the rule-based fuzzy logic approach, **NN**s do not store the knowledge in an explicit form. A survey of the successful applications of these techniques for the advanced monitoring of machining operations was provided by *Teti et al.* [59.93]. It is thus omitted in this section.

## 59.7 Visualization

In the field of production engineering, the complex optimization problems are often characterized by multiple objectives and restrictions. Additionally, the decision space can be high dimensional – like for example in the case of optimizing **NC** paths (Sect. 59.3.2) [59.6]. In order to analyze the optimization problems and the applied optimization approach, an intuitive visualization of the data resulting from the evolutionary process is advisable [59.94]. For this purpose, *Pohlheim* [59.95] reviewed several visualization techniques in order to

obtain a better understanding of the optimization process of real-world problems. He recommended the use of three diagrams in order to analyze the optimization algorithm: A convergence diagram, visualization of the change of the best individual during the optimization approach, and a diagram of the objective values of all individuals in the population of all generations.

*Miller et al.* discussed techniques for an *intuitive visualization and interactive analysis of Pareto sets ap-*

plied on production engineering systems [59.94]. They analyzed different visualization and analysis methods in order to gain insight into both the optimization problem and the optimization algorithm, and to support an intuitive decision-making process. For this purpose, they presented a simultaneous visualization of the decision and the objective space. An interactive navigation through the solution sets supports the user to detect specific process characteristics [59.94]. This also helps to redesign the objective formulation in cases where the optimization results are not in agreement with the actual preferences of the decision maker.

In order to support the trade-off analysis in multiple dimensions, *Obayashi* and *Sasaki* [59.96] presented a visualization approach based on self-organizing maps (**SOMs**). The idea is to map from the high-dimen-

sional objective function space to two-dimensional map units. They showed the applicability of this approach analyzing two multiobjective aerodynamic design problems [59.96].

The *innovation* approach of *Deb* [59.97] provides an automated identification of design principles by searching for common features of the optimal trade-offs in a multiobjective optimization problem. These features are provided by means of analytical relations between the design variables. A successful application of innovation in machining was already reported [59.78]. Another possibility to learn about the structure of the objectives and the effect of the input parameters is provided by visualizations and analyses based on the surrogate models of the process (Sect. 59.4) [59.51, 98].

## 59.8 Summary and Outlook

This chapter focused on applications of **CI** in the optimization of machining problems. For this purpose, the whole process chain – from the design of a machine, tool, or workpiece, as well as the corresponding optimization of process parameters, to the process monitoring and subsequent analysis of the results – was taken into account. Different modeling and simulation techniques, which are necessary to optimize real-world problems, were discussed. Successful examples in the field of production engineering were compiled to present the applicability of the **CI** methods. In conclusion, evolutionary and genetic algorithms are general and powerful solvers for nonlinear optimization tasks,

artificial neural networks can be used for continuous modeling problems, and fuzzy logic provides an intuitive way to represent expert knowledge.

Unfortunately, the generality of **CI**-based techniques often results in problem formulations which are not completely sophisticated. For instance, possibilities of creating good initial solutions, uncertainty in the design variables, and specific aspects of the quality indicators resulting in undesirable scalarizations, are often neglected. **EC** provides the means to appropriately consider these aspects. A proper analysis of the results can assist in identifying such pitfalls and in improving the problem formulation.

# 60. Aerodynamic Design with Physics-Based Surrogates

Emiliano Iuliano, Domenico Quagliarella

Details, references and guidelines are given about the adoption of surrogate models and reduced-order models within the aerodynamic shape optimization context. The aerodynamic design problem and its approximated version are introduced and discussed and then, an overview of various surrogate models and surrogate-based optimization methods is given. Subsequently, the concept of model order reduction is recalled, and the performance analysis of reduced-order models based on proper orthogonal decomposition (POD) is discussed. Within this context, some techniques to adaptively and globally improve the accuracy of POD-based surrogates are illustrated. Finally, an aerodynamic shape design problem of a transonic airfoil is used to practically analyze and compare the performances of various surrogate-based optimization methods.

Modern air vehicle design has been increasingly driven by environmental as well as operational constraints. Environmental concerns, including emissions and noise, are gaining increasing importance in the design and operations of commercial aircraft. Taking into account the current prognoses for the growth in air traffic, the above-mentioned challenges become even more significant [60.1–4]. In this context, the development and assessment of new theoretical methodologies represents a cornerstone for reducing the experimental load, exploring trade-offs, and proposing alternatives along the design path. The fidelity of such methods is essential

to reproduce *real-life* phenomena with a significant degree of accuracy and to take them into account from the very beginning of the design process. Due to the intrinsic complexity of aircraft design, the design space is often huge and difficult to explore fully, so that fast semi-empirical tools and rules [60.5–7], derived from classical configuration data, have been traditionally applied. However, they exhibit a severe lack of accuracy when designing novel and unconventional concepts. Therefore, highly accurate analysis methods have been continuously introduced both in geometric representation and physical modeling, but the main drawback

is that they are computationally expensive. For example, the solution of the Navier–Stokes equations around complex aerodynamic configurations requires a huge amount of computational resources even on modern state-of-art computing platforms. This turns out to be an even bigger issue when hundreds or thousands of analysis evaluations, like in parametric or optimization studies, have to be performed. In order to speed up the computation while keeping a high level of fidelity, the scientific community is increasingly focusing on surrogate methodologies like meta-models, multi-fidelity models, or reduced-order models. These can provide a compact, accurate, and computationally efficient representation of aircraft design performance.

The present chapter will give details and references about the adoption of surrogate models and, in par-

ticular, reduced-order models within the aerodynamic shape optimization context. In Sect. 60.1, the aerodynamic design problem and its approximated version will be introduced. Then, an overview of various surrogate models and surrogate-based optimization methods will be given. In Sects. 60.3 and 60.4, the concept of model order reduction will be recalled and the performance analysis of reduced-order models based on proper orthogonal decomposition (POD) will be discussed. In the Sect. 60.5, some techniques to adaptively and globally improve the accuracy of POD-based surrogates will be presented. Finally, Sect. 60.6 will be devoted to the analysis and comparison of the performances of various surrogate-based optimization methods with respect to the aerodynamic shape design of a transonic airfoil.

## 60.1 The Aerodynamic Design Problem

A broad class of aircraft design applications can be numerically modeled with the minimization of a function  $f$  which depends on two sets of variables: the design variables  $w$ , which the designer can directly control it, and the state variables  $x$ , which provide the evolution of the system representing the underlying physics. The design problem can be formulated as the non-linear programming problem

$$\begin{aligned} \min_{w,x} \quad & f(w,x) \\ \text{subject to} \quad & r(w,x) = 0, \quad h(w,x) = 0, \\ & g(w,x) \leq 0, \\ & w_L \leq w \leq w_U. \end{aligned} \tag{60.1}$$

$f$  is the objective function which the designer wants to minimize to improve performance. In aircraft design, typical objective functions are weight, noise, drag, aerodynamic efficiency, or a combination of thereof.  $r(w,x)$  is the state equations set, which links the design variables and the state variables and it usually represents the governing laws of physics. In aerodynamic design, the state equations are modeled through computational fluid dynamics, e.g., the Navier–Stokes equations, which relate scalar or vector field (state) variables, like pressure or velocity, to the design variable vector. In a shape optimization problem, the design vector is made dependent on the aircraft component shape

by means of a parameterization approach. The vectors  $g(w,x)$  and  $h(w,x)$  are filled, respectively, with inequality and equality constraint functions, which must be satisfied for a design candidate to be considered feasible. Typical constraint functions in aircraft design are related to the generation of a minimum lift level to balance the weight or a threshold pitching moment coefficient to allow for trim.  $w_L$  and  $w_U$  are the lower and upper bounds of the design variables and thus specify the range of allowable values for the design vector  $w$ .

### 60.1.1 Problem Approximation

The computational time required to solve this problem is basically affected by two parameters: the number of function evaluations required to minimize the objective function and the cost of a single evaluation. Given a vector  $w^*$ , the latter is dominated by the computational effort needed to solve the state equations

$$r(w^*, x) = 0.$$

The adoption of a surrogate model reduces the cost per objective function evaluation. A surrogate model consists in replacing the expensive objective  $f$  and constraint functions  $g, h$  with less expensive, lower-fidelity models  $\hat{f}$  and  $\hat{g}, \hat{h}$ . Concerning reduced-order modeling, it can be observed that the dimensionality

of the optimization problem is twofold: the state vector and design vector dimension. As the first one is usually much bigger than the second one, model reduction can be applied to make explicit the dependency of  $x$  on  $w$  and solve the state variables as functions of the design ones. In other words, unlike response surfaces and meta-models, an approximation  $\hat{x}$  of the state variables is available thanks to the model order reduction. As a consequence, the reduced-order approximate form of the optimization problem (60.1) can be cast

as

$$\begin{aligned} \min_w \quad & \hat{f}(w) \\ \text{subject to} \quad & \hat{h}(w) = 0, \quad \hat{g}(w) \leq 0, \\ & w_L \leq w \leq w_U, \end{aligned} \quad (60.2)$$

where the dependence on the state variables has been dropped and the state vector has an explicit approximate relation with the design vector:  $\hat{x} = k(w)$ .

## 60.2 Literature Review of Surrogate-Based Optimization

This section proposes a survey of the most relevant surrogate-based optimization concepts. The topics have been widely discussed in the recent past, thanks to their innovative character and broad application areas. The introduction of surrogate models as fitness approximation within an evolutionary optimization system mitigates the demand for large computational resources associated to such search algorithms, allowing us to find a proper balance between the complete exploration of huge design spaces and limited cost. To this aim, reduced-order modeling through **POD** is a step forward, as a modal decomposition of an ensemble of functions, derived from numerical simulations, is performed to extract the most relevant patterns in the data set. Hence, compared to standard, interpolating meta-models, which are usually trained on an integral function representing the objective, reduced-order models should assure a deeper insight into the phenomena modeled.

Surrogate-based optimization (**SBO**) has been introduced to tackle the number of function evaluations in many engineering optimization problems. In aircraft design common practice, they can be used as a quick evaluator in several tasks: parametric analyses over the design space, optimization and control, and uncertainty quantification. A special challenge is represented by their use in global optimization as state-of-the-art methods, which often requires more function evaluations than can be comfortably affordable. A well-established approach consists in fitting some kind of response functions to basic data obtained by evaluating the objectives and constraints at a few points. The resulting surfaces, affordable at low cost, can provide fast answers in terms of trade-off analysis and optimization, as well as just an intuitive sketch behavior by means of simple visualization. The basic process consists of the following steps:

*sampling the design space* – once the design variables have been chosen, a sampling plan is defined and some initial sample designs are analyzed with an accurate solver; *surrogate model selection and construction* – a surrogate model type is selected and used to build a meta-model of the underlying problem; *model validation* – the model is checked according to some statistical metrics and, if not accurate enough, a search is carried out using the model to identify new design points for analysis; *model updating* – the new results are added to those already available and a new meta-model is built (repeating the last three steps); *optimization* – the refined surrogate is used to provide objective/constraint functions.

As **SBO** covers so many topics, the literature on the subject is huge. Many ideas have been proposed in the last 20 years, which are classified for design space dimensions, surrogate methods, search algorithms, updating algorithms, application areas. Hence, an exhaustive survey of all the possible ideas for each topic and all their possible combinations would go beyond the scope of the present research. Generally speaking, surrogate models can be roughly divided into three classes: data fit surrogates, multi-fidelity models, and reduced-order models. Data fitting models rely on the approximation of data (response values, gradients, and Hessians) generated from the high-fidelity model. In order to give a global behavior to surrogate methods, the whole design space must be sampled in advance by using design of experiments. Global approximations, often referred to as *response surface methods*, can be obtained with polynomial regression [60.8], Gaussian processes, Kriging interpolation [60.9], radial basis function networks [60.10], multi-adaptive regression splines [60.11], and artificial neural networks [60.12].

A second class of surrogates is the hierarchical one (also called multi-fidelity or variable fidelity). Unlike the data fit surrogates, they do not need to be trained on a sampling dataset, but they rely on a lower fidelity approximation which, however, is still inspired by the physical behavior of the system. Multi-fidelity models are classified according to the way they operate the fidelity reduction: examples in aerodynamics are coarser mesh discretization, partially converged solution [60.13], and model fidelity reduction [60.14–16] (e.g., using the Euler model instead of the Navier-Stokes equations by neglecting the effects of fluid viscosity and heat transfer). The name *multi-fidelity* usually refers to the capability of mixing and exploiting both high-fidelity and lower-fidelity models in an efficient way so as to keep the fidelity of the former only when it is needed and to take advantage of the higher speed of the latter otherwise.

A third class is represented by reduced-order models. A reduced-order model (**ROM**) is mathematically derived from a high-fidelity model using a projection technique. It consists in computing a set of basis functions (e.g., eigenmodes, left singular vectors) upon which the available dataset (ensemble) is projected to compute the unknown model parameters. The model reduction is obtained by capturing the principal dynamics of the system and neglecting the less significant from a physical point of view. Hence, similarly to data fit surrogates, reduced-order models require the a-priori solution of the expensive high-fidelity model. The advantage of reduced-order models with respect to data fits is that the most significant features of the flow field can be derived by approximation, thus offering the potential to keep more physics within the surrogate. The proper orthogonal decomposition or principal component analysis (**PCA**) is an elegant and powerful data-reduction method for non-linear physical systems. Its application as a surrogate to the aerodynamic optimization of aircraft components is the core of the present chapter.

Hereinafter, a more in depth look is given at the various methods of constructing a surrogate model and, in particular, at optimization assisted with the surrogate. Jones et al. [60.17] was among the first to propose a response surface methodology based on modeling the objective and constraint functions with stochastic processes (Kriging). The so-called design and analysis of computer experiments (**DACE**) stochastic process model was built as a sum of regression terms and normally distributed error terms. The main conceptual assumption was that the lack of fit due only to

the regression terms can be considered as entirely due to modeling error, not measurement error or noise, because the training data are derived from a deterministic simulation. Hence, by assuming that the errors at different points in the design space are not independent and the correlation between them is related to the distance between the computed points, the authors came up with an interpolating surrogate model that is able to provide not only the prediction of objectives/constraints at a desired sample point, but also an estimation of the approximation error. After the construction of such a surrogate model, the latter powerful property is exploited to perform an efficient global optimization (**EGO**), which can be considered as the progenitor of a long and still in development chain of **SBO** methods. Indeed, they found a proper balance between the need to exploit the approximation surface (by sampling where it is minimized) with the need to improve the approximation (by sampling where prediction error may be high). This was done by introducing the expected improvement (**EI**) concept, already proposed by Schonlau et al. [60.18], which is an auxiliary function to be maximized instead of the original objective. The **EI** function is designed in order to provide a proper balance between exploration and exploitation.

In a further work, Jones [60.19] proposed a taxonomy of global **SBO** methods. Seven methods were identified and classified according to whether they were interpolating (cubic splines, thin-plate splines, multiquadratics, Kriging) or not (quadratic polynomials), whether they provided statistical information (Kriging) or not (splines), and whether the method for selecting search points (updating the model by adding new sample points) was two stage (probability/expected improvement) or one stage (goal-seeking, credibility function).

Gutmann [60.10] reported excellent numerical results for a spline-based implementation of Method 7 and proved the convergence of the method. Compared to previous methods, Method 7 required a high number of true function evaluations to find the global optimum, but, as Jones wrote, *this is the price we pay for the additional robustness*. An overview of **SBO** techniques was also presented by Queipo et al. [60.20] and Simpson et al. [60.21]. They covered some of the most popular methods in design space sampling, surrogate model construction, model selection and validation, sensitivity analysis, and surrogate-based optimization. Forrester and Keane [60.22] recently proposed a review of some advances in surrogate-based optimization. An important lesson learned is that only calling the

true function can confirm the results coming from the surrogate model. Indeed, the path towards the global optimum is made of iterative steps where, even exploiting some surrogate model, only the best results coming from the true function evaluations are taken as optimal or sub-optimal design. The true function evaluation also has to be invoked to improve the surrogate model. With the term *in-filling criteria* we usually mean some principles that allow us to intelligently place new points (infill points) at which the true function should be called. The selection of infill points, also referred to as adaptive sampling or model updating, represent the core of a surrogate-based optimization method and helps to improve the surrogate prediction in promising areas of the objective space.

The right choice of the number of points which the initial sampling plan would comprise and the ratio between initial/in-fill points has been the focus of several recent studies. However, it must be emphasized that no universal rules exist, as each choice should be carefully evaluated according to the design problem (e.g., the number of variables, computational budget, type of surrogate). *Forrester and Keane* [60.22] assumed that there is a maximum budget of function evaluations, so as to define the number of points as a fraction of this budget. They identified three main cases according to the aim of the surrogate construction: pure visualization and design space comprehension, model exploitation, and balanced exploration/exploitation. In the first case, the sampling plan should contain all of the budgeted points, as no further refinement of the model is foreseen. In the exploitation case, the surrogate can be used as the basis for an in-fill criterion, which means some computational budget must be saved for adding points to improve the model. They also proposed to reserve less than one half of the points for the exploitation phase, as a small amount of surrogate enhancement is possible during the in-fill process. In the third case, that is the two-stage balanced exploitation/exploration in-fill criterion, as also shown by *Sóbester et al.* [60.23], they suggested employing one third of the points in the initial sample while saving the remaining for the in-fill stage. Indeed, such balanced methods rely less on the initial prediction, and so fewer points are required. Concerning the choice of the surrogate, the authors observed that it should depend on the problem size, i. e., the dimensionality of the design space, the expected complexity, the cost of the true analyses, and the in-fill strategy to be adopted.

However, for a given problem, there is no general rule. The proper choice could come up after various

model selection and validation criteria. The accuracy of a number of surrogates could be compared by assessing their ability to predict a validation data set. Therefore, part of the true computed data should be used for validation purposes only and not for model training. This approach can be infeasible when the true evaluations are computationally expensive. To overcome this issue, *Goel et al.* [60.24] proposed a weighted average of an ensemble of surrogates. For example, a better model can be achieved by combining Kriging, which might accurately predict the non-linear aspects of a function, and polynomials to better capture the regression trends. *Forrester* also underlined that some in-fill criteria and certain surrogate models are somewhat intimately connected. For a surrogate model to be considered suitable for a give in-fill criterion, the mathematical machinery of the surrogate should exhibit the capability to adapt to unexpected, local non-linear behavior of the true function to be mimicked. From this point of view, polynomials can be immediately excluded since a very high order would be required to match this capability, implying a high number of sampling points. In principle, the convergence to a local optimum might be achieved by simply minimizing the surrogate, evaluating the true function at the minimum point and updating the model database with the new point. Conversely, a global search would require a surrogate model able to provide an estimate of the error it commits when predicting. Thus, the authors suggested the use of Gaussian process-based methods like Kriging, although citing the work of *Gutmann* [60.10] as an example of a one-stage goal seeking approach employing various radial basis functions. Finally, some interesting suitable convergence criterion to stop the surrogate in-fill process were proposed. In an exploitation case, i. e., when minimizing the surrogate prediction, one can rather obviously choose to stop when no further significant improvement is detected. On the other hand, when an exploration method is employed, one is interested in obtaining a satisfying prediction everywhere, so that one can decide to stop the in-filling when some generalization error metrics, e.g., cross-validation, fall below a certain threshold. When using the probability or expectation of improvement, a natural choice is to consider the algorithm converged when the probability is very low or the expected improvement drops below a percentage of the range of objective function values observed. However, the authors also observed that a discussion on convergence criteria may be interesting and fruitful, but *in many real engineering problems we actually stop when*

we run out of available time or resources, as dictated by design cycle scheduling or costs. This is what typically happens in aerodynamic design, where the high-dimensionality of the design space and expensive com-

puter simulations often do not allow us to reach the global optimum of the design problem but suggest that we consider even a premature, sub-optimal solution as a converged point.

## 60.3 POD-Based Surrogates

In this section a review of the mathematical core of POD is presented. POD is a mathematical procedure that allows us to perform a modal decomposition of a large set of multi-dimensional data so as to derive a dimensionality reduction and describe the original system with much fewer unknowns. The mathematical development of POD for fluid flow applications, in particular, is described in some detail in [60.25]. Here, the main aspects related to the construction of a reduced-order model through singular value decomposition are presented and mainly the use of this technique for steady-state problems is addressed.

### 60.3.1 Model Order Reduction

Physics-based approximation concepts require a deep understanding of the governing equations and the numerical methods employed for their solution. The substantial difference between a reduced-order model and data fit model consists in retaining an explicit dependency between state variables, related to the governing equations and design parameters. In other words, reduced-order models operate on the dimensionality of the discretization of the state equations rather than on the design space. Thus, such models are partially independent of a notable increase in the number of design variables. A reduced-order model, in fact, mimics the basic structure of the problem and not just a functional relationship between input and output parameters. Hence, the main advantage of using reduced-order models lies in their being mostly insensitive to the curse of dimensionality.

To illustrate the model order reduction concept, consider the discrete mathematical model (e.g., the Navier–Stokes equations) of a physical system written in the form

$$R(w, x(w)) = 0, \quad (60.3)$$

where  $w \in R^t$  is the vector of design variables and  $x \in R^q$  the discretized vector of state (or field) variables (velocity, energy, density). Note that  $x$  is an implicit vector

function of the design variable vector. Unlike classical data fit methods (e.g., Kriging, RBF) which work on local or integral values of the state variables, reduced-order methods, instead, provide an approximation of the state vector in the form

$$\hat{x} = c_1 \phi_1 + \cdots + c_M \phi_M = \Phi c,$$

where

$$\Phi = \{\phi_1, \dots, \phi_M\} \in R^{q \times M}$$

is a matrix of known basis vectors and

$$c = \{c_1, \dots, c_M\} \in R^M$$

is a vector of unknown coefficients. The underlying approximation is that the state vector lies in the subspace spanned by a set of basis vectors. Obviously, this is not true for each state vector, but a proper choice of an orthonormal basis can lead to the minimization of the approximation error in a least squares sense. This is how a proper orthogonal decomposition is derived. Following this approach, the problem of representing a state vector with  $q$  unknowns can be recast into a problem with  $M$  unknowns and, as usually  $q \gg M$ , it is possible to obtain an approximation of  $x$  very efficiently. The estimation of the vector  $c$  can be obtained with different techniques, classified as intrusive and non-intrusive. The first introduce the approximation in the governing equations and find the coefficients by minimization of the residual norm; the second employ data fit techniques trained on a set of known coefficients.

The basis vectors can be computed starting from state solutions of the discrete governing equations which correspond to  $M$  different values of the parameters  $w$ . As a consequence, the matrix  $\Phi$  contains the basis vectors of the subspace

$$\Phi = \text{span}\{x(w_1), x(w_2), \dots, x(w_M)\} \in R^{q \times M}. \quad (60.4)$$

For instance, the state solutions  $x_i = x(w_i)$  are obtained by solving the Reynolds-averaged Navier–Stokes (**RANS**) equations on  $M$  different configurations generated by applying the parameterization method employed on  $M$  design vectors  $w_i$ . The definition of the  $M$  design sites where to compute the solutions is not a trivial issue; generally speaking, standard design of experiments techniques are used to sample the design space with good coverage properties, but, as will be discussed in next sections, this approach may lead to erroneous results when facing highly multi-modal, highly non-linear problems. Indeed, the quality of the approximation strongly depends on the location of training data in the design space.

### 60.3.2 POD Theory and Solution

The construction and training of **POD**-based surrogate models for aerodynamic applications are described in detail in [60.26, 27]. The singular value decomposition (**SVD**) solution of the **POD** basis vectors and coefficients is used for steady-state problems. This approach is normally preferred to the eigenvalue/eigenvector solution, as it is faster and easier to implement. **POD** modeling is specifically focused on compressible aerodynamic problems, hence the space domain will be represented by the discretized volume occupied by the flowing air, and the snapshot vectors will be defined from computed flow fields. The column vectors of the snapshot matrix (here also referred to as the ensemble matrix) contain the volume grid and flow variables as computed with a computational fluid dynamics (**CFD**) solver.

The **SVD** solution allows us to obtain an optimal basis in the sense of the maximization of the averaged projection of the ensemble onto it. Hence, each snapshot vector can be retrieved as linear combination of the **POD** basis. If a fluid dynamics problem is approxi-

mated with a suitable number of snapshots from which a rich set of basis vectors is available, the singular values become small rapidly and a small number of basis vectors are adequate to reconstruct and approximate the snapshots as they preserve the most significant ensemble energy contribution. In this way, **POD** provides an efficient mean of capturing the dominant features of a multi-degree of freedom system and representing it to the desired precision by using the relevant set of modes. The reduced-order model is derived by projecting the **CFD** model onto a reduced space spanned by only some of the proper orthogonal modes or **POD** eigenfunctions. This process realizes a kind of lossy data compression of the original ensemble.

The resulting **POD**-based reduced-order model can be used in an optimization process to predict state solutions that are not included in the original ensemble. This useful feature requires the transformation of the projection coefficients from the discrete sample space for which they have been computed to a continuous space. In other words, by itself the **POD** model does not have a predictive feature globally, i.e., over the whole design space. Among the possible options to accomplish this task, here a functional relation is established between the **POD** coefficients, which represent the projection of a generic **CFD** flow field onto the set of **POD** basis vectors, and the design variables. It is well known that regression techniques are particularly suitable to fit experimental data, as they filter the random noise out from the data. This behavior is less desirable when working with computer simulations based on determinism. In this case, one asks the data fit model to exactly reproduce the sample data used for training and to consistently catch the local data trends. A radial basis function (**RBF**) network answers to these criteria and, therefore, is used here to interpolate the **POD** coefficients over the whole design space.

## 60.4 Application Example of POD-Based Surrogates

This section proposes an application of **POD**-based reduced-order models to the transonic flow around an airfoil. Indeed, as the **POD** model should introduce more physics within a surrogate approximation, one is interested in comparing such a novel approach to standard methodologies in order to establish, though in a preliminary way, its advantages and drawbacks. We consider a typical case in aircraft aerodynamics which,

far from being considered of industrial interest, retains the main physics features of it. The aerodynamic case is represented by the steady, viscous air flow around a scaled RAE 2822 airfoil. This geometry was selected as it is a standard object in **CFD** numerical modeling and validation [60.28]. The **POD** snapshots are obtained by perturbing the RAE 2822 airfoil by means of the parameterization described later on. A mixed

POD/CFD approach (zonal POD) is proposed to increase the accuracy level of the surrogate model in transonic conditions.

### 60.4.1 Parameterization and Design Space Definition

In the present context, surrogate modeling is aimed at providing a fast and accurate tool to speed up the process in aerodynamic shape design. As a consequence, one of the most important issues is to show its suitability and applicability to the shape optimization problem. Indeed, the definition of the design space through shape modification parameters typically involves a complex, often highly non-linear relation between the flow field and the design variables. Moreover, modifying an aircraft component (e.g., a wing airfoil) requires several parameters, thus enlarging the dimensions of the design space. It is straightforward, then, that the complexity of the problem increases and approaches a real-world application level. The class-shape transformation (CST) method [60.29] provides an analytical form to represent various geometries of aeronautical interest and it shows the interesting properties of continuity, differentiability, and reproducibility of a huge number of test shapes. It allows us to specify the airfoil contour as a product of a class function, which in the proposed case defines the rounded leading edge/pointed trailing edge airfoil class, and a shape function obtained as a linear combination of  $n$ -th-order Bernstein polynomials. The design vector is

$$w = (A_0^u, A_1^u, \dots, A_n^u, A_0^l, A_1^l, \dots, A_n^l),$$

where the first and last parameters  $A_0^{u,l}, A_n^{u,l}$  are related, respectively, to the upper and lower leading edge radius

$$R_{le}^{u,l} \left( A_0^{u,l} = \pm \sqrt{\frac{2R_{le}^{u,l}}{c}} \right)$$

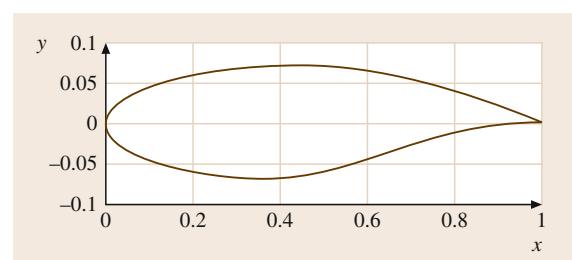

and to the trailing edge closure angle  $\beta$  ( $A_n^{u,l} = \tan \beta^{u,l}$ ), as is shown in detail in [60.29].

In the present context, seventh-order Bernstein polynomials are considered, hence each airfoil side is described by eight design variables. The design space  $DW$  is then a subset of  $\mathbb{R}^{16}$ . A scaled 14% thickness ratio RAE 2822 airfoil is selected as baseline airfoil. The airfoil geometry is shown in Fig. 60.1, where the  $x$ -coordinate is the abscissa along the airfoil chord and  $y$  is given by the aforementioned approach.

The values of the corresponding design parameters, which define the RAE 2822 profile according to the parameterization, and their range of variation, which defines the design space, are reported in Table 60.1.

### 60.4.2 Design of Experiments

The location of sample points is an important issue with respect to the cost and accuracy of any surrogate model. The design of experiment theory (DOE) [60.30] was developed to provide experimentalists with a tool to optimally choose the independent variable values for a limited number of experiments. The aim is generally to use the results of the experiments to study and investigate the response and sensitivity of some dependent quantity to the independent variables. Classical DOE methods were originally designed to alleviate the effects of noise, so they have been generally employed in conjunction with regression techniques. However, computer experiments are not subject to random errors, hence it is worthwhile using a different strategy to obtain as much information as possible about the input-output dependence. A variety of methods have been developed to fill the design space in an optimal sense. One of the most widely adopted is the Latin hypercube sampling (LHS) technique. It was first proposed by McKay et al. [60.31] as an alternative to Monte Carlo techniques for the design of computer experiments. The basic principle of LHS is to bound the randomness of the sample selection in a given region. In fact, given that  $t$  is the number of design variables, each design variable range is divided into  $m$  intervals or bins of equal probability. This generates a total of  $m \times t$  bins in the whole space. Within each bin only one sample is allocated randomly. This ensures that a one-dimensional projection onto the parameter space will produce one sample in each bin, thus eliminating the correlations between the design variables. LHS is useful for the initialization of POD-based surrogate models, but, as will be detailed later on, it exhibits some major

**Fig. 60.1** Baseline geometry, RAE 2822 airfoil

**Table 60.1** Design parameters, values, and ranges

| Parameter | Baseline value | Range            | Parameter | Baseline value | Range              |
|-----------|----------------|------------------|-----------|----------------|--------------------|
| $A_0^u$   | 0.1293         | [0.1293, 0.2293] | $A_0^l$   | -0.1280        | [-0.2280, -0.1280] |
| $A_1^u$   | 0.1282         | [0.1282, 0.2282] | $A_1^l$   | -0.1483        | [-0.2483, -0.1483] |
| $A_2^u$   | 0.1771         | [0.1771, 0.2771] | $A_2^l$   | -0.1080        | [-0.2080, -0.1080] |
| $A_3^u$   | 0.1219         | [0.1219, 0.2219] | $A_3^l$   | -0.2580        | [-0.3580, -0.2580] |
| $A_4^u$   | 0.2393         | [0.2393, 0.3393] | $A_4^l$   | -0.0918        | [-0.1918, -0.0918] |
| $A_5^u$   | 0.1662         | [0.1662, 0.2662] | $A_5^l$   | -0.1079        | [-0.2079, -0.1079] |
| $A_6^u$   | 0.1976         | [0.1976, 0.2976] | $A_6^l$   | -0.0561        | [-0.1561, -0.0561] |
| $A_7^u$   | 0.2110         | [0.2110, 0.3110] | $A_7^l$   | 0.0638         | [-0.0362, 0.0638]  |

limits that prevent it from being used as a standard sampling technique for optimization purposes. Indeed, **LHS** is optimal in the sense of design space coverage, but it does not allow for refining the sampling distribution according to enrichment or improvement criteria, e.g., design space exploration or objective function minimization.

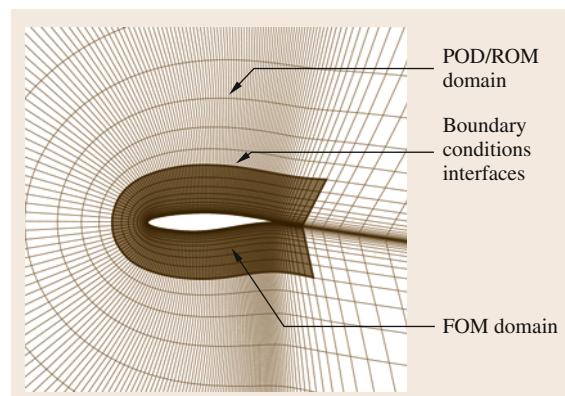

### 60.4.3 Zonal POD

The **POD** surrogate model is mainly designed as a **ROM** within a shape optimization process, where the geometry and, hence, the volume mesh vary with the design site. Moreover, the application is focused on transonic aerodynamics with potential flow separations and shock waves. Therefore, care must be taken with the definition of the snapshot domain and how to extract the integral quantities of interest (e.g., aerodynamic force coefficients) from the snapshot structure. Indeed, as the snapshots are expressed through a linear combination of **POD** modes, shock waves, flow separations, and other non-linearities present in the training ensemble would be captured and replied in the **POD** modes, so that any prediction of a new snapshot would be likely to bring the footprint of those flow features with it. This is desirable behavior on average for a physics-based approach, but when approaching the optima, which should be featured with a shockless and fully attached flow profile, a **POD** approximation of this type would hide the potential improvement behind the trace of the original snapshots. This issue is of paramount importance and can be tackled by introducing and combining two concepts: zonal **POD** and adaptive sampling. The first will allow us to reduce the inherent variability of the snapshots by means of a domain partitioning, thus avoiding the **POD** basis to capture all the physics within the field. The second technique will allow us to enrich the **POD** approximation by sampling at new points, which are *optimal* in the sense of exploration/model improvement balance. In this section, the discussion will be focused

on the zonal **POD** approach. The basic idea proposed in [60.26] is to use a mixed full-order/reduced-order model (**FOM/ROM**) by splitting the solution domain into two sub-domains: the **FOM** (i.e., the **CFD RANS** model) is used only in the vicinity of the surface to accurately solve the near wall boundary layer, non-linearities (e.g., shock waves), and flow separations where they occur; the **ROM** (i.e., the **POD** surrogate model) is exploited to reconstruct the flow field far from the solid wall, where a smoother and weakly varying solution is expected.

Figure 60.2 shows a sketch of the domain decomposition. The **POD**-based surrogate model is built on the spatial domain defined in the light gray region. Once the **POD** model has been trained, the surrogate response on the **FOM/ROM** boundary interface is extracted and used as boundary conditions to iterate the full-order **CFD** solver in the inner domain (dark gray). Details about the specific boundary condition formulation across the two domains can be found in [60.26].

A useful advantage of the zonal **POD** is that any aerodynamic coefficient or surface distribution of interest (e.g., pressure or skin friction distributions) can be

**Fig. 60.2** Zonal approach, **FOM/ROM** domains and volume mesh

directly extracted from the **CFD** solution in the inner domain. On the other hand, when the full **POD** model is used (i.e., trained on the whole domain), the surrogate model would provide a prediction of the mesh and state variables, so that a properly designed *condensation* procedure has to be applied to retrieve the integral coefficients like lift ( $C_l$ ), drag ( $C_d$ ), and pitching moment ( $C_m$ ) coefficients.

#### 60.4.4 Model Training, Validation, and Error Analysis

Training and validation are key phases that **POD** surrogates must undergo for assessment of their performance and potential. Validation means measuring the goodness of a surrogate model with respect to a so-called *truth* response (e.g., the **CFD** solution) and, therefore, drawing information to eventually optimize it. The goal is to evaluate the potential of the model to globally approximate the design space. Once a surrogate model has been trained, classical validation is carried out by sampling the design space once more, estimating the full and reduced-order models on the new sampling set, and computing a set of statistics from the data obtained. This approach requires computing new **CFD** solutions and, for this reason, it is computationally expensive. In order to reduce the number of full order computations, the validation points could be represented by the same set used for training, provided that a cross-validation technique is used (e.g., leave-one-out). Indeed, cross-validation implies the partitioning of a sample of data into complementary subsets: one subset is used for training, the other one for validation or testing. The variability due to the choice of the partitions is usually reduced by performing multiple rounds of cross-validation and averaging over the rounds. Here a classical validation is performed, while cross-validation will be used later on in auto-adaptive sampling, when the estimation of the quality of the **POD** model basis and coefficients will be required.

##### Model Training and Setup

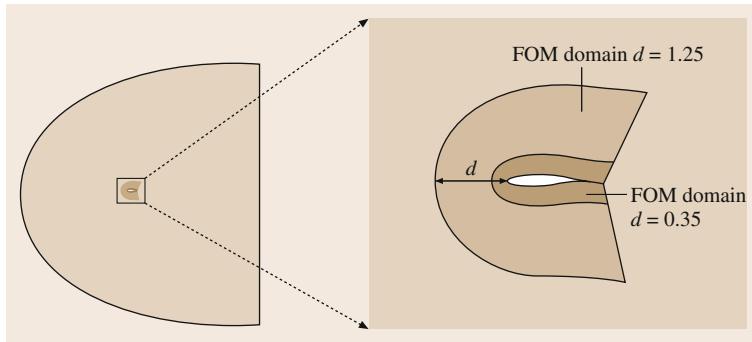

Before getting into the validation process, the **POD/ROM** models have to be trained, so that an initial Latin hypercube sampling is done on the design space made of 16 variables (see Sect. 60.4.1). The size  $M$  of the training sampling is chosen to be very large ( $M = 180$ ) to cover each design variable with a sufficient number of samples. The set of design sites  $\{w_i\}$  is then transformed into the physical representation of the airfoil geometry due to the chosen parameteriza-

tion. The baseline geometry is a modified RAE 2822 airfoil, scaled to 14% thickness-to-chord ratio to amplify compressibility effects. 180 calls of the volume mesh generator and **CFD** solver are launched in parallel at fixed flow conditions to compute the flow field around each airfoil shape. Due to a proper selection of the baseline geometry and design weight ranges, a wide and varied distribution of shock wave locations and flow separations is obtained through the training dataset. This is a highly desirable feature to test the predictive capability of such a physics-based surrogate model. The Mach number is 0.729, the Reynolds number is 6 500 000, and the flow angle of attack is  $2^\circ$ . Fully turbulent flow is assumed. For each airfoil shape, a single-block structured volume mesh made of 25 186 points (12 288 cells) is computed by means of an automatic hyperbolic grid generator. Using fixed topology, mesh parameters, and sizes, standard quality grids are obtained for each geometry. The first cell at the wall is placed so as to have a unit  $y^+$  at the specified flow conditions. A sketch of the volume mesh around the baseline airfoil is shown in Fig. 60.2.

With reference to Fig. 60.3, the mesh partitioning is applied to define the **FOM/ROM** domains, which are required to be non-overlapping and adjoining. This can be easily done when a structured mesh is available as the grid lines can be used as interfaces between domains. To this aim, the  $d$  parameter is introduced as the distance of the **FOM/ROM** interface from the airfoil leading edge. Indeed, different **POD**-based reduced-order models can be defined by varying this distance and, hence, reducing or increasing not only the size but also the inherent variability of the snapshot set. This mechanism has to be carefully considered beside the coexistence of eight heterogeneous variables (spatial coordinates, density, pressure and velocity) in the same snapshots, as it could introduce a bias in the correlation process. For example, the **POD** reduction could give more importance to the flow features related to the snapshot variables which exhibit the largest absolute values or the widest range of variation. To avoid this, a scaling operator is applied to the snapshot set prior to feeding the **POD** model. The scaling factors are designed so as to map each variable to the interval  $[0, 1]$  by normalizing as follows

$$x_h^* = \frac{x_h - \min(x_h)}{\max(x_h) - \min(x_h)}, \quad (60.5)$$

where  $x_h$  is the vector containing the  $h$ -th flow variable in the snapshot  $s = (x_1, x_2, \dots, x_8)^T$  and the minimum

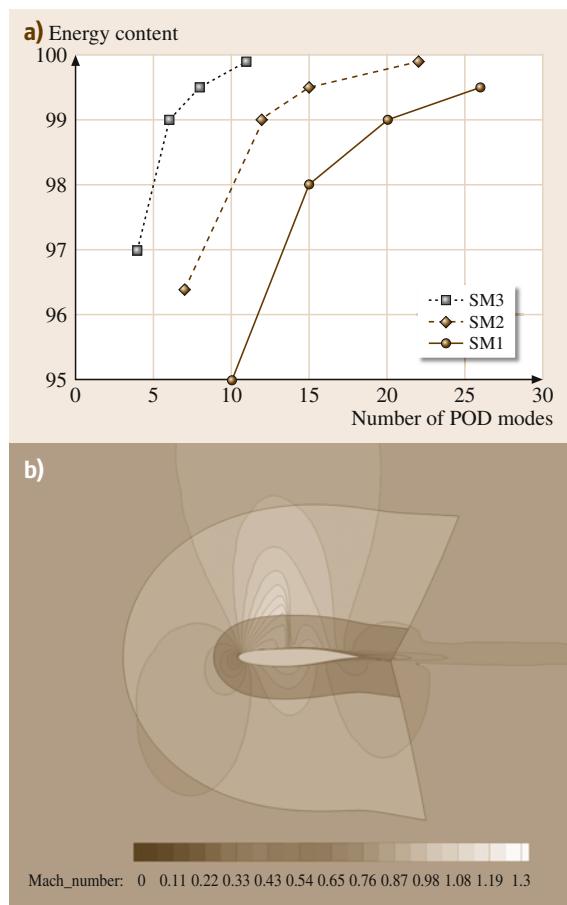

**Fig. 60.3** FOM/ROM domains with varying interface

and maximum are taken over the vector  $x_h$ . In the present investigation the scaling factors are defined once for each variable and kept constant even when varying the FOM/ROM domains (and hence the snapshot size).

Dealing with a zonal approach, we do not know a priori the optimal distance of the domain interface from the airfoil surface. Hence, in order to assess the effects of changing the interface position, three domain partitions are considered, corresponding to three different settings of the domain interface. As a consequence, three POD-surrogate models (here referred to with the initials **SM**) are built exploiting the CFD data obtained in the training phase: **SM1** – a POD model with  $d = 0$ , i.e., the full-order model is not invoked in the validation as the POD approximation is used to get the flow field everywhere and no boundary condition is exchanged, the snapshot size  $N$  is 201 488; **SM2** – a POD model with  $d = 0.35$ , i.e., the full-order domain is the dark gray one in Fig. 60.3, while the POD approximation is used to get the flow field anywhere else, the snapshot size  $N$  is 91 792; **SM3** – a POD surrogate model with  $d = 1.25$ , similar to the previous one but now the full-order domain is the light gray one in Fig. 60.3, the snapshot size  $N$  is 75 232. Besides, two more surrogates are introduced and trained on the same dataset to act as standard meta-models: **SM4** – a Kriging interpolation model with Gaussian correlation using the aerodynamic efficiency  $C_l/C_d$  as response function (Dakota package implementation [60.32]); **SM5** – a quadratic polynomial regression model using the aerodynamic efficiency  $C_l/C_d$  as response function. Given  $t$  the number of design variables, at least  $(t + 1) \times (t + 2)/2$  design sites should be evaluated to train this type of model. In the present case,  $(t + 1) \times (t + 2)/2 = 153$ , hence the size of the a-priori sampling is sufficient.

For each of the POD-based approximations, the ensemble energy content threshold  $\epsilon$  is reported in

**Fig. 60.4a,b** Effect of zonal interface on the energy amount captured by POD

Fig. 60.4a as a function of the number of POD modes. It is clearly evident that **SM1** requires a big number of modes even to reproduce a relatively low energy level (95%), while **SM3** performs considerably better (97%)

with just four modes preserved. **SM2** requires more modes with respect to **SM3** because the corresponding **ROM** domain embeds part of the supersonic region on the airfoil suction side; Fig. 60.4b clarifies this issue as it reports the **FOM/ROM** domains (as in Fig. 60.3) superimposed with the local Mach number contours. The solution is here computed around an airfoil selected within the ensemble database. While the **SM3 ROM** domain is quite far off the supersonic region, the **SM2 FOM/ROM** interface lies across it, thus introducing a stronger source of variability (and of slight discontinuity due to the shock wave) into the ensemble. Therefore, for each model a given energy level is obtained with different number of modes. In order to make a fair assessment, the models will not be compared using a pre-defined number of modes, but at a fixed energy level (95%). Indeed, the number of preserved modes is ten for **SM1** (95%), seven for **SM2** (96.4%), and four for **SM3** (97%).

### Error Estimation

For each design candidate, the aerodynamic efficiency  $E = C_l/C_d$  is computed and used to assess some error measures: the percentage error

$$\text{PE}_i = \left| \frac{E_i - \hat{E}_i}{E_i} \right| \times 100, \quad i = 1, \dots, \bar{M};$$

the mean percentage error (**MPE**)

$$\text{MPE} = \frac{1}{\bar{M}} \sum_{i=1}^{\bar{M}} \text{PE}_i;$$

the standard deviation of the percentage error (**SDPE**)

$$\text{SDPE} = \frac{1}{\bar{M}-1} \sum_{i=1}^{\bar{M}} [\text{PE}_i - \text{MPE}]^2;$$

the  $R$ -squared coefficient of determination

$$R^2 = \frac{1 - \sum_{i=1}^{\bar{M}} (E_i - \hat{E}_i)^2}{\sum_{i=1}^{\bar{M}} (E_i - \frac{1}{\bar{M}} \sum_{i=1}^{\bar{M}} E_i)^2};$$

where index  $i$  denotes the  $i$ -th sample of the **DOE** validation plan, the hat quantities refer to the surrogate predictions, while the hatless ones to the full-order predictions. This type of error measure provides a picture of how the **POD** model reconstruction error is

propagated on a surface integral, as only aerodynamic force coefficients appear. Therefore, it is very useful to understand the suitability of the surrogate model to approximate the fitness function in an aerodynamic optimization process, which usually requires the evaluation of aero-coefficients. However, in order to ensure a more general error analysis, the mean absolute percentage error between the exact **CFD** computation and the predicted value is introduced at snapshot level as

$$\text{Er}_i = \frac{1}{N} \sum_{j=1}^N \left| \frac{s_{i,j} - \hat{s}_{i,j}}{s_{i,j}} \right| \times 100,$$

where  $N$  is the snapshot size,  $s_{i,j}$  ( $\hat{s}_{i,j}$ ) is the  $j$ -th element of the computed (predicted) snapshot vector at the  $i$ -th validation site.

Finally, monotonicity is one of the properties a good surrogate should have in an optimization process. Given two *true* data  $f(w_i)$  and  $f(w_j)$  and the corresponding surrogate predictions  $\hat{f}(w_i)$  and  $\hat{f}(w_j)$ , a surrogate model is monotonic when

$$f(w_i) \leq f(w_j) \implies \hat{f}(w_i) \leq \hat{f}(w_j). \quad (60.6)$$

This property can be global (i.e., valid for each  $w_i, w_j \in DW \subset \mathbb{R}^t$ ) or local. In order to measure the monotonicity, the following metric is introduced

$$G = \sum_{i=1}^{\bar{M}} \sum_{j=1}^i -\min \left( 0, \frac{\Delta \hat{E}_{ij}}{\Delta E_{ij}} \right), \quad (60.7)$$

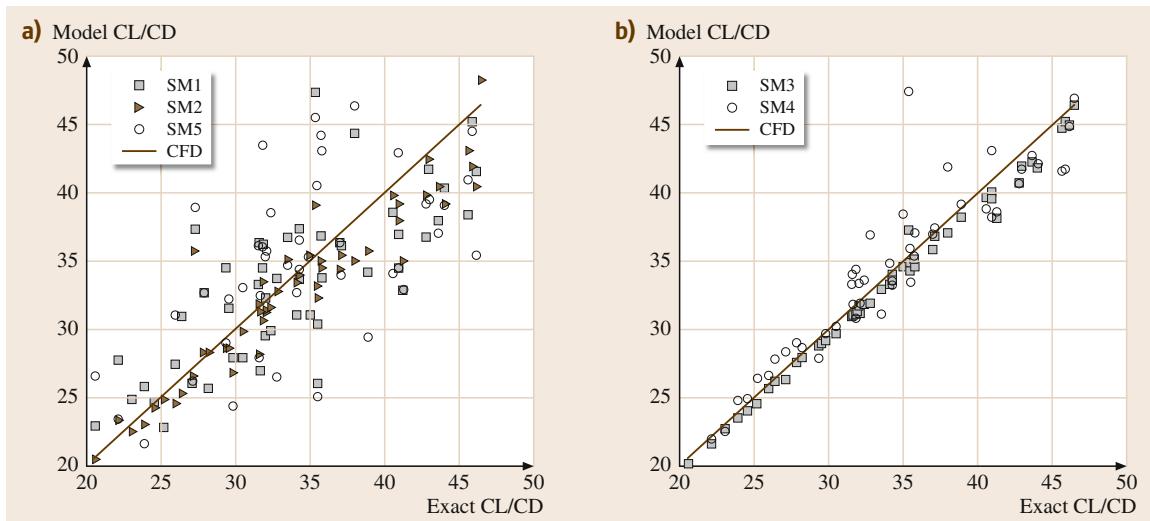

where  $\Delta E_{ij} = E_i - E_j$  and  $\Delta \hat{E}_{ij} = \hat{E}_i - \hat{E}_j$ . The  $G$  index can assume any non-negative value, zero value indicates global monotonicity, and the higher the magnitude, the more significant the monotonicity loss.

### Validation Results and Analysis

The validation plan is generated with a new Latin hypercube sampling of size  $\bar{M} = 50$ . The goodness-of-fit for each model is estimated; the results are summarized in Table 60.2. The surrogate models can be

**Table 60.2** Surrogate goodness-of-fit estimation

| Surrogate  | R-squared | MPE   | SDPE   | G       | Ranking |
|------------|-----------|-------|--------|---------|---------|
| <b>SM1</b> | 0.5876    | 10.33 | 48.14  | 1597.22 | 4       |
| <b>SM2</b> | 0.8899    | 4.55  | 12.85  | 647.83  | 2       |
| <b>SM3</b> | 0.9791    | 2.30  | 1.61   | 171.10  | 1       |
| <b>SM4</b> | 0.8657    | 4.56  | 26.61  | 853.98  | 3       |
| <b>SM5</b> | 0.06074   | 15.62 | 171.62 | 1761.64 | 5       |

**Fig. 60.5a,b** Correlation plot of the prediction of surrogate models

ranked as reported in the rightmost column: **SM3** exhibits superior performances for each quality index, while the quadratic polynomial surface is very poor in approximating the objective function. **SM3** performs very well even on the **SDPE** estimate, which measures the variation of the percentage prediction error along the validation sampling. Hence, the prediction errors at any validation site are comparable and close to the mean value. This is a very desirable feature for a surrogate model designed for optimization. On the other hand, **SM5** shows very poor performances because such a polynomial regression is unable to approximate a multi-modal, rapidly changing objective function.

Looking at the figures in Table 60.2, models **SM2** and **SM4** show similar results, even if they differ completely in methodology and construction. This is a useful indication when seeking the proper balance between the **FOM** and **ROM** domains (i.e., to determine the distance  $d$ ): the **POD** surrogate accuracy increases by moving the **FOM/ROM** interface away from the airfoil

surface, and there exists a peculiar value of the distance  $d$  for which its predictive power is very close to standard and efficient interpolation techniques. As shown in Table 60.2, the monotonicity measure is coherent with the previously introduced indicators and, considering the big difference between **SM3** and other models, it provides additional evidence of the quality of this model.

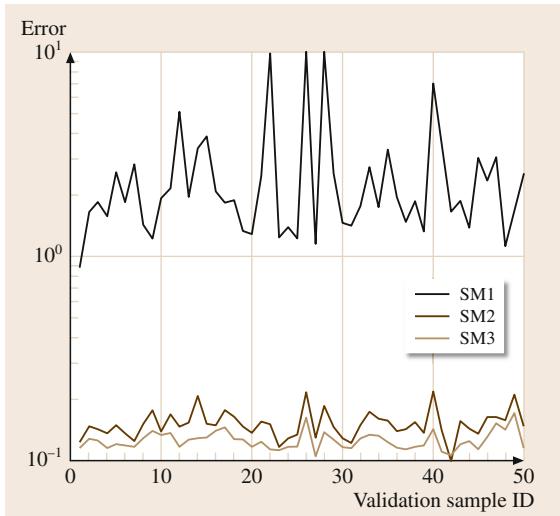

Figure 60.5 reports the correlation plot between the prediction of the model and the *true* **CFD** data. Again, **SM2**, **SM3**, and **SM4** are globally closer to the linear trend, resulting in a better fit. The correlation plot highlights another significant feature of **SM3** model, as it generally underestimates the aerodynamic efficiency. For further comparisons, Table 60.3 summarizes the validation set indices where each model predicts the highest and lowest efficiencies, the corresponding values of aerodynamic efficiency, and the percentage error with respect to the **CFD** datum. This is useful for evaluating the capability of the model identifying the global extrema of the objective function. It is observed that only **SM4** leads to a wrong estimation of the position of the *optimal* airfoil while **SM5** underestimates the performance of the worst profile.

The last two properties, i.e., the capability to preserve the monotonicity of the dataset and to correctly identify the best/worst candidates, are crucial aspects in **SBO**, so that models **SM2** and **SM3** seem to be more suitable for this purpose.

The accuracy of **POD** models is also evaluated and compared in terms of the point-to-point snapshot er-

**Table 60.3** Surrogate estimations of aerodynamic efficiency for best and worst validation airfoils

| Surrogate | ID of max | ID of min | max   | min   | $\Delta$ max (%) | $\Delta$ min (%) |
|-----------|-----------|-----------|-------|-------|------------------|------------------|
| CFD       | 12        | 22        | 46.43 | 20.61 | 0                | 0                |
| SM1       | 12        | 22        | 52.19 | 22.84 | 12.40            | 10.81            |
| SM2       | 12        | 22        | 48.27 | 20.45 | 3.95             | -0.77            |
| SM3       | 12        | 22        | 46.40 | 20.12 | -0.07            | -2.39            |
| SM4       | 26        | 22        | 47.40 | 19.86 | 2.08             | -3.65            |
| SM5       | 12        | 39        | 54.62 | 16.78 | 17.63            | -18.59           |

**Fig. 60.6** Snapshot error prediction

rror. Figure 60.6 shows the results for each snapshot belonging to the validation plan (again ranging from 1 to 50). The error index is plotted in logarithmic scale. It turns out that, in strong transonic conditions, training a **POD** model on the full **CFD** domain (**SM1**) would lead to misleading results in the prediction phase, as the model would not be able to catch the highly non-linear trends that characterize this kind of flow. Indeed, the high number of **POD** modes required and the low goodness-of-fit performance suggest that further modeling is needed to optimize the computation of the basis vectors and modal coefficients in transonic aerodynamics. In the next sections, we will introduce some adaptive sampling concepts to globally improve the reduced-order models predictions.

A final comparison is possible in terms of **POD** model accuracy versus computational time and cell saving. In particular, the *R*-squared prediction error can be taken as a measure of the model accuracy, while the time saving index *TS* and the cell saved index *CS* are defined as

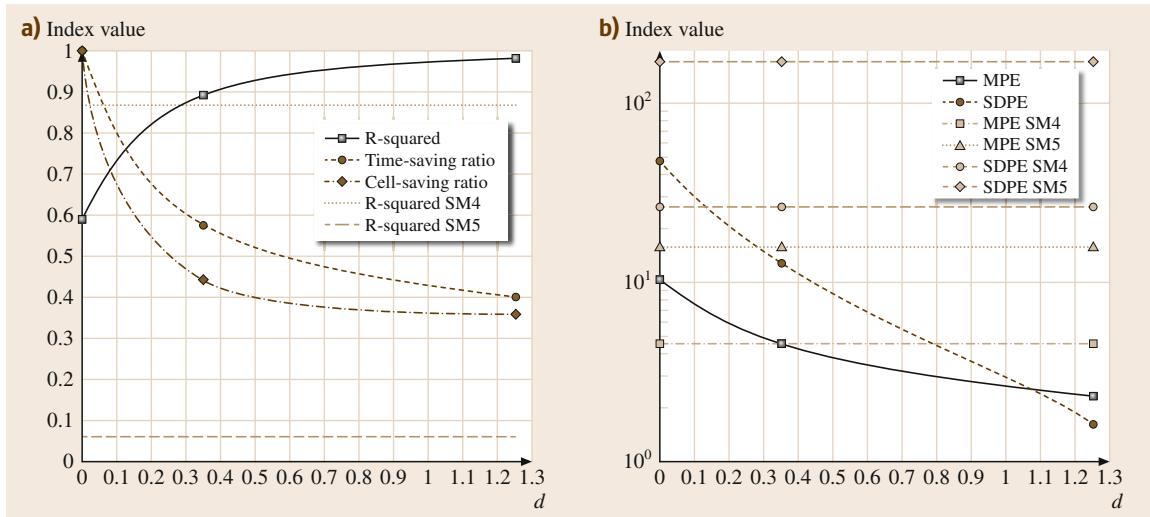

$$TS = \frac{T_{\text{FULL}} - T_{\text{SM}}}{T_{\text{FULL}}}, \quad CS = 1 - \frac{N_{\text{SM}}}{N_{\text{FULL}}}, \quad (60.8)$$

where *T* and *N* are, respectively, the computational time for 1000 **CFD** iterations and the number of solved computational cells. The subscripts **FULL** and **SM** refer to the full grid **CFD** computation and the **CFD** computation on the smaller **FOM** domain. In Fig. 60.7a the three indices (*R*-squared, *TS*, and *CS*) are plotted against

the distance *d* of the **FOM/ROM** interface from the airfoil leading edge. It shows that a clear trade-off exists between accuracy and time/cell saving and provides useful guidelines to tailor the choice of the best **POD** model to the basic requirements of the target application. For instance, if the target is to do a pre-screening of the objective space, one could use a faster and less accurate **POD** model that, however, guarantees the preservation of the physics. Figure 60.7 proposes a comparison between surrogate models in terms of the **MPE** and **SDPE**. The plot shows a graphical picture of the results in Table 60.2 concerning the accuracy of the **POD** models with moving **FOM/ROM** interface and the comparison with more classical meta-models.

### Conclusions

Three **POD/ROM** models have been trained and compared: the first one consisted in feeding the **POD** ensemble with the full field, hence without any domain decomposition; in the second and third one, the zonal approach was applied by defining two different values of the distance of the interface from the airfoil leading edge. Results showed that the model accuracy is strongly dependent on the distance parameter, mainly because of the presence of the supersonic expansion lobe and the pressure jump across the shock wave on the airfoil suction side. In fact, the **SM3** model showed superior performance with respect to both the other **POD** models and standard interpolation techniques like Kriging and regression methods like quadratic polynomial fitting. It also allows us to obtain a very accurate reconstruction of airfoil surface distributions and, hence, of aerodynamic coefficients, which are very often the actual target of aerodynamic design. Another important conclusion of the work is that it seems completely misleading to base the **POD** ensemble on the full flow field when transonic conditions and shape modifications act together. Indeed, as the **POD** reconstruction is a linear combination of **POD** modes, capturing the combined non-linear effects of boundary layer and compressibility is hardly possible when the position and intensity of the shock wave and its interaction with the boundary layer vary too much. Globally, the proposed **POD** surrogate model was shown to have many characteristics that make it suitable for aerodynamic design. However, a trade-off was found between **POD** model accuracy and resource saving as a function of the distance parameter: the smaller the full-order domain, the shorter the computational time required but also the less accurate the reconstruction.

**Fig. 60.7a,b** Performance of surrogate models as a function of FOM/ROM interface positioning

Indeed, one of the key points of the research is to recover the accuracy issues by *optimally* selecting the training candidates. In the proposed example, we selected 180 sites to a-priori sample the 16-dimensional design space, but in principle we do not have any information about the appropriate size and locations of the sample points. Intuitively, we would like to have a sampling strategy that would fill the space in an efficient manner and would allocate more points in

regions of the design space where the simulation response is strongly non-linear or is likely to find an optimum. In industrial practice, this would mean, given a computational budget, improving the quality of the **POD** surrogate by *intelligently* choosing the training samples. Conversely, given a **POD** model with a certain quality level, the rationale would be to reach the same accuracy with less high-fidelity computations.

## 60.5 Strategies for Improving **POD** Model Quality: Adaptive Sampling

In order to get rid of the issues raised in the previous section, a set of strategies has been proposed to update and enhance the surrogate/**POD** model through adaptive **DOE** techniques. Indeed, the selection of the design sites to be included in the **POD** ensemble, instead of being fully derived from an a-priori sampling strategy, can be tailored to match specific **POD**-related improvement requirements. Adaptive sampling strategies can be properly designed to account for these requirements by means of the so-called *in-fill* criteria. While a-priori sampling techniques do not use any information about the model prediction, adaptive techniques incrementally select new sampling points by exploiting the input/output relation observed at the previous stages. Hence, some adaptive **DOE** strategies for **POD**-based reduced-order models are proposed. The main references are the works by *Goblet* and *Lepot* [60.33] and *Sainvitu* et al. [60.34].

### 60.5.1 Rationale

Adaptive sampling is aimed at improving the modal basis or the modal coefficients set, which represents the core of **POD** modeling. Indeed, given a **POD** model built on a snapshot ensemble  $\{s(w_1), s(w_2), \dots, s(w_M)\}$ , the aim is to find a new point  $w_{\text{new}}$  in the design space so that the new **POD** model, built on the new set  $\{s(w_1), s(w_2), \dots, s(w_M), s(w_{\text{new}})\}$ , will provide for improved predictions and better exploration of the design space at the same time. The fundamental idea is to realize a proper trade-off between local accuracy and global design space exploration. On the one hand, we would like to sample *near* those design sites whose *importance* is higher (exploitation). On the other hand, knowing the relative distances between new sampling points and snapshot sites, we would like to sample far away from the known points in order to potentially

enrich the global prediction of the **POD** model (exploration). In other words, we need to know how much a new potential sample is *near* the training set and how much the nearest training sample *weighs* on the **POD** model. Of course, the meaning of *distance* and *importance* needs to be mathematically defined, but the underlying idea is to combine the information about the relative *importance* of the snapshot and the *nearest* distance in order to satisfy both requirements. This leads to the definition of a *potential of enrichment* in the general form

$$V_{\bullet}(w_1, w_2, \dots, w_M, y) = R(w_1, w_2, \dots, w_M, y) \\ \times I_{\bullet}(w_1, w_2, \dots, w_M, y), \quad (60.9)$$

where  $y$  is a generic point in the design space and  $\{w_1, w_2, \dots, w_M\}$  is the usual set of training points. A new sample can be obtained by simply maximizing the enrichment function. The function  $R$  gives a measure of the distance of  $y$  from the set  $\{w_1, w_2, \dots, w_M\}$ , according to a certain norm, and helps to obtain good space-filling properties. The function  $I_{\bullet}$  can be referred to as an *importance* function, as it has to properly provide the information about the quantity to be improved. A natural candidate could be a measure of the error at each new point if the surrogate model would be designed so as to provide for an error estimation at each  $y$ . Otherwise, in a surrogate-based optimization process, the function  $I_{\bullet}$  could be directly linked to the approximation of the objective function to drive the search for a new optimized design sample. With reference to the **POD** modeling presented so far, the *importance* function should be closely tied to the quality of the modal basis  $\{\phi_1, \dots, \phi_M\}$  or the quality of the **RBF** models built on the modal coefficient  $\{\alpha_1(w), \alpha_2(w), \dots, \alpha_M(w)\}$ . Hence, two different approaches can be followed, both based on the leave-one-out cross-validation technique. For the sake of clarity, the superscript  $^{-j}$  will indicate that the referenced element (basis vector, coefficient model, **SVD** matrices) has been obtained by means of a leave-one-out process, i. e., by removing the  $j$ -th sample from the training set and re-computing the model.

### 60.5.2 Improvement of the Modal Basis

The first strategy consists in defining the *importance* function as a measure of the relative influence of each snapshot on the modal basis. This requires evaluating how much the modal basis changes when removing the snapshots one by one. The relative influence of the  $j$ -th

snapshot on the modal basis is defined as

$$I_b^r(w_j) = \frac{I_b(w_j)}{\sum_{k=1}^M I_b(w_k)}, \quad (60.10)$$

where

$$I_b(w_j) = \sum_{i=1}^M \sigma_i \left( \frac{1}{|\langle \phi_i, \phi_i^{-j} \rangle|} - 1 \right), \quad (60.11)$$

is the influence of the  $j$ -th snapshot on the modal basis,  $\sigma_i$  is the singular values associated to the  $i$ -th basis vector, and  $\phi_i^{-j}$  is the  $i$ -th basis vector obtained after the substitution of the  $j$ -th snapshot vector with a null vector in the ensemble matrix. *Gobite* and *Lepot* [60.33] show how to efficiently compute  $\phi_i^{-j}$  for each  $j$ . According to (60.9), this choice of the *importance* function drops the dependency on  $y$ , so that we need to condense it in the distance function.

As was mentioned above, a new optimal sample can be found by maximizing the potential of enrichment. However, in order to avoid solving a maximization problem, the design space is heavily sampled with a Latin hypercube technique, e.g., 100 times the dimension  $t$  of the design space. Then, the Euclidean distance of each new sampled point  $y_i$ ,  $i = 1, \dots, l = 100t$  from each of the snapshot sites  $w_k$ ,  $k = 1, \dots, M$  is computed and, for each  $y_i$ , the distance from the nearest snapshot  $w_{\bar{k}}$  is stored as  $\Delta(w_{\bar{k}}, y_i)$ . This represents the distance function. Hence, for each new candidate  $y_i$ , the potential of enrichment can be written as  $V_{\phi}(y_i) = \Delta(w_{\bar{k}}, y_i) I_b^r(w_{\bar{k}})$ . Finally, a new sample point is selected at  $w_{\text{new}} = \operatorname{argmax}_{y_i} V_{\phi}(y_i)$ .

### 60.5.3 Improvement of the Modal Coefficients

The second adaptive method is conceived to improve the quality of the **RBF** networks built on the **POD** modal coefficients. Two sub-strategies are proposed: the first aims at improving the worst modal coefficient, the second is designed to improve all coefficients simultaneously.

#### First Sub-Strategy

This strategy is applied when one of the coefficient model  $\{\alpha_1(w), \dots, \alpha_M(w)\}$  exhibits low quality with respect to the others. Therefore, we first need to select a modal coefficient. The quality of the  $i$ -th modal coefficient  $\alpha_i(w)$  is estimated by using a leave-one-out

process and computing a weighted form of the Pearson correlation coefficient as

$$P_c(\alpha_i) = \frac{\sigma_i}{\sum_{k=1}^M \sigma_k} \times \frac{\mu(\alpha_i \alpha_i^{-j}) - \mu(\alpha_i) \mu(\alpha_i^{-j})}{\sqrt{\mu(\alpha_i \alpha_i) - [\mu(\alpha_i)]^2} \sqrt{\mu(\alpha_i^{-j} \alpha_i^{-j}) - [\mu(\alpha_i^{-j})]^2}}, \quad (60.12)$$

where  $\mu$  is the arithmetic mean operator applied to a generic dataset  $\kappa = \{\kappa_1, \dots, \kappa_M\}$

$$\mu(\kappa) = \frac{1}{M} \sum_{j=1}^M \kappa_j.$$

Weighting the correlation coefficient is needed because the POD modal coefficients are not equally important but they can be ranked according to the magnitude of the corresponding singular values.

The modal coefficient with the lowest value of the weighted correlation coefficient is selected and tagged as  $\bar{i}$ . The *importance* function is then defined as

$$I_{\alpha_{\bar{i}}}(w_j) = \left| \alpha_{\bar{i}}(w_j) - \alpha_{\bar{i}}^{-j}(w_j) \right|,$$

i.e., the absolute error of the  $\bar{i}$ -th model when leaving out the  $j$ -th snapshot. The choice of the distance function is the same as in the previous case. Hence, for each new candidate  $y_i$ , the potential of enrichment (with respect to the worst coefficient model) is defined as

$$V_{\alpha_{\bar{i}}}(y_i) = \Delta(w_{\bar{k}}, y_i) I_{\alpha_{\bar{i}}}(w_{\bar{k}}).$$

Finally, a new sample point is selected at  $w_{\text{new}} = \operatorname{argmax}_{y_i} V_{\alpha_{\bar{i}}}(y_i)$ .

The evaluation of the quantities  $\alpha_i^{-j}(w)$  is very expensive as, for each  $j$ , a new model has to be computed. However, when using RBF network interpolators for POD coefficient models, the leave-one-out procedure can be performed at no extra cost by using the efficient formula provided by Rippa [60.35].

### Second Sub-Strategy

This sub-strategy is used when the quality of all coefficient models is comparable and it is very similar to the improvement of the modal basis. The *importance* function is defined as a measure of the relative influence of each snapshot on the whole set of coefficient models. This requires evaluating the absolute error of each modal coefficient model when removing the snapshots one by one. The relative influence of the  $j$ -th snapshot on the whole set of coefficient models is defined as

$$I_c^r(w_j) = \frac{I_c(w_j)}{\sum_{k=1}^M I_c(w_k)},$$

where

$$I_c(w_j) = \sum_{i=1}^M \sigma_i I_{\alpha_i}(w_j) = \sum_{i=1}^M \sigma_i \left| \alpha_i(w_j) - \alpha_i^{-j}(w_j) \right|. \quad (60.13)$$

As in the previous cases, the potential of enrichment  $V_{\alpha}$  (with respect to all POD coefficients) is defined as

$$V_{\alpha}(y_i) = \Delta(w_{\bar{k}}, y_i) I_c^r(w_{\bar{k}}).$$

Finally, a new sample point is selected at  $w_{\text{new}} = \operatorname{argmax}_{y_i} V_{\alpha}(y_i)$ .

## 60.6 Aerodynamic Shape Optimization by Surrogate Modeling and Evolutionary Computing

The POD surrogates as well as the adaptive sampling techniques described in Sects. 60.3 and 60.5 have been included within an evolutionary optimization loop. The aim is to assess POD-based surrogate models as fitness function evaluators in a shape optimization problem in transonic flow. Several approaches are proposed, differing for the key ingredients of the methodology: the construction of the POD model (full/zonal approach),

the strategy chosen to compute the training sample (a-priori, auto-adaptive), and the strategy to exploit the optimization results (single optimization, iterative optimization with real-time updating). The optimization approaches share the same target, i.e., to improve the aerodynamic performance of the scaled RAE 2822 airfoil. The surrogate-based shape optimization process consists of an a-priori design of the experiment mod-

ule (e.g., **LHS**), the **CST** parameterization module, an in-house developed automatic mesh generator, the **ZEN CFD** flow solver [60.36], the **POD/ROM** module, which also encloses the adaptive sampling techniques, and the in-house adaptive genetic algorithm optimization library **ADGLIB** [60.15, 37–39].

### 60.6.1 Problem Definition

The geometry parameters, the design variable ranges, the parameterization technique, and the design point from Sect. 60.4.1 will be used. Here, we define the airfoil shape optimization problem in terms of objective/constraint function specifications as

$$\begin{aligned} & \underset{\mathbf{w} \in DW \subset R^{16}}{\text{minimize}} \quad -\frac{C_l}{C_d} \\ & \text{subject to} \quad \left(\frac{t}{c}\right)_{\max} = 0.14, \quad C_l \geq 0.5, \\ & \quad C_m \geq -0.05, \\ & \quad C_m \leq 0.05. \end{aligned} \quad (60.14)$$

In other words, the goal is to maximize the aerodynamic efficiency  $C_l/C_d$  while keeping a minimum level of lift generation ( $C_l \geq 0.5$ ) and pitching moment controllability ( $|C_m| \leq 0.05$ ). Moreover, a geometric constraint is added in order to set the airfoil maximum thickness-to-chord ratio  $t/c$  at 14%: this constraint is implicitly treated within the parameterization. The constraint functions are actually treated as quadratic penalties, hence the constrained optimization is transformed into the following unconstrained problem

$$\begin{aligned} & \underset{\mathbf{w} \in DW \subset R^{16}}{\text{minimize}} \quad -\frac{C_l}{C_d} + K[\min(C_l - 0.5, 0)]^2 \\ & \quad + K[\min(C_m + 0.05, 0)]^2 \\ & \quad + K[\min(-C_m + 0.05, 0)]^2, \end{aligned} \quad (60.15)$$

where  $K$  is a constant weight (equal to  $10^4$ ) which amplifies the relative importance of possible constraint violations. For instance, a unit penalty will be applied to the objective function in the case of an airfoil having a pitching moment of  $\pm 0.06$ .

### 60.6.2 Optimization Strategies and Setup

In Sect. 60.4, three **POD**-based surrogate models were introduced, trained, and validated against an independent dataset. Here, we propose a set of numerical experiments to assess their potential as fitness evaluator and

their suitability for an evolutionary optimization problem. Several optimization approaches were set up and tested in order to possibly cover all the issues concerning surrogate/**ROM** training and prediction. Table 60.4 summarizes the characteristics of each optimization in terms of: fitness evaluator, optimization algorithm, **POD** energy threshold (when using **POD** as surrogate), high-fidelity computational budget, i. e., the total number of computations with the **ZEN RANS** solver during the optimization process, number of a-priori **LHS** samples  $M_{\text{apr}}$ , number of adaptively added samples  $M_{\text{adp}}$ , and number of surrogate-based optima  $M_{\text{opt}}$  which are iteratively added to the ensemble database. It must be noted that not all the optimization strategies use **POD** as a surrogate; in particular, optimizations tagged as Kriging-driven Genetic Algorithm (**KGA**) and **EGO** have been performed by using a Kriging method as the fitness evaluator and the **EGO** algorithm [60.17], based on Kriging and expected improvement evaluation, to compute new optimal samples. The **EGO** algorithm represents a modern state-of-art method in surrogate-based global optimization. In the following, with the term *truth* or *true* we will indicate the results obtained with the Zonal Euler–Navier–Stokes (**ZEN**) **CFD** solver as it is adopted as the reference high-fidelity simulation tool. Each optimization method is described in detail here:

- **DGA** (Direct Genetic Algorithm) – a plain, brute-force genetic optimization with the full high-fidelity solver **ZEN** called as fitness evaluator.
- **FPGA1** (Full **POD** Genetic Algorithm 1) – a surrogate-based optimization where the aerodynamic analysis is carried out through a **POD** model built on the complete flow field of a set of 180 initial samples. This case corresponds to the **POD**-driven *standalone* mode and the surrogate **POD** evaluator is the one presented as **SM1**. No zonal approach is used. The **POD** energy content is 85%. The snapshot size  $N$  is 201 488.
- **FPGA2** (Full **POD** Genetic Algorithm 2), **FPGA3** (Full **POD** Genetic Algorithm 3) – same as **FPGA1**, but the **POD** models are defined by increasing the energy content (95 and 99%, respectively).
- **MPGA1** (Mixed-flow **POD** Genetic Algorithm 1) – a surrogate-based optimization where the zonal **CFD/POD** model is trained on the initial design space sampling (180 snapshots) and adopted as the objective function evaluator throughout the optimization cycle. The **FOM** domain is defined at a distance  $d = 1.25$  chord length from the airfoil's

**Table 60.4** Optimization approaches

| Opt Tag | Fitness evaluator | Optimizer   | POD energy (%) | Budget hi-fi | $M_{apr}$ | $M_{adp}$ | $M_{opt}$ |
|---------|-------------------|-------------|----------------|--------------|-----------|-----------|-----------|
| DGA     | ZEN               | ADGLIB      | –              | 9600         | 0         | 0         | 0         |
| FPGA1   | standalone POD    | ADGLIB      | 85             | 180          | 180       | 0         | 0         |
| FPGA2   | standalone POD    | ADGLIB      | 95             | 180          | 180       | 0         | 0         |
| FPGA3   | standalone POD    | ADGLIB      | 99             | 180          | 180       | 0         | 0         |
| MPGA1   | zonal POD         | ADGLIB      | 95             | 180          | 180       | 0         | 0         |
| MPGA2   | zonal POD         | ADGLIB      | 99             | 180          | 180       | 0         | 0         |
| KGA     | Kriging           | Dakota SOGA | –              | 190          | 180       | 0         | 10        |
| EGO     | Kriging           | Dakota EGO  | –              | 553          | 153       | 400       | 0         |
| AFPGA1  | standalone POD    | ADGLIB      | 99             | 96           | 32        | 16        | 48        |
| AFPGA2  | standalone POD    | ADGLIB      | 99             | 96           | 16        | 32        | 48        |
| AFPGA3  | standalone POD    | ADGLIB      | 99             | 96           | 4         | 44        | 48        |
| AMPGA1  | zonal POD         | ADGLIB      | 99             | 112          | 8         | 56        | 48        |
| AMPGA2  | zonal POD         | ADGLIB      | 99             | 96           | 8         | 40        | 48        |

leading edge. The **POD** model used here has been already validated as **SM3** in previous sections. The **POD** energy threshold is set at 95%. The snapshot size is 75 232.

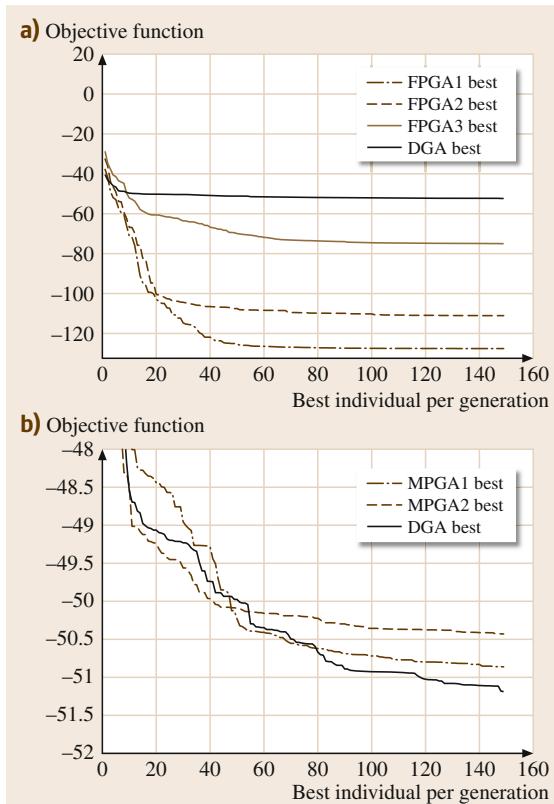

- **MPGA2** (Mixed-flow **POD** Genetic Algorithm 2) – same as **MPGA1**, but the **POD** energy content is increased up to 99%.
- **KGA** – a surrogate-based optimization where a Kriging meta-model, built on the objective function, is coupled to the genetic optimization. Here, the DAKOTA package [60.32] is used both for optimization process control and algorithm capabilities. The John Eddy Genetic Algorithm (**JEGA**) library [60.40] was used for optimization purposes. In particular, the single-objective genetic algorithm (**SOGA**) was used to perform optimization on a single objective function with general constraints. Kriging is initially trained on the 180 samples dataset. Then, a classical surrogate-based iterative optimization scheme is performed, consisting in building the surrogate, optimizing the surrogate objective, evaluating the minimizers with the **truth** (**CFD**) model, and rebuilding the surrogate. In the present optimization, 10 **SBO** iterations are performed.
- **EGO** – the key idea in **EGO** [60.17–19] is to exploit the Gaussian process capability to provide both the prediction at a new input location as well as the uncertainty associated with that prediction.
- **AFPGA1** (Adaptive Full **POD** Genetic Algorithm 1), **AFPGA2** (Adaptive Full **POD** Genetic Algorithm 2), **AFPGA3** (Adaptive Full **POD** Genetic Algorithm 3) – the surrogate model employed is the same as **FPGA3**, but the training method is different and an adaptive sampling strategy is

added. In particular, it was decided to follow a different approach: the aim was to check whether, with a limited computational budget, better results can be obtained by adaptively training the **POD** model. Hence, the surrogate training phase was split into three contributions: an a-priori contribution, sampling the design space with the **LHS** technique and producing  $M_{apr}$  samples, an iterative, adaptive sampling aimed at improving the modal basis and enriching the ensemble dataset with  $M_{adp}$  samples, and a series of  $M_{opt}$  genetic optimizations, each producing an optimal candidate to update the ensemble and recompute the surrogate. The last phase is also called real-time updating. The three strategies differ for the relative amount of these three contributions as highlighted in Table 60.4, keeping fixed the total computational budget. The **POD** energy content is 99%. The snapshot size  $N$  is 201 488.

- **AMPGA1** – the surrogate model employed is the **SM2**. The **FOM/ROM** interface is defined at  $d = 0.35$  chord length from the airfoil's leading edge. However, the training method is different as it embeds a-priori, auto-adaptive, and optimal samples as described earlier. The **POD** energy content is 99%. The snapshot size  $N$  is 91 792;
- **AMPGA2** – the surrogate model employed is again the **SM3**, but it differs from **MPGA2** because the training method embeds a-priori, auto-adaptive, and optimal samples as described before. The **POD** energy content is 99%. The snapshot size  $N$  is 75 232.

The optimization setup is the same for all the approaches, except for **AMPGA1** and **AMPGA2**. A population of 64 individuals is let to evolve for 150 gen-

erations with an 80% bit crossover rate and a 2% bit mutation rate. The genetic evolution is repeated every time a new optimal sample has to be added to the ensemble. Hence, a total number of 9600 evaluations are required for each optimization process. The setup of **AMPGA1** and **AMPGA2** differ slightly because the surrogate models adopted are more expensive (Fig. 60.7a). In order to increase the frequency of model updating stages, a population of 48 individuals is let to evolve for just 10 generations and the process is repeated 48 times to iteratively provide new optimal samples. The new feature is that each optimization step is a restart of the previous one with re-evaluation of the population candidates as the surrogate model has meanwhile been updated. In other words, the idea is to update the surrogate model more frequently (after just 10 genetic algorithm (**GA**) generations instead of 150) even if with smaller amounts of improvement (10 generations are not enough to converge the **GA**).

**Fig. 60.8a,b** Non-adaptive POD-driven optimization history

By looking at the details of the **SBO** approaches described so far, it seems quite natural to divide them into two main classes: non-adaptive (FPGAx, MPGAx), i.e., those without any adaptation/real-time updating, and adaptive optimizations (**KGA**, **EGO**, AFPGAx, AMPGAx). Consequently, the presentation of the results obtained will follow this logical sequence.

### 60.6.3 Non-Adaptive Optimization Results

Figure 60.8 shows the convergence history of the three **FPGA** optimizations compared to the plain **DGA** (solid black line) on the left and the two **MPGA** optimization histories on the right. The graphs show the sequence of the best candidates for each generation. It must be pointed out that while the **DGA** predictions (solid black lines) are obtained with the **CFD** solver, the **POD**-based predictions (dash, dotted, and dash-dotted lines) are the surrogate ones. For example, the dash-dotted line does not indicate that **FPGA1** reached objective levels significantly lower than **DGA**, but simply that the predicted values of the airfoil performances were significantly overestimated. The plot clearly highlights that whatever the energy content, the full-**POD** approximation is not able to match the *true* data during the search process. Moreover, the general trend is towards an overestimation of the aerodynamic characteristics, which leads to lower values of the objective function. On the other hand, the **MPGA** model agreement with the **CFD** progress is very satisfying, both in terms of trends and accuracy.

### 60.6.4 Adaptive Optimization Results

Figure 60.9a shows the convergence history of the iterative **SBSO** (which stands for surrogate based shape optimization) **KGA** run. As was already mentioned, it is made of ten sequential surrogate optimizations; at the end of each of them, the optimal candidate is re-evaluated with the **CFD** solver and injected in the training set, so that an updated surrogate is available. The left-hand figure compares the surrogate and *true* prediction of the optimal candidate at each iteration. After about 6–7 **SBO** iterations, the Kriging model has been improved enough to predict very closely to the **CFD** solver. In Fig. 60.9b, the convergence history corresponding to the tenth **SBO** iteration is superimposed with the **DGA** run: a noticeable agreement is found, both in the initial drop in the fitness function and in the final plateau. Among the **SBO** minimizers, the ninth iteration shows

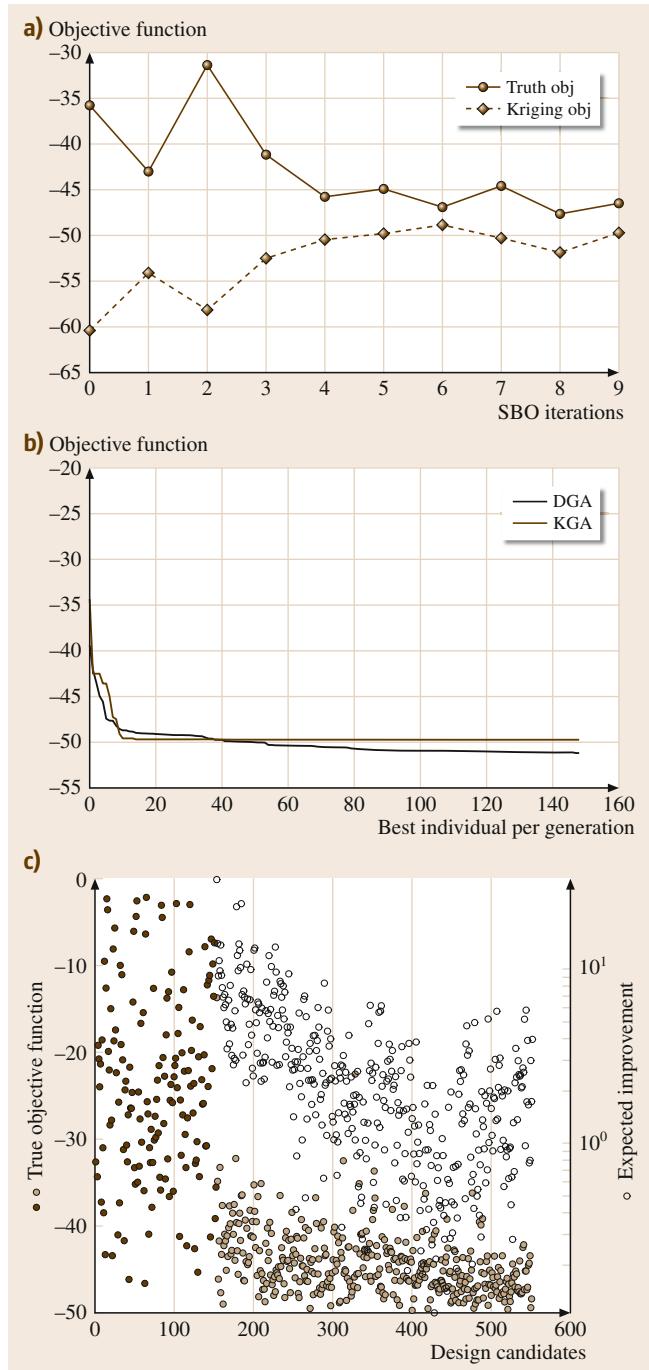

**Fig. 60.9a–c** Kriging-based optimization ►

the lowest *true* objective function value, so that it will be considered as the actual **KGA** optimum.

Figure 60.9c reports the convergence history of the **EGO** optimization. Dark gray circles depict the initial DOE sampling (153 candidates), while light gray circles denote the subsequent 400 candidates found by minimizing the expected improvement. The graph also reports the expected improvement values in gray white-filled circles and logarithmic scale (right axis). It is clearly evident how the progressive decrease of the EIF produces a better quality of the Kriging model, which in turn results in a minimization of the *true* objective function.

The convergence histories of the **AFPGA1**, **AFPGA2**, and **AFPGA3** optimizations are reported in Fig. 60.10a together with the objective function values computed on the training points. In the plot, each point represents a single high-fidelity evaluation, the squares depict the a-priori and adaptive training sites, while the circles connected with lines represent the sequence of optima from  $M_{\text{opt}}$  **GA** optimizations. It is fairly evident that adaptive sampling is often helpful as it allows us to find sub-optimal solutions even before optimization (see **AFPGA1** and **AFPGA2**). On the other hand, this somewhat disappointing behavior in the optimization step is due to the fact that the surrogate underestimates the objective function, thus pushing the surrogate-based optimizer to explore uninteresting design space regions. In particular, results show that the more adapted the initial sampling, the smaller the underestimation. Hence, the ratio  $M_{\text{apr}}/M_{\text{adp}}$  should be kept low. However, another important feature is related to the **AFPGA3** method; it shows that by lowering the ratio  $M_{\text{apr}}/M_{\text{adp}}$  too much (up to 0.09), the performance of the method deteriorates, as the final **AFPGA3** optimum is worse than the previous ones. Indeed, leaving too much room for adaptive criteria seems to produce a sampling with very poor exploratory capabilities.

These considerations give a helpful hint about the right combination of a-priori and adaptive sampling: the ratio  $M_{\text{apr}}/M_{\text{adp}}$  should be kept between 0.1 and 0.5, which is in line with the value of the **EGO** and goal-seeking methods proposed by *Jones* [60.19]. This information is exploited in tuning the parameters for **AMPGA1** and **AMPGA2** optimization. Figure 60.10b shows the *true* objective functions of the training samples and of the sequence of optima candidates. Even if the **AMPGA1** performs quite well, it exhibits simi-

lar characteristics to the **AFPGAx** optimization. On the other hand, the **AMPGA2** optimum outperforms the optima seen so far and, as it will be clear in the next

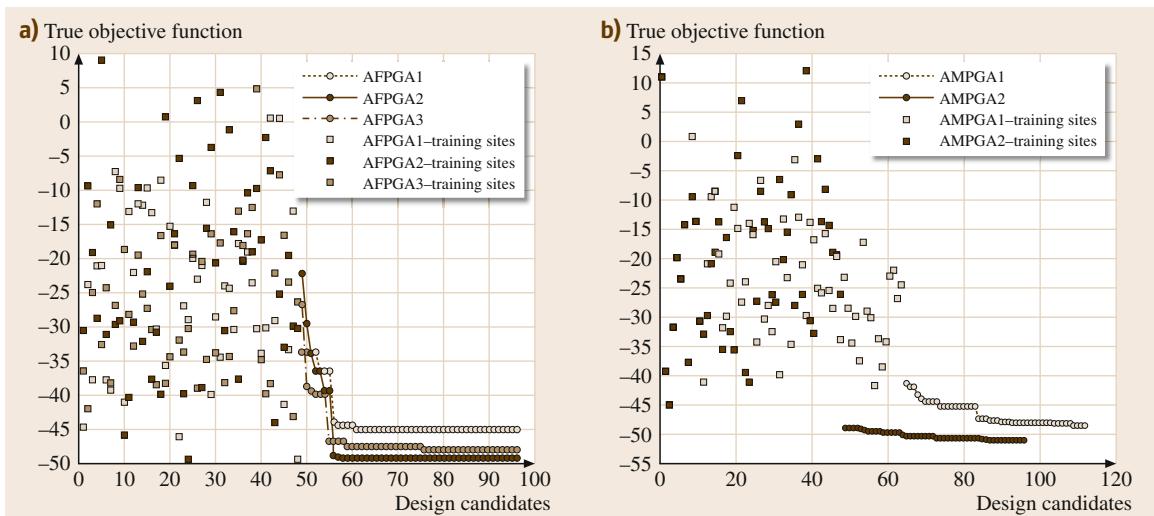

Fig. 60.10a,b Convergence history of POD-based optimization

Table 60.5 Optimal candidates, objective function breakdown

| Opt. run ID | Truth obj. | Predicted obj. | Penalty | $C_l$ | $C_d$  | $C_m$   |
|-------------|------------|----------------|---------|-------|--------|---------|
| DGA         | -51.18     | -51.18         | 1.025   | 0.619 | 0.0118 | -0.0602 |

section, it is the only candidate to get very close to the *truth* optimum, i. e., the DGA optimum.

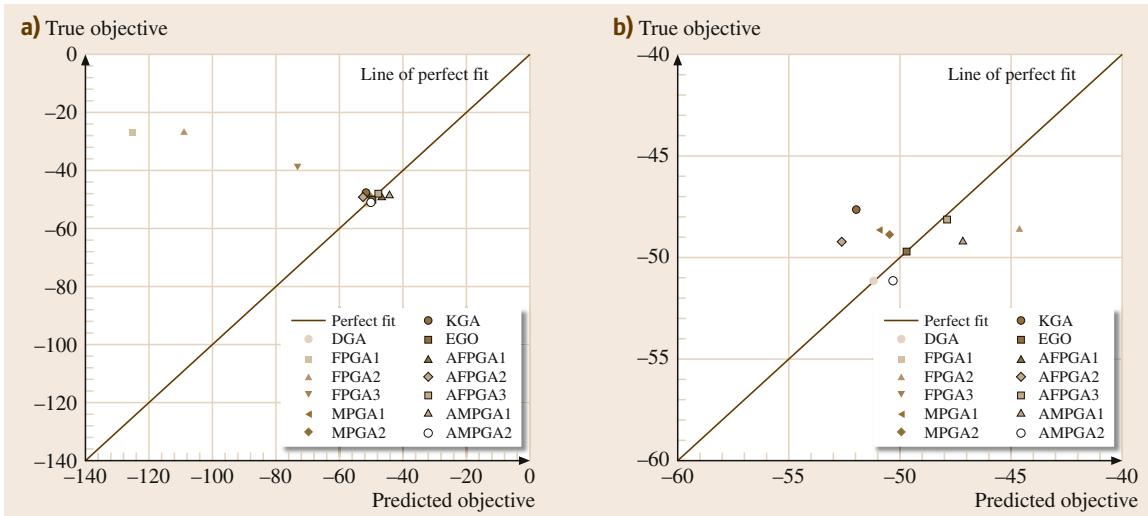

### 60.6.5 Optima Analysis

This section gives details about the optima computed with each of the methodologies presented. In the following, ten optimal candidates will be considered to assess the optimization results, namely the optima from runs DGA, FPGA3, MPGA1, KGA, EGO, AFPGA1, AFPGA2, AFPGA3, AMPGA1, and AMPGA2. FPGA3 and MPGA1 have been selected among the FPGAx and MPGAx optima because they are the closest to the high-fidelity DGA optimum. The objective function breakdown for each optimal candidate is summarized in Table 60.5. The table reports both the *true* data, obtained by re-computing each design with the CFD solver, and the predicted objective function as cal-

culated by the surrogate model. Each optimum does not satisfy the pitching moment constraint because the quadratic penalty function and its weight, chosen in the problem definition, purposely do not enforce this constraint strictly to have a less stiff optimization problem. Indeed, getting precisely into the constraint boundaries would probably have penalized the aerodynamic efficiency to much, i. e., the actual objective function, while applying small penalties near a constraint boundary gives more flexibility to the search of the optimal design.

#### Non-Adaptive Optima

Among the non-adaptive methods (here KGA is considered as non-adaptive to set a comparison), optimal designs coming from MPGA1 and KGA are closer to the plain one in terms of global performance. The MPGA1 optimum catches the DGA constraint viola-

**Fig. 60.11a,b** Computed optima in the surrogate vs truth objective plane

tion almost perfectly, while **KGA** design performs even better on pitching moment but at the cost of a slightly lower aerodynamic efficiency. **FPGA3** design, although using 75 POD modes, does not belong to an optimal sub-set but exhibits a small penalty. The best surrogate solution is the **MPGA1**, where a weak shock appears on the suction side but at a lower lift level. Indeed, the optimal leading edge radius is almost twice the **DGA** value, and this feature causes an over-expansion on the suction side, which in turn makes the shock wave occur more upstream and more strongly. The Kriging-based best candidate shows a reduced rear loading to limit nose-down pitching moment and trim drag associated with the rear location of the center of pressure. This beneficial feature is counterbalanced by the lift production increase in the fore airfoil part and, consequently, by a more pronounced pressure jump across the shock wave.

#### Adaptive Optima

In order to highlight the undertaken improvement path, Fig 60.11 reports a correlation plot where the whole set of optima is depicted in the surrogate objective – the true objective plane. Two different zooming levels

are set, as they reflect the non-adaptive and adaptive process: the **FPGA1**, **FPGA2**, and **FPGA3** optima show very large discrepancies between true value and surrogate prediction, hence they are located very far from the line of perfect fit. However, a trend is observable as, increasing the POD energy content (i.e., passing from **FPGA1** to **FPGA3**), the best candidate gets closer to the true optimum. By looking at the top part of the figure, a clustering of the remaining optima is observable, so that a closer look is offered in the bottom figure for better understanding. Among the adaptive optima, **AMPGA2** and **EGO** produce the best results and demonstrate the benefits of opportunely coupling the zonal approach and an *intelligent* design space sampling. Indeed, these optimal candidates are the closest to the target point in the sense of the Euclidean distance in the objective plane. From a more strict aerodynamic point of view, turning on the adaptive criteria brought the quality of the optimization result to a level that is very close to the expectations of the designer, as a shockless profile featured with a gentle re-compression on the suction side represents the *golden* goal for the proposed optimization problem.

## 60.7 Conclusions

The aim of the present book chapter was to review and investigate ad-hoc computational techniques to ease the solution of complex aerodynamic shape optimiza-

tion problems such as those commonly encountered in aerospace design at industrial level. Among the various approaches that are the subject of research in-

vestigations, we chose to focus on ad-hoc surrogate methods. In particular, we demonstrated that the well-known proper orthogonal decomposition approach is not adequate to provide reliable predictions in peculiar aerodynamic conditions like transonic flow and when the boundary of the computational domain changes like in shape optimization. We proposed a zonal approach to de-couple the strong non-linearities occurring near the body-wall from the **POD** approximation. This zonal approach proved to give reliable results at a reduced computational cost compared to the full **CFD** simulation. Furthermore, we showed that the zonal approach can give an accurate approximation of the true optimum when trained with specifically designed adaptive sampling techniques. The latter have been purposely conceived to improve **POD** model machinery, namely the basis vectors and coefficients. By using such an *intelligent* design of experiment method, the high-fidelity computational budget can be further reduced and the overall performance of the design loop increases. The beneficial effects of this approach have been illustrated by a comparison of several surrogate-based optimization processes on the shape design of a two-dimensional airfoil. The extension of the methodology to complex three-dimensional problems is straightforward and under way. Indeed, one of the main advantages of the proposed methodology is its relative insensitivity to the curse of dimensionality of the design parameter space. On the other hand, the larger snapshot size required by three-dimensional **CFD** flow fields, where millions of unknowns may be handled, does not repre-

sent a big issue with current linear algebra numerical solver technology. Another significant advantage of the zonal approach with respect to other surrogates lies in its favorable scaling property when the third dimension is introduced because the ratio between **CFD**-solved and **POD**-predicted points decreases. Furthermore, zonal **POD** allows us to solve the high-fidelity flow field locally, i. e., only where it is required by geometry-driven considerations. This represents a tremendous benefit when the complexity of the design case grows. As an example, if the goal is to optimally fit a nacelle body in an already optimal wing, the high-fidelity computation zone can be restricted to catch only the wing-nacelle interaction phenomena, leaving the **POD** model to predict the flow field outside. To further bridge the gap with real-world applications and needs, future work will be focused on validating the proposed methodology in large-scale, multi-point aerodynamic problems involving huge design parameter spaces and aiming at predicting the aerodynamic characteristics in deep transonic flow. Finally, improvements towards a more efficient exploitation of approximate models in the search algorithm are under investigation. In particular, a bi-objective approach seems promising where the first objective is the true function evaluation and the second is the surrogate one. An asymmetric algorithm, i. e., an algorithm that invokes the surrogate many more times than the high-fidelity one, was already proposed in a multi-fidelity environment [60.16] and will be extended to adaptive **POD**-based surrogate models.

# 61. Knowledge Discovery in Bioinformatics

# Knowledge D

Julie Hamon, Julie Jacques, Laetitia Jourdan, Clarisse Dhaenens

Biomedical research progresses rapidly, in particular in the area of genomic and postgenomic research. Hence many challenges appear for biostatistics and bioinformatics to deal with the large amount of data generated. After presenting some of these challenges, this chapter aims at presenting evolutionary combinatorial optimization approaches proposed to deal with knowledge discovery in bioinformatics. Therefore, the chapter will focus on three main tasks of data mining (association rules, feature selection, and clustering) widely encountered in bioinformatics applications. For each of them, a description of the task will be given as well as information about their uses in bioinformatics. Then, some evolutionary approaches proposed to cope with such a task will be exposed and discussed.

## 61.1 Challenges in Bioinformatics

Biomedical research progresses rapidly, in particular in the area of genomic and postgenomic research. Hence many challenges appear for biostatistics and bioinformatics to deal with the large amount of data generated. This data, related to the sequencement of the genome, may deal, for example, with the identification of more than 1 million single nucleotide polymorphisms (**SNPs**) – corresponding to genetic variations – that can be used to carry out genome-wide association studies (**GWAS**). Analyzing such data requires advanced methods able to deal with such a large number of information and with their specificities. This is the reason why knowledge discovery approaches have

been proposed to either:

1. Extract interesting rules or
2. Reduce the dimensionality of the data or
3. Classify/cluster data.

All these knowledge discovery tasks have been addressed by several communities: statistics, machine learning, and combinatorial optimization. This latest is the subject of this chapter and a recent review reports synergies between operations research and data mining [61.1]. In this chapter, we focus on evolutionary combinatorial optimization and see how it may be used to extract knowledge for bioinformatics.

Many problems arise in bioinformatics. In order to illustrate this chapter, three types of applications will be mainly used. They are described hereafter:

- *Microarray – Gene expression data:* A typical bioinformatics application requiring knowledge discovery deals with **DNA** microarray data analysis. Indeed, **DNA** microarray experiments are of great interest and importance for biologists; thanks to their ability to simultaneously measure the expressions and interactions of thousands of genes. Such experiments are used to point out, for example, genes of predisposition to some diseases such as diabetes, cancer, etc. These experiments are generating huge amounts of data that need to be analyzed. Those data are mainly represented in gene expression matrix. Some experiments add the time parameter (to analyze the evolution of the expressions after a stress, for example) and report results at different time points. This special case is sometimes called **3-D**-microarray (three-dimensional microarray). For microarray data analysis several data mining approaches have been proposed (association rule discovery, feature selection, clustering, and bi-clustering) [61.2] and benchmarks are available to compare efficiency of methods. Hence it will provide a good illustrative application along this chapter. As the number of genes to consider is huge many heuristics, and in particular evolutionary algorithms, have been proposed to deal with such data.
- *Genome-wide association studies:* Another interesting approach to find genetic susceptibility for disease is to track genetic variations. Indeed, as indicated by *Moore et al.* in their recent study of *Bioinformatics challenges for genome-wide association studies*, the sequencing of the human genome has made possible to identify more than 1 million **SNPs** (genetic variations) across the genome that can be used to carry out **GWAS** in order to reveal genetic basis of disease susceptibility [61.3]. First approaches used to deal with these massive

amounts of **GWAS** data, mainly based on biostatistics have enabled the discovery of new associations. However, as such approaches consider only one **SNP** at a time and most of the time ignore the genomic and environmental contexts, more complex approaches, that consider genotype–phenotype relationships have to be proposed. Regarding the large number of **SNPs** to consider and the complexity of the relationships to discover, the knowledge discovery paradigm has been used to deal with such data and optimization approaches have been proposed.

- *Protein analysis:* There are now plenty of identified proteins that are not completely known. For example, their function may still be unknown (even if the sequence may be known). However, the knowledge of their functions is crucial for the development of new drugs. Hence, *automated function prediction* is an active research field and computational techniques that use high-throughput experimental data (protein and genome sequences, protein interaction networks, phylogenetic profiles, etc.), have been developed. Once again such experiments produce a large amount of data that need to be analyzed.

Considering this variety of applications, this chapter aims at presenting evolutionary combinatorial optimization approaches proposed to deal with knowledge discovery in bioinformatics. Therefore, the chapter will focus on three main tasks of data mining widely encountered in bioinformatics applications. These tasks are: association rules, feature selection, and clustering (unsupervised classification). For each of them, a description of the task will be given as well as information about their uses in bioinformatics. Then, some evolutionary approaches proposed to cope with such a task will be exposed and discussed. A table provides an overview of these approaches and serves as a guideline for the reader to know which type of approach to use in a specific context.

## 61.2 Association Rules by Evolutionary Algorithm in Bioinformatics

### 61.2.1 Association Rules Discovery

#### Task Description

The problem of discovering association rules was first formulated in [61.4] and was called the market-basket

problem. The initial problem was the following: given a set of items and a large collection of sales records, which consist of a transaction date and the items purchased in that transaction, the task is to find significant relationships between the items contained in different

transactions. Since this first application, many other problems, in particular in bioinformatics, have been studied with association rules that may be defined in a more general way. Let us consider a database composed of transactions (records or objects) described according to several – maybe many – attributes (features or columns). Association rules provide a very simple (but useful) way to present correlations or other relationships among attributes (features) expressed in the form  $A \Rightarrow C$ , where  $A$  is the antecedent part (condition) and  $C$  the consequent part (prediction).  $A$  and  $C$  are sets of attributes that are disjoint. The best-known algorithm to mine association rules is A-priori, proposed by Agrawal and Srikant [61.5]. This two-phase algorithm first finds all *frequent item sets* (sets of items – or attributes – that often occur together within transactions) that have at least a given minimum level of *confidence*. This is done via an efficient search exploiting the downward closure property of *support* (which measures the frequency of the rules). A lot of improvements upon the initial method, as well as efficient implementations (including parallel implementations) have been proposed to be able to deal with very large databases [61.6–8].

We note that a specific case of rule mining deals with classification rules where the consequent is the same for every rule. This may be seen as a straightforward classification task; however, the models and methods used for this are closed to those used more generally in rule mining; hence it will be considered in this section.

The task of discovering effective association rules may be seen as a combinatorial optimization problem, as rules are combinations of attributes. Each attribute may participate to the rule in the antecedent or the consequent part. Each attribute may have several values that have to be checked. As the number of attributes may be very large (up to several thousands), the number of possible rules (choice of the attributes that participate to the rule and their values) may be very large. Therefore, efficient methods (heuristic approaches and in particular evolutionary approaches) are direly needed.

### Use in Bioinformatics

In their survey, Atluri et al. present different types of association patterns and discuss some of their applications in bioinformatics [61.9]. They indicate that association rules discovery has not been widely used yet in bioinformatics except to deal with microarray data and data on genetic variations (SNP data) for which several works exist. Their feeling is that association rules have been underutilized in bioinformatics and they propose, in their article, to give hints on how to exploit the

potential benefits of such an approach to deal with protein function prediction and in particular to address the noise and the incompleteness issues of currently protein interaction network data.

In addition, association rules discovery allows the integration of external biological information with gene expression data. For example, Carmona-Saez et al. propose an approach based on co-occurrence patterns, that integrates gene annotations and expression data to discover intrinsic associations among both data sources [61.10].

## 61.2.2 Evolutionary Approaches for Association Rules in Bioinformatics

### Motivations

Association rules are a very general model and may overcome some drawbacks of other classical knowledge discovery tasks such as classification. For example, considering microarray data in which relationships between genes are searched for, using classification will impose a gene participating to several relations to be classified in a single group. Classification will also have difficulty to point out relations between genes belonging to a same group and finally, classification will be made according to the whole set of experiments which do not allow to exhibit relationships between genes in a subset of conditions. Association rules may overcome these drawbacks by providing relationships between genes that occur in certain conditions.

However, one of the drawback of classical association rules discovery approaches (algorithm A-priori for example), is the role played by the *support* measure. Indeed, allowing to identify low support rules (but still interesting information as rare rules may be very important in the context of bioinformatics) will generate a huge number of rules that will be difficult to interpret. In this sense other types of approaches, using different quality measures, have to be proposed.

In this sense, for example, Khabzaoui et al. proposed to analyze microarray data with an association rule-based technique. They modeled this problem as a multiobjective combinatorial optimization problem (which allows us to use other quality criteria than the *support*) and solved it using an evolutionary algorithm based on a genetic algorithm. Therefore, specific mechanisms (mutation and crossover operators, elitism, and so on) are designed for this task [61.11]. In order to improve the quality of the rules obtained, cooperative approaches are proposed [61.12].

## Overview

Firstly, this section will introduce common approaches used in evolutionary rule mining, like learning classifier systems (**LCS**s), rough sets approach or genetic programming. Secondly, Pittsburgh and Michigan rule designs will be detailed. Finally, implementation details of genetic algorithms for rule mining with applications in bioinformatics will be presented, and a summary table will be provided.

**Some Classical Approaches.** Learning classifier systems (**LCS**) come from the machine learning community and are useful for classification tasks using classification rules. **LCS** evolve a population of classifiers – decision trees, rules, or rule sets – using a genetic algorithm and a credit assignment module that awards good classifiers. A more detailed introduction to **LCS** can be found in [61.13]. Some bioinformatics applications have been realized with **GAssist** algorithm [61.14] and its successor (**BioHEL**) (*bioinformatics-oriented hierarchical evolutionary Learning*) [61.15].

The rough set approach consists in finding approximation sets of features: a lower set, whose features allows us to identify objects that certainly belong to approximated set, and an upper set whose features describe objects that probably belong to approximated set. Rules can be generated from these resulting sets. More complete information about rough set theory and applications can be found in [61.16]. In [61.17, 18], Rosetta toolkit was used to solve bioinformatics problems; Vinterbo and Øhrn explained in [61.19] the implementation of a genetic algorithm for rough sets in Rosetta toolkit and show that this algorithm allows us to produce smaller rules with better predictability. They measured the predictability with the **AUC** score (area under **ROC** curve). The **ROC** curve (receiver operating characteristic) is often used in data mining to assess the performance of classification algorithms. It is plotted using true positive rate (known as *sensitivity*) and false positives rate (also called *1 – specificity*) as axes. More details can be found in [61.20].

**ROC** curve is often used in data mining to assess the performance of classification algorithms, especially ranking algorithms. It is plotted using true positive rate (known as *sensitivity*) and false positives rate (also called *1 – specificity*) as axes. More details can be found in [61.20].)

**Genetic programming** has been used to extract rules from biological data. For example, *Pappa* and *Freitas* proposed an original approach to predict protein postsynaptic activity [61.22]. Since there are a lot of

classification algorithms, and the impact of the choice of the algorithm is important, they chose to design an algorithm that searches for a good classification algorithm. Therefore, they use *grammar-based genetic programming* (**GGP**). The main difference with the genetic programming approach implemented by Yang et al. [61.23] is the use of a grammar.

**Rule Design.** When mining rules, two designs are available: in *Michigan design*, each solution is a rule, while in *Pittsburgh design* each solution is a rule set. Pittsburgh design has a larger search space; moreover, fitness and operators are harder to implement. However, with this design there is no need to use a covering algorithm to encourage rules from the same solution (rule set) to cover different objects. With the Michigan design, without any covering algorithm, solutions (rules) can cover the same objects. This point may cause problems when searching for classification rules. In [61.26], *Bacardit* and *Butz* compared Michigan and Pittsburgh **LCS**. They concluded that both are suitable for data mining. Michigan **LCS** tend to overfit the data – rules are too specific – while Pittsburgh **LCS** are sometimes too general and miss some search subspaces.

**Genetic Algorithm Design.** As many genetic algorithms have been proposed to deal with rule mining (Table 61.1), this paragraph presents the main components used:

- **Initial population:** Most of the time, the initial population is composed of random individuals. However, *Cho* et al. initialized their population with rules generated by a neural network [61.21]. In [61.14], the population is initialized by iteratively choosing one object and generating a rule covering it.
- **Fitness function:** It often contains an objective on the rule size to limit bloat effect and overfitting, both responsible of generating specific and complicated rules. This is an application of the *minimum description length* (**MDL**) principle. It is frequently associated to a performance measure: quality of hitting sets in rough sets, accuracy, coverage, confidence, or **AUC**. As many measures have been proposed, we will not detail all of them, but refer to the review of *Geng* and *Hamilton* on rule interestingness measures [61.27]. *Pappa* and *Freitas* recommend to use sensitivity × specificity as the fitness function when class distribution is unbalanced (in their protein data, only 6.04% of objects had the positive class) [61.22]. The majority of bioinformat-

| Protein binding              | GA   | Rough sets  | Michigan   | Size, coverage                                   | Binary                   | SUS                                     | [61.18]   |
| Microarray                   | GP   |             | Michigan   | Size, coverage                                   | Binary                   | Elite selection, cut & splice crossover | [61.23]   |
| Microarray                   | MOEA |             | Michigan   | Support, jmeasure, interest surprise, confidence |                          | RWS                                     | [61.11]   |
| Microarray                   | GA   | LCS         | Pittsburgh | Accuracy, misclassification rate                 | Binary                   | Tournament selection, 1-point crossover | [61.24]   |
| 3-D-Microarray (time series) | GA   | Rough sets  | Michigan   | Size, coverage                                   | Binary                   | SUS                                     | [61.25]   |

**MOEA:** multiobjective evolutionary algorithm, **GA:** genetic algorithm, **GP:** genetic programming, **GGP:** grammar-based genetic programming, **SUS:** stochastic universal sampling, **LCS:** learning classifier systems, **NN:** neural network, **RWS:** roulette wheel selection

ics applications use an aggregation to combine these multiple objectives. Weights are sometimes introduced to balance between objectives. For example, *Bacardit* uses an automatic weighting function that changes weights while the algorithm is running [61.28]. However, weights can be difficult to configure; therefore, multiobjective algorithms can overcome this problem [61.11, 29].

- **Encoding:** For the greater part, encoding is binary. In rough sets approach, it is fixed size and matches selected features of the approximated sets. Rules can be encoded as binary or list of values or features and values. In [61.15] a rule representation for real-values features is used: hyper-rectangle instead

of fuzzy rules approaches or data preparation with discretization methods. *Pappa* and *Freitas* encoding differentiates itself from others because of a grammar derivation tree encoding [61.22]. This is needed since they search for classification algorithms, and not for rules.

- **Operators:** Mostly used crossover operators are 1-point crossovers. *Casillas* et al. proposed adapted crossover and mutation operators to deal with rule overlapping when using rule sets [61.29]. Parents are mainly selected using fitness proportionate selection, as stochastic universal sampling (**SUS**) or roulette wheel. Less frequently, elite selection and tournament are used.

## 61.3 Feature Selection for Classification and Regression by Evolutionary Algorithm in Bioinformatics

### 61.3.1 Feature Selection

Feature selection is an active research domain in statistics (variable selection) and data mining communities. Feature selection can, jointly used with classification (or clustering), significantly improve the comprehensibility of the resulting classifier models and often build a model that generalizes better unseen points. The main

idea of feature selection is to choose a subset of input variables by eliminating features with little or no predictive information. Hence, finding the correct subset of predictive features is an important problem in itself.

Feature selection for classification can be classified in three classes depending on how the selection process is combined with the classifier: the wrapper approach, the filter approach, and the embedded approach.

The *wrapper approach* model uses learning algorithms during the feature selection process and assesses the selected features by the learning algorithm's performance using, for example, accuracy, sensitivity, or specificity. The *filter approach model* considers statistical characteristics of a dataset directly without involving any learning algorithm. In the *embedded approach* model, the learning algorithm uses its own embedded feature selection algorithm (either explicit or implicit). Let us remark that an *hybrid approach* model is sometimes used to, first adopt a filter approach that will reduce the number of features to consider, and then realize, with the remaining features, a wrapper approach that will select features in a more accurate way.

The general task of feature selection can be formulated as an optimization problem. Binary values of the variables  $x_i$  are used in order to indicate the presence ( $x_i = 1$ ) or the absence ( $x_i = 0$ ) of the feature  $i$  in the optimal feature set. Then, the problem is formulated as  $\max_{x=(x_1, \dots, x_n) \in \{0;1\}^n} F(x)$  for a function  $F$  that has to be determined regarding the context (filter, wrapper, or embedded approach and application under study). In filter approaches, many different statistical feature selection measures, such as the correlation feature selection (CFS) measure, the minimal-redundancy-maximal-relevance (mRMR) measure, the discriminant function, or the Mahalanobis distance have been used to assess to each feature a score. In wrapper approaches, classification algorithms may be used to assign to a selection of features a score that represents the ability of the selection to lead to a correct classification. Such classical algorithms are **KNNs** ( $k$  nearest neighbors), **SVMs** (support vector machines), **NN** (neural networks), etc.

As reported by *Kim et al.*, traditional approaches to feature selection with a single criterion have shown some limitations [61.30]. Therefore, they propose to consider this problem as a multiobjective one and present an adaptation of (**ELSA**) (evolutionary local selection algorithm), inspired from artificial life models of adaptive agents to cope with this multiobjective problem. Another multiobjective approach may be found in *García-Nieto et al.* where a multiobjective genetic algorithm is used for cancer diagnosis from gene selection in microarray datasets [61.31].

### Use in Bioinformatics

As indicated by *Saeys et al.*, feature selection in bioinformatics is motivated by the high-dimensional nature of modeling tasks (sequence analysis over microarray analysis, spectral analyses, literature mining,

etc.) [61.32]. Let us remark, that in contrast with other dimensionality reduction techniques (based on projection, or compression, for example), feature selection techniques do not modify data. Thus they preserve the original semantics of the variables which helps the interpretability of results.

In their review of *Feature selection techniques in bioinformatics*, *Saeys et al.* identify three classes of problems where feature selection is involved [61.32]:

- Sequence analysis
- Microarray analysis
- Mass spectra analysis.

*Sequence analysis* deals with the study of either the content of the sequence or its signal. As far as the content is concerned, the prediction of subsequences that code for proteins requires a feature selection to cope with the large number of features that can be extracted from a sequence and the lack of samples available. Recently, feature selection approaches have also been used for other applications such as the recognition of promoter regions or the prediction of microRNA target. Regarding the signal analysis, the aim is mainly to identify more or less conserved signals in the sequence (motifs), representing binding sites for proteins. Therefore, regression approaches are proposed to relate motifs to gene expression levels and feature selection can be used to search for the best motif.

*Microarray analysis*, as already said, poses a great challenge for computational techniques because of their large dimensionality. *Saeys et al.* give in their survey an overview of the most influential techniques [61.32]. In particular, genetic algorithms can be used to deal with microarray data in wrapper type approaches.

*Mass spectra analysis* deals with the analysis of thousands of signal intensity measures. This context, even if data are different, is very similar to microarray analysis and feature selection is an important step to reduce the dimensionality of the problem. Genetic algorithms and nature inspired algorithms have been proposed to deal with such data, using wrapper approaches.

### 61.3.2 Evolutionary Approaches for Feature Selection for Classification and Regression in Bioinformatics

#### Motivations

With the development of technologies, many bioinformatics applications deal with large datasets, often with more features than objects (samples). However, among these features, some are irrelevant or redundant. That is

why feature selection aims to select a subset of relevant features. Reducing the dimension of the problem, this method can reduce the computational time and improve prediction accuracy. Indeed, including nonsignificant features can induce a noise and may mask significant ones.

Traditional feature subset selection methods are sequential and based on greedy heuristics. For example, sequential forward selection (**SFS**) starts with an empty subset and iteratively adds some features, whereas the sequential backward selection (**SBS**) starts with the full feature set and iteratively removes features [61.47]. An

important drawback of these methods is that they consider one feature at a time, ignoring possible interactions between features. Fairly recently, more advanced methods such as evolutionary algorithms have been proposed to explore the space of feature subsets [61.35, 48].

### Overview

Evolutionary algorithms for feature selection in bioinformatics are rarely used in a filter approach as such approaches ignore the effects of the selected feature subset on the performance of the classifier and do not consider existing correlations between features. Hence,

**Table 61.2** Overview of evolutionary feature selection applications in bioinformatics

| Application                   | EA            | Approach | Classifier | Evaluation function                           | Encoding                    | Operators                                                                   | Reference |

EA: evolutionary algorithm, **MOEA**: multiobjective evolutionary algorithm, **GA**: genetic algorithm, **GP**: genetic programming, GPSO: geometric particle swarm optimization. Approach: wrapper (W), embedded (E), hybrid (H). Classifiers: **KNN**: *k* nearest neighbor, **SVM**: support vector machine, AP: all paired, **MLR**: multiple linear regression, **PLS**: partial least square. Evaluation functions: **CA**: classification accuracy, **AUC**: area under curve, **LOOCV**: leave-one-out cross-validation, **RMSEP**: root-mean-square error of prediction. Operators: **SUS**: stochastic universal sampling, **RWS**: roulette wheel selection, **SSOCF**: subset size-oriented common features

considering jointly the feature subset selection and the classification (or regression) process is more promising. This can be performed by three different approaches: embedded [61.40], hybrid [61.41], or more frequently wrapper approaches.

Any evolutionary algorithm can be used for feature selection. For example, some methods use genetic programming [61.42], but the vast majority uses genetic algorithms (GAs). Table 61.2 reports some works about evolutionary feature selection applications in bioinformatics. These works are described according to the application field, the evolutionary algorithm used, the approach (embedded, hybrid, wrapper), the classifier used (when one is used), the evaluation function and the specificities about encoding and operators. This table helps to identify tendencies of the use of evolutionary algorithms for feature selection in bioinformatics:

- *Encoding:* Solutions are mainly encoded with binary vectors of size  $n$  (initial number of features), each bit indicating if a feature is selected or not. However, in their studies, Jourdan et al. [61.45] and Li et al. [61.34] propose to use a discrete vector encoding, where each solution is described by the list of the selected features that is particularly well adapted for large datasets as encountered in bioinformatics.
- *Evaluation functions:* As explained before, evolutionary algorithms are mainly used jointly with a classification algorithm such as **KNN** [61.35] or **SVM** [61.36]. Using such a classifier, allows us to evaluate the potential of the selection to lead to a good classification by the computation of the classification accuracy. This accuracy can be computed with various methodologies such as  $k$ -fold cross-validation (10-fold, for example), leave-one-out

cross-validation (**LOOCV**) or bootstrap methodology. The 0.632 bootstrap has been proven to be the best estimator in [61.49], but the drawback of this method is its computational cost in comparison to **LOOCV**. For this reason, most of the authors use **LOOCV** which is fast and almost unbiased [61.35]. When dealing with larger datasets, 10-fold cross-validation can also be used [61.38].

The evaluation function can also take into account other parameters such as the number of features [61.39]. In this context (feature subset size minimization and performance maximization), feature selection can be viewed as a multiobjective optimization problem [61.31, 44].

- *Operators:* In terms of operators, some works deal with specific ones [61.39], but classical operators are mainly used. For example, we may cite the **SUS** or the roulette wheel selection (**RWS**) [61.37] for the selection, the 1-point or 2-point crossovers [61.36] for the evolution of solutions, the bit-flip mutation etc.

Feature selection is often used for classification, in order to predict a discrete trait and to classify samples (disease or not, for example). However, to predict a quantitative trait (a value indicating the good disposition for a treatment, for example), regression is used instead of classification. The problem is the same, as if too many features are available, including nonsignificant ones, the regression method will have difficulties to give good results. Hence, feature selection may also be used in a regression context. For example, Broadhurst et al. combined a genetic algorithm with a multiple linear regression (**MLR**) or with a partial least square (**PLS**) regression on a mass spectrometry problem [61.46].

## 61.4 Clustering by Evolutionary Algorithm in Bioinformatics

### 61.4.1 Clustering

#### Task Description

Clustering or unsupervised classification aims at decomposing or partitioning a (usually multivariate) dataset into groups so that objects in a group are similar to each other, and are as different as possible from objects of other groups. A survey of clustering algorithms can be found in [61.50]; thus we will just introduce generalities below.

Clustering techniques can be broadly divided into three main types: partitional, hierarchical, and overlap-

ping. Partitional and hierarchical clusterings produce a hard partition of data as an object must belong to one and a single group, whereas in overlapping clustering objects may belong to several groups. In clustering, the number of groups can be known and fixed before realizing the clustering or must be determined directly by the algorithm.

For partitional-based methods, the most common algorithm is  $k$ -means [61.51], which is often described as a local search. For hierarchical clustering, two distinct types of hierarchical methods are identifiable: The agglomerative ones and the divisive ones.

### Use in Bioinformatics

Clustering is the most popular method currently used in the first step of gene expression matrix analysis. Clustering is appropriate when there is no a priori knowledge about the data. In such circumstances, the only possible approach is to study the similarity between different samples or experiments. There are two straightforward ways to study the gene expression matrix: comparing expression profiles of genes by comparing rows in the expression matrix and comparing expression profiles of samples by comparing columns in the matrix. By comparing rows, we may find similarities or differences between different genes and thus conclude about the correlation between the two genes. If we find that two rows are similar, we can hypothesize that the respective genes are co-regulated and possibly functionally related. By comparing samples, we can find which genes are differentially expressed in different situations.

## 61.4.2 Evolutionary Approaches for Clustering in Bioinformatics

### Motivations

Evolutionary clustering has been particularly used in bioinformatics as datasets are particularly large and classical methods are inefficient as they often lead to suboptimal solutions. A good survey of the use of evolutionary algorithms for clustering can be found in [61.52]. The authors proposed a classification of algorithms taking into consideration different aspects of evolutionary data clustering:

- Fixed or variable number of clusters
- Cluster-oriented or nonoriented operators
- Context-sensitive or context-insensitive operators
- Binary, integer, or real encoding
- Centroid-based, medioid-based, label-based, tree-based, or graph-based representations.

Other surveys can be found on genetic based [61.53] and on multiobjective clustering [61.54, 55].

### Overview

Evolutionary algorithms for clustering bioinformatics data are applied to both, fixed number of clusters and variable number of clusters. The majority of the applications concerns microarray data. In Table 61.3, some works are presented through important components (application field, evolutionary algorithm used, fixed or variable number of clusters ( $k$  is known or not?), etc.). Here below an attempt to describe tendencies of existing methods is proposed by separating the two cases:

fixed or variables number of clusters. At the end, information will be given about biclustering that is more and more used in bioinformatics.

**Fixed Number of Clusters.** The number of clusters can be fixed before finding a clustering model through evolutionary algorithms. Therefore, the number of clusters (often denoted by  $k$ ) can be fixed by an expert of the domain (here a biologist for example) or by using some specific criteria like a naive criterion  $k \approx \sqrt{\frac{n}{2}}$ , where  $n$  is the number of objects, or more specific ones based on an information criterion approach such as the Akaike information criterion (AIC), Bayesian information criterion (BIC), or the deviance information criterion (DIC):

- **Encoding:** For a fixed number of clusters, there exist several possible encodings: binary, integer, and real. For binary encoding, both prototype or partition could be realized. For integer encoding, two usual representations are used: *label-based encoding* where each gene represents an object and the value indicates the label of the cluster it is assigned to [61.60]; the *medioid-based encoding* represents the prototype of each cluster (the object that depicts the cluster). The *real encoding* is used to represent the coordinates of the center of each cluster and corresponds to the *centroid-based representation* [61.57, 62, 63].
- **Fitness function:** One other specific component for evolutionary clustering of bioinformatics data is the fitness function. Many clustering validity criteria exist and can be adapted to measure the quality of a solution of an evolutionary algorithm. Some examples are: minimization of the sum of within-cluster distances, minimization of the sum of the squared Euclidian distance of the objects from their respective cluster means [61.57], minimization of the distortion of the cluster (intracluster diversity), sum of the within cluster distances, etc.
- **Operators:** Concerning operators, some authors use classical operators like the 1-point crossover but a lot of articles show the drawbacks of classical genetic operators [61.57] and prefer to use context-sensitive operators [61.56].

### Variable Number of Clusters.

- **Encoding:** For a variable number of clusters, where evolutionary algorithms aim at optimizing both the number of clusters and the partition of objects, the previously mentioned representations can be used

**Table 61.3** Overview of applications of evolutionary clustering in bioinformatics

| Application                                   | EA           | K? | Evaluation function                        | Encoding                           | Operators                                                 | Reference   |
|-----------------------------------------------|--------------|----|--------------------------------------------|------------------------------------|-----------------------------------------------------------|-------------|
| Microarrays                                   | GA           | Y  | Interestingness measure                    | Set of clusters + label of objects | Specific crossover, specific mutation                     | [61.56]     |
| Microarrays (HL-60, HD-4cl, Yeast)            | Memetic (GA) | Y  | Minimum sum of square                      | Centroid                           | Kmean (LS), Uniform + specific crossover, split mutation  | [61.57]     |
| Microarrays (AD400_10_10, Yeast, Human, Rats) | GA           | N  | XB<br>(Cluster validity index)             | Centroid                           | RWS, specific crossover, mutation value                   | [61.58]     |
| Microarrays                                   | MOEA         | N  | Overall deviation + connectivity           | Set of clusters                    | Binary tournament, specific crossover, no mutation        | [61.59]     |
| Microarrays                                   | GA           | N  | Silhouette + K                             | Label                              | Mutation: split + eliminate a cluster, specific crossover | [61.60]     |
| Microarrays (Lung + Leukemia)                 | GA           | N  | Silhouette + VRC                           | Label + K + distance + centroid    | Centroid-based crossover                                  | [61.61]     |
| Microarrays                                   | GA           | N  | Bayesian validation                        | Centroid                           | RWS, 1-point crossover, mutation value                    | [61.62, 63] |
| Protein structure                             | Chaotic GA   | N  | Max clustering coefficient                 | Binary                             | Specific crossover, specific mutation                     | [61.64]     |
| Protein–Protein functional interaction        | MOEA         | N  | Cluster size + 3 problem related functions | Centroid                           | No crossover, mutation: split + delete, merge             | [61.65]     |

K?: is the number of clusters known? (Y: yes, N: no), MOEA: multiobjective evolutionary algorithm, GA: genetic algorithm, K: number of clusters, VCR: variance ratio criterion, XB: Xie-Beni cluster validity index, LS: local search, RWS: roulette wheel selection

but there are also some new ones. For example, the number of clusters can be stored in the representation [61.61]. There are also some rule-based representations [61.66], graph-based representations...

- *Operators:* As the encodings can be more complex than in the case of a fixed number of clusters [61.61], operators are adapted to the representation and the context of clustering.
- *Fitness function:* Concerning the evaluation, the authors often use criteria of validity of clustering [61.67]. We can also observe that the silhouette coefficient is often used to evaluate the quality of a clustering [61.60]. The authors can also add some problem-related functions as in [61.65].

**Biclustering.** Biclustering, (also called co-clustering or two-mode clustering) has for objective to compute biclusters (or co-clusters) that are associations

of (possibly overlapping) sets of objects with sets of features. A biclustering algorithm computes simultaneously linked partitions on both rows and columns. Many formulations of the biclustering problem have been proposed, such as hierarchical model, biclustering model, and pattern-based model. The term biclustering has been introduced by Cheng and Church in [61.68]. Up to now, in the context of bioinformatics, biclustering approaches have been proposed mainly to deal with microarray data [61.69]. As clusters may overlap in the two dimensions of the matrix and no constraint is given about their size, it may be possible to find a very large number of significant biclusters. Hence, to have a concise description of the data through biclusters, the size aspect is often considered as an additional objective. This leads to multiobjective models for which MOEAs have been proposed [61.70, 71].

## 61.5 Conclusion

Bioinformatics research generates a lot of data and knowledge extracted from this data is still basic. Much more knowledge could be discovered with the proposition of new data mining methods. Many of these data mining problems can be modeled as combinatorial

optimization problems and efficient algorithms such as evolutionary algorithms can be used to explore the huge search space of these problems. Some research has been conducted in this sense and the aim of this chapter was to present the tendencies of these works. It shows that

some promising results have been obtained for several applications in bioinformatics.

However, there is much room for future research since the problems in bioinformatics presented in this chapter require even more effective approaches to gain important knowledge from the biological and biomedical experiments. In particular, information about the domain under study is still underutilized within research methods. Biological aspects should be more present and this may be done thanks to a more accurate modeling or the incorporation of biological concepts within

evaluation functions, for example. This could lead to multiobjective modelizations of these problems, where classical data mining criteria are jointly used with biological ones. Some interesting works on multiobjective optimization in bioinformatics and computational biology are reported in [61,72].

Another interesting perspective is the cooperation between methods coming from different domains. Indeed, several communities are working of these problematics and each of them acquired experience that can be exploited by making them cooperating.

# 62. Integration of Metaheuristics and Constraint Programming

Luca Di Gaspero

A promising research line in the optimization community regards the hybridization of exact and heuristics methods. In this chapter we survey the specific integration of two complementary optimization paradigms, namely Constraint Programming, for the exact part, and metaheuristics.

## 62.1 Constraint Programming and Metaheuristics

Constraint programming (**CP**) [62.1, 2] is an effective methodology for the solution of combinatorial problems that has been successfully applied in many domains. In a nutshell, **CP** is a declarative programming paradigm based on the idea of describing the relations (i. e., constraints) between variables that must hold in all solutions of the combinatorial problem at hand. For example, in the solution to a Sudoku puzzle, the numbers to be placed must be unique with respect to columns, rows, and blocks of the board.

**CP** has an interdisciplinary nature, since it relies on contributions and methods from the communities of logic programming (**LP**), artificial intelligence (**AI**), and operations research (**OR**). Indeed, the simple declarative modeling language of **CP**, consisting of variables and constraints, is very similar to those available in classical **LP** languages such as Prolog. The solution method features constraint propagation which, in its essence, is a reasoning or inference procedure typical of **AI**. Finally, especially for optimization problems, the solution process makes use of **OR** inspired branch and bound procedures and/or of dedicated **OR** solvers for specific types of variables/constraints (e.g., the simplex method for real variables and linear constraints).

A **CP** model is an encoding of the problem statement using the basic **CP** building blocks, i. e., variables and constraints. Once a **CP** model of the problem under consideration has been stated, a **CP** solver is used to systematically search the solution space by alternating deterministic phases (constraint propagation) and non-deterministic phases (variable assignment, tree search), thus exploring implicitly or explicitly the whole search space. To this respect, **CP** belongs to the family of *complete* (or *exact*) solution methods. In other words, **CP** guarantees finding the (optimal) solution of the problem or proving that the problem is not satisfiable.

A different approach is usually taken by metaheuristics [62.3], such as local search [62.4], evolutionary algorithms [62.5], and ant colony optimization [62.6], just to name a few. These methods are *incomplete*, since they rely on heuristic information to focus on *interesting areas* of the search space and, in general, do not explore it entirely but are stopped after a given time limit. As a consequence, these algorithms do not guarantee finding the (optimal) solution, trading completeness for a (possibly) greater (empirical) efficiency in the solution process.

Just looking at completeness, it seems that the clear choice for solving combinatorial problems would

be to always prefer **CP** over metaheuristics as the solution method. However, in practice completeness is hindered by the high computational effort due to the worst case complexity of the problems considered (usually NP-complete or NP-hard). Therefore, for practical purposes, also the execution of **CP** solvers is terminated before the whole search space has been explored and a number of heuristics is used to focus the search in the regions where it is more likely to find the solutions of the problem. Consequently, **CP** and metaheuristics could be seen as complementary approaches.

Although these two kinds of methods have been individually studied by separated scientific communities (for historical reasons), in recent years we have witnessed an increasing interest in the integration of the methods. In many cases, indeed, each approach has its own strengths and weaknesses, and the general aim of method integration is to create hybrid algorithms that enhance the strengths of both approaches and (possibly) overcome some of the weaknesses. To this respect, *Yunes* maintains a web page listing a number of success stories of hybrid solution methods [62.7], that is, papers describing integrated approaches that outperform single optimization methods.

A number of conferences and workshops specifically aiming at bringing together researchers working on the integration of solution techniques for combinatorial problems have also recently started. Notable examples are the series of **CP-AI-OR** conferences [62.8, 9], started in 1999, and the Hybrid Metaheuristics workshops [62.10–16], started in 2004. The scope of these conferences is not limited to the integration of **CP**

techniques with metaheuristics, but they also consider hybridization among other methods.

Additionally, a few surveys on the integration of complete methods with metaheuristics have appeared in the literature [62.17–19]. However, these surveys either deal with a particular class of metaheuristics (i.e., local search) [62.17, 19] and/or with a different class of complete methods (integer linear programming) [62.17, 18]. *Jourdan* et al. [62.20] also took **CP** methods into account, but they provide mostly a taxonomy of cooperation between optimization methods rather than surveying the specific integrations. *Wallace* and *Azevedo* et al. [62.21, 22] surveys hybrid algorithms, but from a constraint programming viewpoint and mainly in the settings of hybrid exact methods. In their recent review of hybrid metaheuristics *Blum* et al. [62.23] include a section on the integration of **CP** with local search and ant colony optimization (**ACO**). However, to the best of our knowledge, at present no specific survey on the integration of metaheuristics and constraint programming has been published in the literature. This work tries to overcome this lack and to review the different approaches specifically employed in the integration of **CP** methods within metaheuristics.

The chapter is organized as follows. In Sect. 62.2 the basic concepts of the constraint programming paradigm are introduced. They include modeling (Sect. 62.2.1), solution methods (Sect. 62.2.2), and **CP** systems (Sect. 62.2.3). The integration of **CP** with metaheuristics is presented in Sect. 62.3, which is organized on the basis of the metaheuristic type involved in the integration. Finally, in Sect. 62.4 some conclusions are drawn.

## 62.2 Constraint Programming Essentials

In this section, we will briefly describe the essential concepts of **CP**, which are needed to understand the following sections. The readers interested in a more detailed introduction to **CP** are referred to the book of *Apt* [62.1] and to the recent comprehensive *Handbook of Constraint Programming* [62.2].

In order to apply constraint programming to a combinatorial problem one first needs to model it through the specific formalism of constraint satisfaction or constrained optimization problems. Afterwards, the model can be solved by a **CP** solver, which alternates the analysis of constraints with tree search. Let us review these basic concepts.

### 62.2.1 Modeling

Constraint satisfaction problems (**CSPs**) are a useful formalism for modeling many real-world problems, either discrete or continuous. Remarkable examples are planning, scheduling, timetabling, just to name a few.

A **CSP** is generally defined as the problem of associating values (taken from a set of domains) to variables subject to a set of constraints. A solution of a **CSP** is an assignment of values to all the variables so that the constraints are satisfied. In some cases not all solutions are equally preferable and we can associate a cost function to the variable assignments. In these cases, we talk

about constrained optimization problems (**COPs**), and we are looking for a solution that (without loss of generality) minimizes the cost value. These concepts are formally introduced in the following.

### Constraint Satisfaction Problems

Given:

- $\mathcal{X} = \{x_1, \dots, x_k\}$  is a set of *variables*.
- $\mathcal{D} = \{D_1, \dots, D_k\}$  is a set of *domains* associated to the variables. In other words, each variable  $x_i$  can assume value  $d_i$  if and only if  $d_i \in D_i$ .
- $\mathcal{C}$  is a set of *constraints*, i. e., mathematical relations over  $\mathbf{Dom} = D_1 \times \dots \times D_k$ .

We say that a tuple  $\langle d_1, \dots, d_k \rangle \in \mathbf{Dom}$  satisfies a constraint  $C \in \mathcal{C}$  if and only if  $\langle d_1, \dots, d_k \rangle \in C$ .

A *constraint satisfaction problem* (**CSP**)  $\mathcal{P}$ , described by the triple  $\langle \mathcal{X}, \mathcal{D}, \mathcal{C} \rangle$ , is the problem of finding the tuples  $d = \langle d_1, \dots, d_k \rangle \in \mathbf{Dom}$  that satisfy every constraint  $C \in \mathcal{C}$ . Such tuples are called *solutions* of the **CSP**, and the set of solutions of  $\mathcal{P}$  is denoted by  $\text{sol}(\mathcal{P})$ .

$\mathcal{P}$  is said to be *consistent* or *satisfiable* if and only if  $\text{sol}(\mathcal{P}) \neq \emptyset$ .

Notice that, depending on the modeling of the combinatorial problem at hand, we could be interested in determining different properties of the **CSP**. In the extreme case, for example, one could just want to know whether the problem is satisfiable, regardless of the actual solutions. The most common case is to search and provide a single solution to the problem, whereas sometimes one could be interested in all the solutions.

### Constrained Optimization Problems

A *constrained optimization problem* (**COP**)  $\mathcal{O} = \langle \mathcal{X}, \mathcal{D}, \mathcal{C}, f \rangle$  is a **CSP**  $\mathcal{P} = \langle \mathcal{X}, \mathcal{D}, \mathcal{C} \rangle$  with an associated *objective function*  $f : \text{sol}(\mathcal{P}) \rightarrow E$ , where  $\langle E, \leq \rangle$  is a well-ordered set (typically,  $E$  is one of the sets  $\mathbb{N}, \mathbb{Z}, \mathbb{R}$ ).

Differently from the previous case, the tuples  $\bar{d} \in \text{sol}(\mathcal{O})$  that satisfy every constraint are called *feasible solutions*, and the set of these tuples is usually assumed to be non-empty. A *solution* of the **COP**  $\mathcal{O}$  is a feasible solution  $\bar{e} \in \text{sol}(\mathcal{O})$  for which the value of the objective function  $f$  is minimized, i. e.,

$$\forall \bar{d} \in \text{sol}(\mathcal{O}) f(\bar{e}) \leq f(\bar{d}).$$

### Observations

A few observations about this formalism are worth noting. First, notice that the general framework does not

impose any restriction on either the type of domains and constraints or on the form of the objective function that can be used to express the problem. The basic type of domain is a finite set of integer values (also known as a *finite domain*), but there are other possibilities that enhance the expressive power of the modeling framework and capture some combinatorial substructures of the problem more naturally. For example, it is possible to deal with variables whose values are finite (multi)sets, (hyper)graphs, real valued intervals, or resources of a scheduling problem. Moreover, also the kind of constraints that can be employed is quite rich and includes arithmetic constraints, set constraints, permutation, counting and other types of combinatorial constraints, resource scheduling constraints, path constraints on graphs, and constraints expressible through regular expressions, just to name a few possibilities (see [62.24] for a comprehensive set of constraints and their implementation in actual **CP** systems).

These features clearly make the modeling phase easier and more precise with respect to other formalisms such as integer linear programming. Indeed, part of the combinatorial structure of the problem can be directly captured by the use of complex domains/constraints and, as for the objective function, there is no general limitation on its form, in particular, there is no assumption of linearity.

Another important point to be noticed regards the role of constraints. Differently from other modeling formalisms, which distinguish between constraints that *must* be satisfied (called *hard constraints*) and that *should preferably* be satisfied (*soft constraints*), in the original **CSP/COP** framework constraints are all hard and the solution methods, described in the following section, consider it mandatory to satisfy all of them. There have been several attempts in the **CP** literature to include soft constraints in the general framework (see, e.g., [62.25] for a review) but the most common way to handle them is to include a measure of their violation in the objective function of the problem.

## 62.2.2 Solution Methods

**CP** solution methods basically exploit a form of tree search that interleaves a branching phase with an analysis of constraints called constraint propagation. These two components are described in the following.

### Branching and Tree Search

Once the combinatorial problem has been modeled as a **CSP** or a **COP**, **CP** solves it by constructing a solution

by a process that exploits a non-deterministic *variable assignment*, where one value is selected together with one value in its current domain. This phase is also called *labeling* using (constraint) logic programming terminology, and a solution to the problem is a complete labeling. The process proceeds by recursively checking whether the current labeling can be extended to a consistent solution or, in the negative case, undoing the current assignment.

The pseudocode of the procedure, called (chronological) *backtracking*, is given in Algorithm 62.1. The procedure is at first called with the full set of variables and empty labeling as follows  $\text{Backtracking}(X, \emptyset, C, \text{Dom})$ . The procedure performs an implicit form of tree search, where a *branch* is identified by the selection of one variable (a node of the search tree) and all the possible values for that variable (the edges).

Note that, at each step of the recursive procedure, the choice of the variable and the value to branch on is non-deterministic. Therefore, these choices are susceptible to heuristics to enhance performances.

In addition, there are also other possibilities to define a branching rule. For example, instead of selecting a possible value for the variable selected (i.e., the assignment  $x_i := v$ ), the branching rule could split the domain of a given variable  $x_i$  in two by selecting a value  $v \in D_i$  and adding the constraint  $x_i \leq v$  on one branch and  $x_i > v$  on the other.

### Consistency and Constraint Propagation

The check for solution *consistency* does not need all the variables to be instantiated, in particular for detecting the unsatisfiability of the *CSP* with respect to some constraint. For example, in Algorithm 62.2, the most straightforward implementation of the procedure *Consistent*( $L, C, \text{Dom}$ ) is reported. The procedure simply checks whether the satisfiability of a given constraint can be ascertained according to the current labeling (i.e., if all of the constraint variables are assigned). However, the reasoning about the current labeling with respect to the constraints of the problem and the domains of the unlabeled variables does not necessarily need all the variables appearing in a constraint to be instantiated. Moreover, the analysis can prune (as a side effect) the domains of the unlabeled variables while preserving the set of solutions  $\text{sol}(\mathcal{P})$ , making the exploration of the subtree more effective. This phase is called *constraint propagation* and is interleaved with the variable assignment. In general, the analysis of each constraint is repeated until a fixed point for the current

situation is achieved. In the case that one of the domains becomes empty consistency cannot be achieved and, consequently, the procedure returns a fail.

Different notions of consistency can be employed. For example, one of the most common and most studied notions is hyper-arc consistency [62.26]. For a  $k$ -ary constraint  $C$  it checks the compatibility of a value  $v$  in the domain of one of the variables with the currently possible combinations of values for the remaining  $k - 1$  variables, pruning  $v$  from the domain if no supporting combination is found. The algorithms that maintain hyper-arc consistency have a complexity that is polynomial in the size of the problem (measured in terms of number of variables/constraints and size of domains). Other consistency notions have been introduced in the literature, each having different pruning capabilities and computational complexity, which are, usually, proportionally related to their effectiveness.

One of the major drawbacks of (practical) consistency notions is that they are *local* in nature, that is, they just look at the current situation (partial labeling and current domains). This means that it would be impossible to detect future inconsistencies due to the interaction of variables. A basic technique, called *forward checking*, can be used to mitigate this problem. This method exploits a one-step *look-ahead* with respect to the current assignment, i.e., it simulates the assignment of pair of variables, instead of a single one, thus evaluating the next level of the tree through a consistency notion. This technique can be generalized to several other problems.

### Algorithm 62.1 Backtracking ( $U, L, C, \text{Dom}$ )

```

1: if  $U = \emptyset$  then
2:   return  $L$ 
3: end if
4: pick variable  $x_i \in U$ 
   /*possibly  $x_i$  is selected non-deterministically*/
5: for  $v \in D_i$       /*Try to label  $x_i$  with value  $v$ */ do
6:    $\text{Dom}' \leftarrow \text{Dom}$ 
7:   if Consistent( $L \cup \{x := v\}, C, \text{Dom}'$ )
      /*consistency notions can be different and have
       side effects on  $\text{Dom}'$ */ then
8:      $r \leftarrow \text{Backtracking}(U \setminus \{x\}, L \cup \{x := v\}, C, \text{Dom}')$ 
9:     if  $r \neq \text{fail}$  then
10:       return  $r$  /*a consistent assignment has
        been found for the variables in  $U \setminus \{x_i\}$  with
        respect to  $x_i := v$ */
11:     end if
12:   end if
13: end for

```

14: **return** fail /\*backtrack to the previous variable (no consistent assignment has been found for  $x_i$ )\*/

#### Algorithm 62.2 Consistent ( $L, C, \text{Dom}$ )

```

1: for  $C \in \mathcal{C}$  do
2:   if all variables in  $C$  are labeled in  $L \wedge C$  is not satisfied by  $L$  then
3:     return fail
4:   end if
5: end for
6: return true

```

#### Algorithm 62.3 BranchAndBound ( $U, L, C, \text{Dom}, f, b, L_b$ )

```

1: if  $U = \emptyset$  then
2:   if  $f(L) < b$  then
3:      $b \leftarrow f(L)$   $L_b \leftarrow L$ 
4:   end if
5: else
6:   pick variable  $x_i \in U$ 
    /*possibly  $x_i$  is selected non-deterministically*/
7:   for  $v \in D_i$  /*Try to label  $x_i$  with value  $v$ */ do
8:      $\text{Dom}' \leftarrow \text{Dom}$ 
9:     if Consistent( $L \cup \{x := v\}, C, \text{Dom}'$ )  $\wedge$ 
        bound( $f, L \cup \{x := v\}, \text{Dom}'$ )  $< b$ 
        /*additionally verify whether the current
        solution is bounded*/ then
10:      BranchAndBound( $U \setminus \{x\}, L \cup \{x := v\}, C,$ 
         $\text{Dom}', f, b, L_b$ )
11:    end if
12:   end for
13: end if

```

#### Branch and Bound

In the case of a **COP**, the problem is solved by exploring the set  $\text{sol}(\mathcal{O})$  in the way above, storing the best value for  $f$  found as sketched in Algorithm 62.3. However, a constraint analysis ( $\text{bound}(f, L \cup \{x := v\}, \text{Dom}')$ ) based on a partial assignment and on the best value already computed, might allow to sensibly prune the search tree. This complete search heuristic is called (with a slight ambiguity with respect to the same concept in operations research) *branch and bound*.

#### 62.2.3 Systems

A number of practical **CP** systems are available. They mostly differ with regards to the targeted pro-

gramming language and modeling features available. For historical reasons, the first constraint programming systems were built around a Prolog system. For example, SICStus Prolog [62.27], was one of the first logic programming systems supporting constraint programming which is still developed and released under a commercial license. Another Prolog-based system specifically intended for constraint programming is *ECL<sup>i</sup>PS<sup>e</sup>* [62.28], which differently from SICStus Prolog is open source. Thanks to their longevity, both systems cover many of the modeling features described in the previous sections (such as different type of domains, rich sets of constraints, etc.).

Another notable commercial system specifically designed for constraint programming is the ILOG **CP** optimizer, now developed by IBM [62.29]. This system offers modeling capabilities either by means of a dedicated modeling language (called **OPL** [62.30]) or by means of a callable library accessible from different imperative programming languages such as C/C++, Java, and C#. The modeling capabilities of the system are mostly targeted to scheduling problems, featuring a very rich set of constructs for this kind of problems. Interestingly, this system is currently available at no cost for researchers through the IBM Academic Initiative.

Open source alternatives that can be interfaced with the most common programming languages are the C++ libraries of Gecode [62.31], and the Java libraries of Choco [62.32]. Both systems are well documented and constantly developed.

A different approach has been taken by other authors, who developed a number of modeling languages for constraint satisfaction and optimization problems that can be interfaced to different type of general purpose **CP** solvers. A notable example is MiniZinc [62.33], which is an expressive modeling language for **CP**. MiniZinc models are translated into a lower level language, called FlatZinc, that can be compiled and executed, for example, by Gecode, *ECL<sup>i</sup>PS<sup>e</sup>* or SICStus prolog.

Finally, a mixed approach has been taken by the developers of Comet [62.34]. Comet is a hybrid **CP** system featuring a specific programming/modeling language and a dedicated solver. The system has been designed with hybridization in mind and, among other features, it natively supports the integration of metaheuristics (especially in the family of local search methods) with **CP**.

## 62.3 Integration of Metaheuristics and CP

Differently from Wallace [62.21], we will review the integration of CP with metaheuristics from the perspective of metaheuristics, and we classify the approaches on the basis of the type of metaheuristic employed. Moreover, following the categorization of Puchinger and Raidl [62.18], we are mostly interested in reviewing the *integrative* combinations of metaheuristics and constraint programming, i.e., those in which constraint programming is embedded as a component of a metaheuristic to solve a subproblem or vice versa.

Indeed, the types of collaborative combinations are either straightforward (e.g., collaborative-sequential approaches using CP as a constructive algorithm for finding a feasible initial solution of a problem) or rather uninvestigated (e.g., parallel or intertwined hybrids of metaheuristics and CP).

### 62.3.1 Local Search and CP

Local search methods [62.4] are based on an iterative scheme in which the search moves from the current solution to an adjacent one on the basis of the exploration of a *neighborhood* obtained by perturbing the current solutions.

The hybridization of constraint programming with local search metaheuristics is the most studied one and there is an extensive literature on this subject.

#### CP Within Local Search

The integration of CP within local search methods is the most mature form of integration. It dates back to the mid 1990s [62.35], and two main streams are identifiable to this respect. The first one consists in defining the search of the candidate neighbor (e.g., the best one) as a constrained optimization problem. The neighborhoods induced by these definitions can be quite large, therefore, a variant of this technique is known by the name of *large neighborhood search* (LNS) [62.36]. The other kind of integration, lately named *constraint-based local search* (CBLS) [62.34], is based on the idea of expressing local search algorithms by exploiting constraint programming primitives in their control (e.g., for constraint checks during the exploration of the neighborhood) [62.37]. In fact, the two streams have a non-empty intersection, since the CP primitives employed in CBLS could be used to explore the neighborhood in a LNS fashion. In the following sections we review some of the work in these two areas.

A few surveys on the specific integration between local search and constraint programming exist, for example [62.38, 39].

**Large Neighborhood Search.** In LNS [62.36, 40] an existing solution is not modified just by applying small perturbations to solutions but a large part of the problem is perturbed and searched for improving solutions in a sort of *re-optimization* approach. This part can be represented by a set  $\mathcal{F} \subseteq \mathcal{X}$  of *released* variables, called *fragment*, which determines the neighborhood relation  $\mathcal{N}$ . Precisely, given a solution  $\bar{s} = \langle d_1, \dots, d_k \rangle$  and a set  $\mathcal{F} \subseteq \{X_1, \dots, X_k\}$  of free variables, then

$$\begin{aligned}\mathcal{N}(s, \mathcal{F}) = & \{\langle e_1, \dots, e_k \rangle \in \text{sol}(O) \\ & : (X_i \notin \mathcal{F}) \rightarrow (e_i = d_i)\}.\end{aligned}$$

Given  $\mathcal{F}$ , the neighborhood exploration is performed through CP methods (i.e., propagation and tree search).

The pseudocode of the general LNS procedure is shown in Algorithm 62.4. Notice that in the procedure there are a few hotspots that can be customized. Namely, one of the key issues of this technique consists in the criterion for the selection of the set  $\mathcal{F}$  given the current solution  $\bar{s}$ , which is denoted by SelectFragment( $\bar{s}$ ) in the algorithm. The most straightforward way to select it is to randomly release a percentage of the problem variables. However, the variables in  $\mathcal{F}$  could also be chosen in a *structured* way, i.e., by releasing related variables simultaneously. In [62.41], the authors compare the effectiveness of these two alternative choices in the solution of a job-shop scheduling problem.

Also the upper bounds employed for the branch and bound procedure can be subject to a few design alternatives. A possibility, for example, is to set the bound value to  $f(\bar{s}_b)$ , the best solution value found so far, so that the procedure is forced to search at each step only for improving solutions. This alternative can enhance the technique when the propagation on the cost functions is particularly effective in pruning the domains of the released variables. At the opposite extreme, instead, the upper bound could be set to an infinite value so that a solution is searched regardless whether or not it is improving the cost function with respect to the current incumbent.

Moreover, another design point is the solution acceptance criterion, which is implemented by the AcceptSolution function. In general, all the classical lo-

cal search solution acceptance criteria are applicable, obviously in dependence on the neighborhood selection criterion employed. For example, in the case of randomly released variables a Metropolis acceptance criterion could be adequate to implement a sort of simulated annealing.

Finally, the TerminateSearch criterion is one of those usually adopted in non-systematic search methods, such as the expiration of a time/iteration budget, either absolute or relative, or the discovery of an optimal solution.

---

**Algorithm 62.4 LargeNeighborhoodSearch ( $X, C, \text{Dom}, f$ )**

```

1: create a (feasible) initial solution  $\bar{s}_0 = \langle d_1^0, \dots, d_k^0 \rangle$ 
   /*possibly random or finding the first feasible
    solution of the full CP model*/
2:  $\bar{s}_b \leftarrow \bar{s}_0$ 
3:  $i \leftarrow 0$ 
4: while not TerminateSearch( $i, \bar{s}_i, f(\bar{s}_i), \bar{s}_b$ ) do
5:    $\mathcal{F} \leftarrow \text{SelectFragment}(\bar{s}_i)$ 
     /*strategy for selecting the released variables*/
6:    $L \leftarrow \{x_j := d_j^i : x_j \notin \mathcal{F}\}$ 
7:    $U \leftarrow \mathcal{F}$ 
8:   BranchAndBound( $U, L, C, \text{Dom}, f$ ,
    ChooseBounds( $\bar{s}_i, \bar{s}_b$ )
     /*neighborhood exploration*/
9:   if AcceptSolution( $L$ ) then
10:     $\bar{s}_{i+1} \leftarrow L$ 
11:    if  $f(\bar{s}_{i+1}) < f(\bar{s}_b)$  then
12:       $\bar{s}_b \leftarrow \bar{s}_{i+1}$ 
13:    end if
14:   else
15:      $\bar{s}_{i+1} \leftarrow \bar{s}_i$ 
16:   end if
17:    $i \leftarrow i + 1$ 
18: end while
19: return  $\bar{s}_b$ 
```

---

**LNS** has been successfully applied to routing problems [62.36, 42–45], nurse rostering [62.46], university course timetabling [62.47], protein structure prediction [62.48, 49], and car sequencing [62.50].

Cipriano et al. propose **GELATO**, a modeling language and a hybrid solver specifically designed for **LNS** [62.51–53]. The system has been tested on a set of benchmark problems, such as the asymmetric traveling salesman problem, minimum energy broadcast, and university course timetabling.

The developments of the **LNS** technique in the wider perspective of very large neighborhood search

(**VLNS**) was recently reviewed by Pisinger and Ropke [62.54]. Charchrae and Beck [62.55] also propose a methodological contribution to this area with some design principles for **LNS**.

**Constraint-Based Local Search.** The idea of encoding a local search algorithm by means of constraint programming primitives was originally due to Pesant and Gendreau [62.35, 56], although in their papers they focus on a framework that allows neighborhoods to be expressed by means of **CP** primitives. The basic idea is to extend the original **CP** model of the problem with a sort of surrogate model comprising a set of variables and constraints that intentionally describe a *neighborhood* of the current solution.

A pseudocode of **CBLS** defined along these lines is reported in Algorithm 62.5. The core of the procedure is at line 5, which determines the neighborhood model on the basis of the current solution. The main components of the neighborhood model are the new set of variables  $Y$  and constraints  $C_{X,Y}$  that act as an interface of the neighborhood variables  $Y$  with respect to those of the original problem  $X$ . For example, the classical *swap* neighborhood, which perturbs the value of two variables of the problem by exchanging their values, can be modeled by the set  $Y = \{y_1, y_2\}$ , consisting of the variables to exchange, and with the interface constraints

$$(y_1 = i \wedge y_2 = j) \iff (x_i = s_j \wedge x_j = s_i) \\ \forall i, j \in \{1, \dots, n\}.$$

Moreover, an additional component of the neighborhood model is the evaluator of the move impact  $\Delta f$ , which can be usually computed incrementally on the basis of the single move.

It is worth noticing that the use of different modeling viewpoints is common practice in constraint programming. In classical **CP** modeling the different viewpoints usually offer a convenient way to express some constraint in a more concise or more efficient manner. The consistency between the viewpoints is maintained through the use of *channeling* constraints that link the different modelings. Similarly, although with a different purpose, in **CBLS** the linking between the full problem model and the neighborhood model is achieved through interface constraints.

---

**Algorithm 62.5 ConstraintBasedLocalSearch ( $X, C_X, \text{Dom}_X, f$ )**

```

1: create a (feasible) initial solution  $\bar{s}_0 = \langle d_1^0, \dots, d_k^0 \rangle$ 
   /*possibly random or finding the first feasible
    solution of the original CP model*/
```

```

2:  $\bar{s}_b \leftarrow \bar{s}_0$ 
3:  $i \leftarrow 0$ 
4: while not TerminateSearch( $i, \bar{s}_i, f(\bar{s}_i), \bar{s}_b$ ) do
5:    $(Y, C_{X,Y}, \mathbf{Dom}_Y, \Delta f) \leftarrow$ 
     NeighborhoodModel( $\bar{s}_i$ )
6:    $L \leftarrow \emptyset$ 
7:    $U \leftarrow Y$ 
8:   BranchAndBound( $U, L, C_{X,Y}, \mathbf{Dom}_Y, \Delta f$ )
    /*neighborhood exploration*/
9:   if AcceptSolution( $L$ ) then
10:     $\bar{s}_{i+1} \leftarrow \text{Apply}(L, \bar{s}_i)$ 
11:    if  $f(\bar{s}_{i+1}) < f(\bar{s}_b)$  then
12:       $\bar{s}_b \leftarrow \bar{s}_{i+1}$ 
13:    end if
14:   else
15:      $\bar{s}_{i+1} \leftarrow \bar{s}_i$ 
16:   end if
17:    $i \leftarrow i + 1$ 
18: end while
19: return  $\bar{s}_b$ 

```

This stream of research has been revamped thanks to the design of the Comet language [62.34, 57], the aim of which is specifically to support declarative components inspired from **CP** primitives for expressing local search algorithms. An example of such primitives are *differentiable invariants* [62.58], which are declarative data structures that support incremental differentiation to effectively evaluate the effect of local moves (i. e., the  $\Delta f$  in Algorithm 62.5). Moreover, Comet support control abstractions [62.59, 60] specifically designed for local search such as the *neighbors* construct, which aims at expressing the unions of heterogeneous neighborhoods. Finally, Comet has been extended also to support distributed computing [62.61].

The embedding of local search within a constraint programming environment and the employment of a common programming language makes it possible to automatize the synthesis of **CBLS** algorithms from a high-level model expressed in Comet [62.62, 63]. The synthesizer analyzes the combinatorial structure of the problem, expressed through the variables and the constraints, and combines a set of basic *recommendations*, which are the basic constituents of the synthesized algorithm.

**Other Integrations.** The idea of exploring with local search a space of incomplete solutions (i. e., those where not all variables have been assigned a value) exploiting constraint propagation has been pursued, among others, by *Jussien* and *Lhomme* [62.64] for

an open-shop scheduling problem. Constraint propagation employed in the spirit of forward checking and, more in general, look-ahead has been effectively employed, among others, by *Schaerf* [62.65] and *Prestwich* [62.66], respectively, for scheduling and graph coloring problems.

### Local Search Within **CP**

Moving to the integration of local search within constraint programming, the most common utilization of local search-like techniques consists in limiting the exploration of the tree search only to paths that are “close” to a reference one. An example of such a procedure is *limited discrepancy search (LDS)* [62.67], an incomplete method for tree search in which only *neighboring* paths of the search tree are explored, where the proximity is defined in terms of different decision points called *discrepancies*. Only the paths (i. e., complete solutions) with at most  $k$  discrepancies are considered, as outlined in Algorithm 62.6.

---

#### Algorithm 62.6 LimitedDiscrepancySearch ( $X, C, \mathbf{Dom}, f, k$ )

```

1:  $\bar{s}^* \leftarrow \text{FirstSolution}(X, C, \mathbf{Dom}, f)$ 
2:  $\bar{s}_b \leftarrow \bar{s}^*$ 
3: for  $i \in \{1, \dots, k\}$  do
4:   for  $\bar{t} \in \{\bar{s} : \bar{s} \text{ differs w.r.t. } \bar{s}^* \text{ for}$ 
     exactly  $i$  variables} do
5:     if Consistent( $\bar{t}, \mathbf{Dom}$ )  $\wedge f(\bar{t}) < f(\bar{s}_b)$  then
6:        $\bar{s}_b \leftarrow \bar{t}$ 
7:     end if
8:   end for
9: end for
10: return  $\bar{s}_b$ 

```

---

Another approach due to *Prestwich* [62.68] is called *incomplete dynamic backtracking*. Differently from **LDS**, in this approach proximity is defined among *partial* solutions, and when backtracking needs to take place it is executed by randomly unassigning (at most)  $b$  variables. This way, the method could be intended as a local search on partial solutions. In fact, the method also features other **CP** machinery, such as forward checking, which helps in boosting the search.

An alternative possibility is to employ local search in constraint propagation. Local probing [62.69, 70] is based on the partition of constraints into the set of *easy* and *hard* ones. At each choice point in the search tree the set of easy constraints is dealt with a local search metaheuristic (namely simulated annealing), while the hard constraints are considered by classi-

cal constraint propagation. This idea generalizes the approach of *Zhang* and *Zhang* [62.71], who first presented such a combination. Another similar approach was taken by *Sellmann* and *Harvey* [62.72], who used local search to propagate redundant constraints.

In [62.73] the authors discuss the incorporation of the tabu search machinery within **CP** tree search. In particular, they look at the memory mechanisms for limiting the size of the tree and the elite candidate list for keeping the most promising choices in order to be evaluated first.

### 62.3.2 Genetic Algorithms and **CP**

A genetic algorithm [62.5] is an iterative metaheuristic in which a population of strings, which represent candidate solutions, evolves toward better solutions in a process that mimics natural evolution. The main components of the evolution process are crossover and mutation operators, which, respectively, combine two parent solutions generating an offspring and mutate a given solution. Another important component is the strategy for the offspring selection, which determines the population at the next iteration of the process.

To the best of our knowledge, one of the first attempts to integrate constraint programming and genetic algorithms is due to *Barnier* and *Brisset* [62.74]. They employ the following genetic representation: given a **CSP** with variables  $\{X_1, \dots, X_k\}$ , the  $i$ -th gene in the chromosomes is related to the variable  $X_i$  and it stores a subset of the domain  $D_i$  that is allowed to be searched. Each chromosome is then decoded by **CP**, which searches for the best solution of the sub-**CSP** induced by the restrictions in the domains. The genetic operators used are a mutation operator that changes values on the subdomain of randomly chosen genes and a crossover operator that is based on a recombination of the set-union of the subdomains of each pair of genes. The method was applied to a vehicle routing problem and outperformed both a **CP** and a **GA** solver.

A different approach, somewhat similar to local probing, was used in [62.75] for tackling a production scheduling problem. In this case, the problem variables are split into two sets, defining two coupled subproblems. The first set of variables is dealt with by the genetic algorithm, which determines a partial schedule. This partial solution is then passed to **CP** for completing (and optimizing) the assignment of the remaining variables.

Finally, **CP** has been used as a post-processing phase for optimizing the current population in the spirit

of memetic algorithms. In [62.76] **CP** actually acts as an unfeasibility repairing method for a university course timetabling problem, whereas in [62.77] the optimization performed by **CP** on a flow-shop scheduling problem is an alternative to the classical local search applied in memetic algorithms. This approach is illustrated in Algorithm 62.7.

---

**Algorithm 62.7 A Memetic Algorithm with **CP** for Flow-Shop scheduling (adapted from [62.77])**

```

1: generate an initial population  $P = \{p_1, \dots, p_l\}$  of permutations of  $n$  jobs (each composed of  $k$  tasks  $\tau_{ij}$  whose start time and end time are denoted by  $\sigma_{ij}$  and  $\eta_{ij}$  respectively)
2:  $g \leftarrow 0$ 
3: while not TerminateSearch( $g, P, \min_{p \in P} f(p)$ ) do
4:   select  $p_1$  and  $p_2$  from  $P$  by binary tournament
5:    $c \leftarrow p_1 \otimes p_2$  /*apply crossover*/
6:   if  $f(c) \geq \min_{p \in P} f(p)$  then
7:     mutate  $c$  under probability  $p_m$ 
8:   end if
9:   decode  $c = \langle c_1, \dots, c_n \rangle$  to the set of precedence
   constraints  $C = \{\eta_{kj} \leq \sigma_{1j+1} : j=1, \dots, n-1\}$ 
10:   $L \leftarrow \emptyset$ 
11:   $U \leftarrow \{\sigma_{ij}, \eta_{ij} : i=1, \dots, k, j=1, \dots, n\}$ 
12:  BranchAndBound( $U, L, C \cup \{\eta_{ij} \leq \sigma_{i+1j} : i=1, \dots, k\}, \text{Dom}, f$ )
13:  if  $f(c) \geq \max_{p \in P} f(p)$  then
14:    discard  $c$ 
15:  else
16:    select  $r$  by reverse binary tournament
17:     $c$  replaces  $r$  in  $P$ 
18:  end if
19:   $g \leftarrow g + 1$ 
20: end while
21: return  $\arg \min_{p \in P} f(p)$ 

```

---

### 62.3.3 ACO and **CP**

Ant colony optimization [62.6] is an iterative constructive metaheuristic, inspired by ant foraging behavior. The **ACO** construction process is driven by a probabilistic model, based on pheromone trails, which are dynamically adjusted by a learning mechanism.

The first attempt to integrate **ACO** and **CP** is due to *Meyer* and *Ernst* [62.78], who apply the method for solving a job-shop scheduling problem. The proposed procedure employs **ACO** to learn the variable and value ordering used by **CP** for branching in the tree search. The solutions found by the **CP** procedure are fed back

to the **ACO** in order to update its probabilistic model. In this approach, **ACO** can be conceived as a master online-learning branching heuristic aimed at enhancing the performance of a slave **CP** solver.

A slightly different approach was taken by *Khichane* et al. [62.79, 80]. Their hybrid algorithm works in two phases. At first, **CP** is employed to sample the space of feasible solutions, and the information collected is processed by the **ACO** procedure for updating the pheromone trails according to the solutions found by **CP**. In the second phase, the learned pheromone information is employed as the value ordering used for **CP** branching. This approach, differently from the previous one, uses the learning capabilities of **ACO** in an offline-learning fashion.

More standard approaches in which **CP** is used to keep track of the feasibility of the solution constructed by **ACO** and to reduce the domains through constraint propagation have been used by a number of authors. *Khichane* et al. apply this idea to job-shop scheduling [62.78] and car sequencing [62.79, 81]. Their general idea is outlined in Algorithm 62.8, where each ant maintains a partial assignment of values to variables. The choice to extend the partial assignment with a new variable/value pair is driven by the pheromone trails and the heuristic factors in lines 7–8 through a standard probabilistic selection rule. Propagation is employed at line 10 to prune the possible values for the variables not included in the current assignment.

Another work along this line is due to *Benedettini* et al. [62.82], who integrate a constraint propagation phase for Boolean constraints to boost a **ACO** approach for a bioinformatics problem (namely, haplotype inference). Finally, in the same spirit of the previous idea, *Crawford* et al. [62.83, 84] employ a look-ahead technique within **ACO** and apply the method to solve set covering and set partitioning problems.

---

**Algorithm 62.8 Ant Constraint Programming (adapted from [62.79])**

```

1: initialize all pheromone trails to  $\tau_{\max}$ 
2:  $g \leftarrow 0$ 
3: repeat
4:   for  $k \in \{1, \dots, n\}$  do
5:      $\mathcal{A}_k \leftarrow \emptyset$ 
6:     repeat
7:       select a variable  $x_j \in X$  so that  $x_j \notin \text{var}(\mathcal{A}_k)$ 
         according to the pheromone trail  $\bar{\tau}_j$ 
8:       choose a value  $v \in D_j$  according to the
         pheromone trail  $\tau_{jv}$  and a heuristic factor  $\eta_{jv}$ 
9:       add  $\{x_j := v\}$  to  $\mathcal{A}_k$ 
10:      Propagate( $\mathcal{A}_k, C$ )
11:      until  $\text{var}(\mathcal{A}_k) = X$  or Failure
12:      update pheromone trails using  $\{\mathcal{A}_1, \dots, \mathcal{A}_n\}$ 
13:    end for
14:  until  $\text{var}(\mathcal{A}_i) = X$  for some  $i \in \{1, \dots, n\}$  or
     TerminateSearch( $g, \mathcal{A}_i$ )

```

---

## 62.4 Conclusions

In this chapter we have reviewed the basic concepts of constraint programming and its integration with metaheuristics. Our main contribution is the attempt to give a comprehensive overview of such integrations from the viewpoint of metaheuristics.

We believe that the reason why these integrations are very promising resides in the complementary merits of the two approaches. Indeed, on the one hand, metaheuristics are, in general, more suitable to deal with optimization problems, but their treatment of constraints can be very awkward, especially in the case of tightly constrained problems. On the other hand, constraint programming is specifically designed for finding

feasible solutions, but it is not particularly effective for handling optimization. Consequently, a hybrid algorithm that uses **CP** for finding feasible solutions and metaheuristics to search among them has good chances to outperform its single components.

Despite the important steps made in this field during the last decade, there are still promising research opportunities, especially in order to investigate topics such as collaborative hybridization of **CP** and metaheuristics and validate existing integration approaches in the yet uninvestigated area of multiobjective optimization. We believe that further research should devote more attention to these aspects.

# Graph Coloring and Recombination

Rhyd Lewis

It is widely acknowledged that some of the most powerful algorithms for graph coloring involve the combination of evolutionary-based methods with exploitative local search-based techniques. This chapter conducts a review and discussion of such methods, principally focussing on the role that recombination plays in this process. In particular we observe that, while in some cases recombination seems to be usefully combining substructures inherited from parents, in other cases it is merely acting as a macro perturbation operator, helping to reinvigorate the search from time to time.

## 63.1 Graph Coloring

Graph coloring is a well-known NP-hard combinatorial optimization problem that involves using a minimal number of colors to paint all vertices in a graph such that all adjacent vertices are allocated different colors. The problem is more formally stated as follows: given an undirected simple graph  $G = (V, E)$ , with vertex set  $V$  and edge set  $E$ , our task is to assign each vertex  $v \in V$  an integer  $c(v) \in \{1, 2, \dots, k\}$  so that:

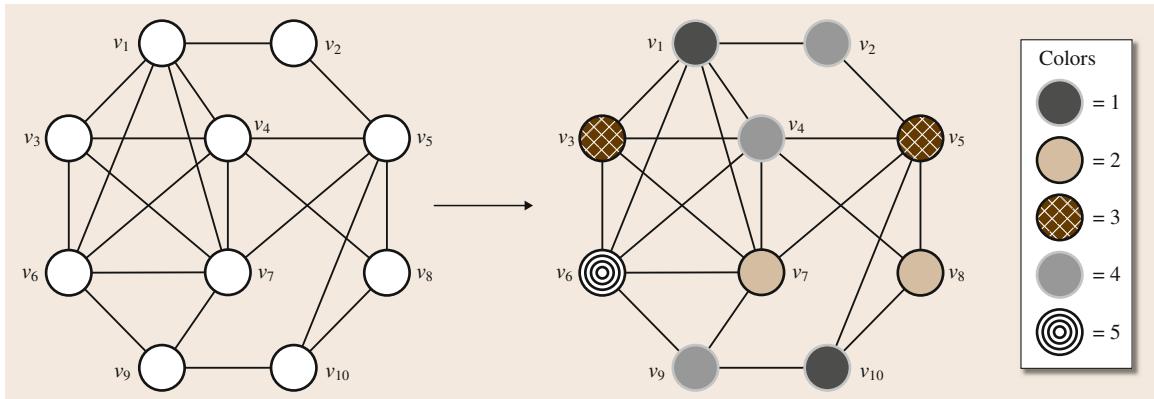

- $c(v) \neq c(u) \forall \{v, u\} \in E$
- $k$  is minimal.

Though essentially a theoretical problem, graph coloring is seen to underpin a wide variety of seemingly unrelated operational research problems, including satellite scheduling [63.1], educational timetabling [63.2, 3], sports league scheduling [63.4], frequency assignment problems [63.5, 6], map coloring [63.7], airline crew scheduling [63.8], and compiler register allocation [63.9]. The design of effective algorithms for graph coloring thus has positive implications for a large range of real-world problems.

Some common terms used with graph coloring are as follows:

- A coloring of a graph is called *complete* if all vertices  $v \in V$  are assigned a color  $c(v) \in \{1, \dots, k\}$ ; else it is considered *partial*.
- A *clash* describes a situation where a pair of adjacent vertices  $u, v \in V$  are assigned the same color (that is,  $\{u, v\} \in E$  and  $c(v) = c(u)$ ). If a coloring contains no clashes, then it is considered *proper*; else it is *improper*.
- A coloring is *feasible* if and only if it is both complete and proper.
- The *chromatic number* of a graph  $G$ , denoted  $\chi(G)$ , is the minimal number of colors required in a feasible coloring. If a feasible coloring uses  $\chi(G)$  colors, it is considered *optimal*.
- An *independent set* is a subset of vertices  $I \subseteq V$  that are mutually non-adjacent. That is,  $\forall u, v \in I$ ,  $\{u, v\} \notin E$ . Similarly, a *clique* is a subset of vertices  $C \subseteq V$  that are mutually adjacent:  $\forall u, v \in C$ ,  $\{u, v\} \in E$ .

Given these definitions, we might also view graph coloring as a type of partitioning/grouping problem where the aim is to split the vertices into a set of subsets  $U = \{U_1, \dots, U_k\}$  such that  $U_i \cap U_j = \emptyset (1 \leq i < j \leq k)$ .

**Fig. 63.1** A simple graph (left) and a feasible five-coloring (right)

If  $\bigcup_{i=1}^k U_i = V$ , then the partition represents a complete coloring. Moreover, if all subsets  $U_1, \dots, U_k$  are independent sets, the coloring is also feasible.

To exemplify these concepts, Fig. 63.1 shows an example graph with ten vertices, together with a corresponding coloring. In this case the presented coloring is both complete and proper, and therefore feasible. It is also optimal because it uses just five colors, which happens to be the chromatic number in this case. The graph also contains one clique of size 5 (vertices  $v_1, v_3, v_4, v_6$ , and  $v_7$ ), and numerous independent sets, such as vertices  $v_2, v_5, v_8$ ,

and  $v_9$ . As a partition, this coloring is represented  $\mathcal{U} = \{\{v_1, v_{10}\}, \{v_7, v_8\}, \{v_3, v_5\}, \{v_2, v_4, v_9\}, \{v_6\}\}$ .

It should be noted that various subsidiary problems related to the graph coloring problem are also known to be NP-hard. These include computing the chromatic number itself, identifying the size of the largest clique, and determining the size of the largest independent set in a graph [63.10, 11]. In addition, the decision variant of the graph coloring problem, which asks: *given a fixed positive integer k, is there a feasible k-coloring of the vertices?* is NP-complete.

## 63.2 Algorithms for Graph Coloring

Graph coloring has been studied as an algorithmic problem since the late 1960s and, as a result, an abundance of methods have been proposed. Loosely speaking, these methods might be grouped into two main classes: *constructive methods*, which build solutions step-by-step, perhaps using various heuristic and backtracking operators; and *stochastic search-based methods*, which attempt to navigate their way through a space of candidate solutions while optimizing a particular objective function.

The earliest proposed algorithms for graph coloring generally belong to the class of constructive methods. Perhaps the simplest of these is the *first-fit* (or *greedy*) algorithm. This operates by taking each vertex in turn in a specified order and assigning it to the lowest indexed color where no clash is induced, creating new colors when necessary [63.12]. A development on this method is the DSATUR algorithm [63.13, 14] in

which the ordering of the vertices is determined dynamically – specifically, by choosing at each step the uncolored vertex that currently has the largest number of different colors assigned to adjacent vertices, breaking ties by taking the vertex with the largest degree. Other constructive methods have included backtracking strategies, such as those of *Brown* [63.15] and *Korman* [63.16], which may ultimately perform complete enumerations of the solution space given excess time. A survey of backtracking approaches was presented by *Kubale* and *Jackowski* [63.17] in 1985.

Many of the more recent methods for graph coloring have followed the second approach mentioned above, which is to search a space of candidate solutions and attempt to identify members that optimize a specific objective function. Such methods can be further classified according to the composition of their search spaces, which can comprise:

- (a) The set of all feasible solutions (using an undefined number of colors)
- (b) The set of complete colorings (proper and improper) for a fixed number of colors  $k$
- (c) The set of proper solutions (partial and complete), also for a fixed number of colors  $k$ .

Algorithms following scheme (a) have been considered by, among others, *Culberson* and *Luo* [63.18], *Mumford* [63.19], *Erben* [63.20], and *Lewis* [63.21]. Typically, these methods consider different permutations of the vertices, which are then fed into a constructive method (such as first-fit) to form feasible solutions. An intuitive cost function in such cases is simply the number of colors used in a solution, though other more fine-grained functions have been suggested, such as the following due to *Erben* [63.20]

$$f_1 = \frac{\sum_{U_i \in U} [\sum_{v \in U_i} \deg(v)]^2}{|U|}. \quad (63.1)$$

Here, the term  $(\sum_{v \in U_i} \deg(v))$  gives the sum of the degrees of all vertices assigned to a color class  $U_i$ . The aim is to maximize  $f_1$  by making increases to the numerator (by forming large color classes that contain high-degree vertices), and decreases to the denominator (by reducing the number of color classes).

On the other hand, algorithms following scheme (b) operate by first proposing a fixed number of colors  $k$ . At the start of a run, each vertex will be assigned to one of the  $k$  colors using heuristics, or randomly. However, this may involve the introduction of one or more clashes, resulting in a complete, improper  $k$ -coloring. The cost of such a solution might then be evaluated using the following cost function, which is simply a count on the number of clashes

$$f_2 = \sum_{\forall \{v,u\} \in E} g(v,u) \quad \text{where}$$

$$g(v,u) = \begin{cases} 1 & \text{if } c(v) = c(u) \\ 0 & \text{otherwise.} \end{cases} \quad (63.2)$$

The strategy in such approaches is to make alterations to a solution such that the number of clashes is reduced to zero. If this is achieved  $k$  can be reduced; alternatively if all clashes cannot be eliminated,  $k$  can be increased. This strategy has been quite popular in the literature, involving the use of various stochastic search methodologies, including simulated annealing [63.22, 23], tabu search [63.24], greedy randomized adaptive search procedure (**GRASP**) methods [63.25],

iterated local search [63.26, 27], variable neighborhood search [63.28], ant colony optimization [63.29], and evolutionary algorithms (**EA**) [63.30–35].

Finally, scheme (c) also involves using a fixed number of colors  $k$ ; however in this case, rather than allowing clashes to occur in a solution, vertices that cannot be feasibly assigned to a color are placed into a set of uncolored vertices  $S$ . The aim is, therefore, to make changes to a solution so that these vertices can eventually be feasibly colored, resulting in  $S = \emptyset$ . This approach has generally been less popular in the literature than scheme (b), though some prominent examples include the simulated annealing approach of *Morgenstern* [63.36], the tabu search method of *Blochliger* and *Zufferey* [63.37], and the **EA** of *Malaguti* et al. [63.38]. More recently, *Hertz* et al. [63.39] also suggested an algorithm that searches different solution spaces during different stages of a run. The idea is that when the search is deemed to have stagnated in one space, a procedure is used to alter the current solution so that it becomes a member of another space (e.g., clashing vertices are *uncolored* by transferring them to  $S$ ). Once this has been done, the search can then be continued in this new space where further improvements might be made.

### 63.2.1 EAs for Graph Coloring

In this section we now examine the ways in which **EAs** have been applied to the graph coloring problem, particularly looking at issues surrounding the recombination of solutions.

#### Assignment-Based Operators

Perhaps the most intuitive way of applying **EAs** to the graph coloring problem is to view the task as one of assignment. In this case, a candidate solution can be viewed as a mapping of vertices to colors  $c : V \rightarrow \{1, \dots, k\}$ , and a natural chromosome representation is a vector  $(c(v_1), c(v_2), \dots, c(v_{|V|}))$ , where  $c(v_i)$  gives the color of vertex  $v_i$  (the solution given in Fig. 63.1 would be represented by  $(1, 4, 3, 4, 3, 5, 2, 2, 4, 1)$  under this scheme). However, it has long been argued that this sort of approach brings disadvantages, not least because it contradicts a fundamental design principle of **EAs**: the principle of minimum redundancy [63.40], which states that each member of the search space should be represented by as few distinct chromosomes as possible. To expand upon this point, we observe that under this *assignment-based* representation, if we are given a solution using  $l \leq k$  colors, the number of different chromosomes representing this solution will be  ${}^k P_l$  due

to the arbitrary way in which colors are allocated labels. (For example, swapping the labels of colors 2 and 4 in Fig. 63.1's solution would give a new chromosome (1,2,3,2,3,5,4,4,2,1), but the same solution.) Of course, this implies a search space that is far larger than necessary.

Furthermore, authors such as *Falkenauer* [63.41] and *Coll* et al. [63.42] have also argued that traditional recombination schemes such as 1, 2, and  $n$ -point crossover with this representation have a tendency to recklessly break up building-blocks that we might want promoted in a population. As an example, consider a recombination of the two example chromosomes given in the previous paragraph using two-point crossover: (1,4,3,4,3,5,2,2,4,1) crossed with (1,2,3,2,3,5,4,4,2,1) would give (1,4,3,4,3,5,4,4,4,1) as one of the offspring. Here, despite the fact that the two parent chromosomes actually represent the same feasible solution, the resultant offspring seems to have little in common with its parents, having lost one of its colors, and seen a number of clashes having been introduced. Thus, it is concluded by these authors that such operations actually constitute more of a random perturbation operator, rather than a mechanism for combining meaningful substructures from existing solutions. Nevertheless, recent algorithms following this scheme are still reported in the literature [63.43].

In recognition of the proposed disadvantages of the assignment-based representation, *Coll* et al. [63.42] proposed a procedure for relabeling the colors of one of the parent chromosomes before applying crossover. Consider two (not necessarily feasible) parent solutions represented as partitions:  $\mathcal{U}_1 = \{U_{1,1}, \dots, U_{1,k}\}$ , and  $\mathcal{U}_2 = \{U_{2,1}, \dots, U_{2,k}\}$ . Now, using  $\mathcal{U}_1$  and  $\mathcal{U}_2$ , a complete bipartite graph  $K_{k,k}$  is formed. This bipartite graph has  $k$  vertices in each partition, and the weights between two vertices  $i,j$  from different partitions are defined as  $w_{i,j} = |\mathcal{U}_{1,i} \cap \mathcal{U}_{2,j}|$ . Given  $K_{k,k}$ , a maximum weighted matching can then be determined using any suitable algorithm (e.g., the Hungarian algorithm [63.44] or auc-

tion algorithm [63.45]), and this matching can be used to re-label the colors in one of the chromosomes.

Figure 63.2 gives an example of this procedure and shows how the second parent can be altered so that its color labelings maximally match those of parent 1. In this case, we note that the color classes  $\{v_1, v_{10}\}$ ,  $\{v_3, v_5\}$ , and  $\{v_6\}$  occur in both parents and will be preserved in any offspring produced via a traditional crossover operator. However, this will not always be the case and will depend very much on the best matching that is available in each case.

A further scheme for color relabeling that also addresses the issue of redundancy was proposed by *Tucker* et al. [63.46]. This method involves representing solutions using the assignment-based scheme, but under the following restriction

$$c(v_1) = 1, \quad (63.3)$$

$$c(v_{i+1}) \leq \max\{c(v_1), \dots, c(v_i)\} + 1. \quad (63.4)$$

Chromosomes obeying these labeling criteria might, therefore, be considered as being in their canonical form such that, by definition, vertex  $v_1$  is always colored with color 1,  $v_2$  is always colored with color 1 or 2, and so on. (The solution given in Fig. 63.1 would be represented by (1,2,3,2,3,4,5,5,2,1) under this scheme.) However, although this ensures a one-to-one correspondence between the set of chromosomes and the set of vertex partitions (thereby removing any redundancy), research by *Lewis* and *Pullin* [63.47] demonstrated that this scheme is not particularly useful for graph coloring, not least because minor changes to a chromosome (such as the recoloring a single vertex) can lead to major changes to the way colors are labeled, making the propagation of useful solution substructures more difficult to achieve when applying traditional crossover operators.

### Partition-Based Operators

Given the proposed issues with the assignment-based approach, the last 15 years or so have also seen a num-

| Parent 1                       | Parent 2                       | $ \mathcal{U}_{1,i} \cap \mathcal{U}_{2,j} $ |

| $U_{1,2} = \{v_7, v_8\}$       | $U_{2,2} = \{v_2, v_4\}$       |                                              |
| $U_{1,3} = \{v_3, v_5\}$       | $U_{2,3} = \{v_1, v_{10}\}$    |                                              |
| $U_{1,4} = \{v_2, v_4, v_9\}$  | $U_{2,4} = \{v_7, v_8, v_9\}$  |                                              |
| $U_{1,5} = \{v_6\}$            | $U_{2,5} = \{v_6\}$            |                                              |
| <b>Parent 2 relabelled</b>     |                                |                                              |
| (1, 4, 3, 4, 3, 5, 2, 2, 2, 1) |                                |                                              |

**Fig. 63.2** Example of the relabeling procedure proposed by *Coll* et al. [63.42]. Here, parent 2 is relabeled as 1 → 3, 2 → 4, 3 → 1, 4 → 2, and 5 → 5

ber of articles presenting recombination operators focussed on the partition (or grouping) interpretation of graph coloring. The philosophy behind this approach is that it is actually the color classes (and the vertices that are assigned to them) that represent the underlying building blocks of the graph coloring problem. In other words, it is not the color of individual vertices per se, but the *way in which vertices are grouped* that form the meaningful substructures. Consequently, the focus should be on the design of operators that are successfully able to combine and promote these within a population.

Perhaps the first major work in this area was due to *Falkenauer* [63.48] in 1994 (and later [63.41]) who argued in favor of the partition interpretation in the justification of his grouping genetic algorithm (**GGA**) – an **EA** methodology specifically designed for use with partitioning problems. *Falkenauer* applied this **GGA** to two important operational research problems: the bin-packing problem and bin-balancing problem, with strong results being reported. In subsequent work, *Erben* [63.20] also tailored the **GGA** for graph coloring. Erben's approach operates in the space of feasible colorings and allows the number of colors in a solution to vary. Solutions are then stored as partitions, and evaluated using (63.1). In this approach, recombination operates by taking two parent solutions and randomly selecting a subset of color classes from the second. These color classes are then copied into the first parent, and all color classes coming from the first parent containing duplicate vertices are deleted. This opera-

tion results in an offspring solution that is proper, but most likely partial. Thus uncolored vertices are then reinserted into the solution, in this case using the first-fit algorithm. A number of other recombination operators for use in the space of feasible solutions have also been suggested by *Mumford* [63.19]. These operate on permutations of vertices, which are again decoded into solutions using the first-fit algorithm.

Another recombination operator that focusses on the partition interpretation of graph coloring is due to *Galinier* and *Hao*, who in 1999 proposed an **EA** that, at the date of writing, is still understood to be one of the best performing algorithms for graph coloring [63.33, 38, 49, 50]. Using a fixed number of colors  $k$ , Galinier and Hao's method operates in the space of complete (proper and improper)  $k$ -colorings using cost function  $f_2$  (63.2). A population of candidate solutions is then evolved using local search (based on tabu search) together with a specialized recombination operator called greedy partition crossover (**GPX**). The latter is used as a global operator and is intended to guide the search over the long term, gently directing it towards favorable regions of the search space (exploration), while the local search element is used to identify high quality solutions within these regions (exploitation).

The idea behind **GPX** is to construct offspring using large color classes inherited from the parent solutions. A demonstration of how this is done is given in Fig. 63.3. As is shown, the largest (not necessarily proper) color class in the parents is first selected and copied into the offspring. Then, in order to avoid dupli-

|    | Parent 1                       | Parent 2                 | Offspring                   |                                                                                        |

|    | $U_3 = \{v_9\}$                | $\{\}$                   | $\{v_1, v_3\}$              |                                                                                        |
| e) | $U_1 = \{\}$                   | $\{v_9\}$                | $\{v_4, v_5, v_6, v_7\}$    | A complete (though not necessarily proper) solution results.                           |
|    | $U_2 = \{v_9\}$                | $\{\}$                   | $\{v_2, v_8, v_{10}, v_9\}$ |                                                                                        |
|    | $U_3 = \{\}$                   | $\{\}$                   | $\{v_1, v_3\}$              |                                                                                        |

Fig. 63.3 Demonstration of the **GPX** operator using  $k = 3$

cate vertices occurring in the offspring at a later stage, these copied vertices are removed from both parents. To form the next color, the other (modified) parent is then considered and, again, the largest color class is selected and copied into the offspring, before again removing these vertices from both parents. This process is continued by alternating between the parents until the offspring's  $k$  color classes have been formed. At this point, each color class in the offspring will be a subset of a color class existing in one or both of the parents. That is

$$\forall U_i \in \mathcal{U}_c \exists U_j \in (\mathcal{U}_1 \cup \mathcal{U}_2) : U_i \subseteq U_j, \quad (63.5)$$

where  $\mathcal{U}_c$ ,  $\mathcal{U}_1$ , and  $\mathcal{U}_2$  represent the offspring, and parents 1 and 2, respectively.

One feature of the **GPX** operator is that on production of an offspring's  $k$  color classes, some vertices may be missing (this occurs with vertex  $v_9$  in Fig. 63.3). *Galinier* and *Hao* [63.33] suggest assigning these uncolored vertices to random classes, which of course could introduce further clashes. This element of the procedure might, therefore, be viewed as a type of perturbation (mutation) operator in which the number of random assignments (the size of the perturbation) is determined by the construction stages of **GPX**. However, *Glass* and *Prugel-Bennett* [63.49] observe that GPX's strategy of inheriting the largest available color class at each step (as opposed to a random color class) generally reduces the number of uncolored vertices. This means that the amount of information inherited directly from the parents is increased, reducing the potential for disruption. Once a complete offspring is formed, it is then modified and improved via a local search procedure before being inserted into the population.

Since the proposal of **GPX** by *Galinier* and *Hao* [63.33], further recombination schemes based on this method have also been suggested, differing primarily in the criteria used for selecting the color classes that are inherited by the offspring. *Lü* and *Hao* [63.34], for example, extended the **GPX** operator to allow more

than two parents to play a part in producing a single offspring (Sect. 63.5). On the other hand, *Porumbel* et al. [63.35] suggest that instead of choosing the largest available color class at each stage of construction, classes with the least number of clashes should be prioritized, with class size (and information regarding the degrees of the vertices) then being used to break ties. *Malaguti* et al. [63.38] also use a modified version of **GPX** with an **EA** that navigates the space of partial, proper solutions. In all of these cases the authors combined their recombination operators with a local search procedure in the same manner as *Galinier* and *Hao* [63.33] and, with the problem instances considered, the reported results are generally claimed to be competitive with the state of the art.

### Assessing the Effectiveness of EAs for Graph Coloring

In recent work carried out by the author of this chapter [63.50], a comparison of six different graph coloring algorithms was presented. This study was quite broad and used over 5000 different problem instances. Its conclusions were also rather complex, with each method outperforming all others on at least one class of problems. However, a salient observation was that the **GPX**-based **EA** of *Galinier* and *Hao* [63.33] was by far the most consistent and high-performing algorithm across the comparison.

In the remainder of this chapter we pursue this matter further, particularly focussing on the role that **GPX** plays in this performance. Under a common **EA** framework, described in Sect. 63.3, we first evaluate the performance of **GPX** by comparing it to two other recombination operators (Sect. 63.4). Using information gained from these experiments, Sect. 63.5 then looks at how the performance of the **GPX**-based **EA** might be enhanced, particularly by looking at ways in which population diversity might be prolonged during a run. Finally, conclusions and a further discussion surrounding the virtues of recombination in this problem domain are presented in Sect. 63.6.

## 63.3 Setup

The **EA** used in the following experiments operates in the same manner as *Galinier* and *Hao*'s [63.33]. To form an initial population, a modified version of the DSATUR algorithm is used. Specifically, each individual is formed by taking the vertices in turn according to

the DSATUR heuristic and then assigning it to the lowest indexed color  $i \in \{1, \dots, k\}$  where no clash occurs. Vertices for which no clash-free color exists are assigned to random colors at the end of this process. Ties in the DSATUR heuristic are broken randomly, providing di-

**Table 63.1** Details of the five problem instances used in our analysis

| #; Name      | V    | Density | Vertex degree |       |      | Best known<br>(colors) |
|--------------|------|---------|---------------|-------|------|------------------------|
|              |      |         | min; med; max | Mean  | SD   |                        |
| 1: Random    | 1000 | 0.499   | 450; 499; 555 | 499.4 | 16.1 | 83                     |
| 2: Flat(10)  | 500  | 0.103   | 36; 52; 61    | 51.7  | 4.4  | 10                     |
| 3: Flat(100) | 500  | 0.841   | 393; 421; 445 | 420.7 | 7.6  | 100                    |
| 4: TT(A)     | 682  | 0.128   | 0; 77; 472    | 87.4  | 62.0 | 27                     |
| 5: TT(B)     | 2419 | 0.029   | 0; 47; 857    | 71.3  | 92.3 | 32                     |

versity in the initial population. Each individual is then improved by the local search routine.

The EA evolves the population using recombination, local search, and replacement pressure. In each iteration two parent solutions are selected at random, and the selected recombination operator is used to produce one offspring. This offspring is then improved via local search and inserted into the population by replacing the weaker of its two parents.

The local search element of this EA makes use of tabu search – specifically the TABUCOL algorithm of Hertz and de Werra [63.24], run for a fixed number of iterations. In this method, moves in the search space are achieved by selecting a vertex  $v$  whose assignment to color  $i$  is currently causing a clash, and moving it to a new color  $j \neq i$ . The inverse of this move is then marked as tabu for the next  $t$  steps of the algorithm (meaning that  $v$  cannot be re-assigned to color  $i$  until at least  $t$  further moves have been performed). In each iteration, the complete neighborhood is considered, and the non-tabu move that is seen to invoke the largest decrease in cost (or failing that, the smallest increase) is performed. Ties are broken randomly, and tabu moves are also carried out if they are seen to improve on the best solution observed so far in the process. The tabu search routine terminates when the iteration limit is reached (at which case the best solution found during the process is taken), or when a zero cost solution is achieved. Further descriptions of this method, including implementation details, can be found in [63.51].

In terms of parameter settings, in all cases we use a population size of 20 (as in [63.34, 35]) and set the tabu search iteration limit to  $16|V|$ , which approximates the settings used in the best reported runs in [63.33]. As with other algorithms that use this local search technique [63.29, 33, 37], the tabu tenure  $t$  is made proportional to the current solution cost: specifically,  $t = \lceil 0.6f_2 \rceil + r$ , where  $r$  is an integer uniformly selected from the range 0–9 inclusive.

Finally, because this algorithm operates in the space of complete  $k$ -colorings (proper and improper), values for  $k$  must be specified. In our case, initial values are

determined by executing DSATUR on each instance and setting  $k$  to the number of colors used in the resultant solution. During runs,  $k$  is then decremented by 1 as soon as a feasible  $k$ -coloring is found, and the algorithm is restarted. Computational effort is measured by counting the number of constraint checks carried out by the algorithm, which occur when the algorithm requests information about a problem instance, including checking whether two vertices are adjacent (by accessing an adjacency list or matrix), and referencing the degree of a vertex. In all trials a cut-off point of  $5 \times 10^{11}$  checks is imposed, which is roughly double the length of the longest run performed in [63.33]. In our case, this led to run times of  $\approx 1$  h on our machines (algorithms were coded in C++ and executed on a PC under Windows XP using a 3.0 GHz processor with 3.18 GB of RAM).

### 63.3.1 Problem Instances

For our trials a set of five problem instances is considered. Though this set is quite small, its members should be considered as case studies that have been deliberately chosen to cover a wide range of graph structure – a factor that we have found to be very important in influencing the relative performance of graph coloring algorithms [63.50]. The first three graphs are generated using the publicly available software of Culberson [63.52], while the remaining two are taken from a collection of real-world timetabling problems compiled by Carter et al. [63.53]. Names and descriptions of these graphs now follow. Further details are also given in Table 63.1:

#1: *Random*. This graph features  $|V| = 1000$  and is generated such that each of the  $\binom{|V|}{2}$  pairs of vertices is linked by an edge with probability 0.5. Graphs of this nature are nearly always considered in comparisons of coloring algorithms.

#2: *Flat(10)*. Flat graphs are generated by partitioning the vertices into  $K$  equi-sized groups and then adding edges between vertices in different groups with probability  $p$ . This is done such that the vari-

ance in vertex degrees is kept to a minimum. It is well known that feasible  $K$ -colored solutions to such graphs are generally easy to achieve except in cases where  $p$  is within a specific range of values, which results in problems that are notoriously difficult. Such ranges are commonly termed *phase transition regions* [63.54]. This particular instance is generated so that it features a relatively small number of large color classes (using  $V = 500$  and  $K = 10$ , implying  $\approx 50$  vertices per color). A value of  $p = 0.115$  is used, which has been observed to provide very difficult instances for a range of different graph coloring algorithms [63.50].

- #3 *Flat(100)*. This graph is generated in the same manner as the previous one, using  $|V| = 500$ ,  $K = 100$ , and  $p = 0.85$ . Solutions thus feature a relatively large number of small color classes ( $\approx 5$  vertices per color).

#4: *TT(A)*. This graph is named *car\_s\_91* in the original dataset of Carter et al. [63.53]. It is chosen because it is quite large and, unlike the previous three graphs, the variance in vertex degrees is quite high. This problem's structure is also much less regular than the previous three graphs, which are generated in a fairly regimented manner.

#5: *TT(B)*. This graph, originally named *pur\_s\_93*, is the largest problem in Carter's dataset, with  $|V| = 2419$ . It is also quite sparse compared to the previous graph, though it still features a high variance in vertex degrees (Table 63.1).

The rightmost column of Table 63.1 also gives information on the best solutions known for each graph. These values were determined via extended runs of our algorithms, or due to information provided by the problem generator.

## 63.4 Experiment 1

Our first set of experiments looks at the performance of **GPX** by comparing it to two additional recombination operators. To gauge the advantages of using a global operator (recombination in this case), we also consider the performance of TABUCOL on its own, which iterates on a single solution until the run cut-off point is met.

Our first additional recombination operator follows the assignment-based scheme discussed in Sect. 63.2.1 and, in each application, utilizes the procedure of Coll et al. [63.42] (Fig. 63.2) to relabel the second parent. Offspring are then formed using the classical  $n$ -point crossover, with each gene being inherited from either parent with probability 0.5.

Our second recombination operator is based on the grouping genetic algorithm (**GGA**) methodology (Sect. 63.2.1), adapted for use in the space of  $k$ -colorings. An example is given in Fig. 63.4. Given

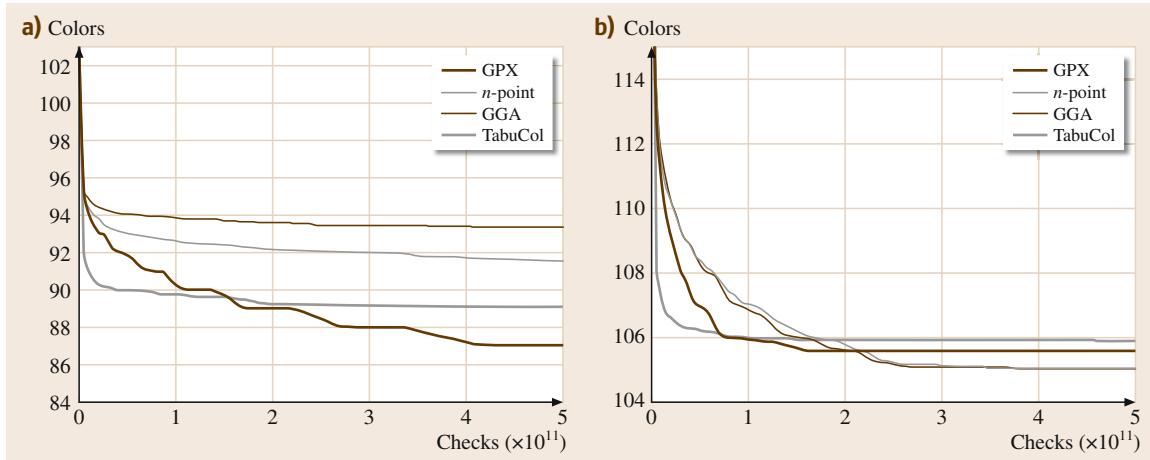

two parents, the color classes in the second parent are first relabeled using Coll et al.'s procedure. Using the partition-based representations of these solutions, a subset of colors in parent 2 is then chosen randomly, and these replace the corresponding colors in a copy of parent 1. Duplicate vertices are then removed from color classes originating from parent 1 and uncolored vertices are assigned to random color classes. Note that like **GPX**, before uncolored vertices are assigned, the property defined by (63.5) is satisfied by this operator; however, unlike **GPX** there is no requirement to inherit larger color classes or to inherit half of its color classes from each parent.

A summary of the results achieved by the three recombination operators (together with TABUCOL) is given in Table 63.2. For each instance the same set of 20 initial populations was used with the **EAs**, and entries in bold signify samples that are significantly different to the non-bold **EA** entries according to a Wilcoxon signed-rank test at the 0.01 significance level. For graph #1 we see that **GPX** has clearly produced the best results – indeed, even its worst result features two fewer colors than the next best solution. However, for graphs #2 and #5, no significant difference between the **EAs** is observed, while for #3 and #4, better results are produced by the **GGA** and the  $n$ -point crossover.

Figure 63.5 shows run profiles for two example graphs. We see that in both cases TABUCOL provides

| Parent 1                  | Parent 2                                 | Offspring                             |
|---------------------------|------------------------------------------|---------------------------------------|
| $U_1 = \{v_1, v_{10}\}$   | $U_1 = \{v_1, v_9\}$                     | $U_1 = \{v_1, v_{10}\}$               |
| $U_2 = \{v_7, v_8\}$      | $U_2 = \{v_7\}$                          | $U_2 = \{v_7, \text{#}_8\}$           |
| $U_3 = \{v_3, v_5\}$      | $\triangleright U_3 = \{v_3, v_5\}$      | $U_3 = \{v_3, v_5\}$                  |
| $U_4 = \{v_2, v_4, v_9\}$ | $\triangleright U_4 = \{v_2, v_4, v_9\}$ | $U_4 = \{v_2, v_4, v_9\}$             |
| $U_5 = \{v_6\}$           | $U_5 = \{v_6, v_{10}\}$                  | $U_5 = \{v_6\}$ Uncolored = $\{v_9\}$ |

**Fig. 63.4** Demonstration of the **GGA** recombination operator. Here, color classes in parent 2 are labeled to maximally match those of parent 1

**Fig. 63.5a,b** Run profiles for the instances (mean of 20 runs): (a) #1 (random). (b) #3 (Flat 100)

the fastest rates of improvement, though it is eventually overtaken by at least one of the EAs. Table 63.2, however, also reveals that TABUCOL performs very poorly with graphs #4 and #5. This seems due to the high degree variance in these cases, which we observe makes the cost of neighboring solutions in the search space vary more widely. This suggests a more *spiky* cost landscape in which the use of local search in isolation exhibits a susceptibility for becoming trapped at local optima (see also [63.50]).

An important factor behind the differing performances of these EAs is the effect that recombination has on the population diversity. To examine this, we first define a metric for measuring the distance between two solutions: Given a solution  $\mathcal{U}$ , let  $P_{\mathcal{U}} = \{\{u, v\} : c(u) = c(v)\}$ , for  $\forall u, v \in V, u \neq v$ . The *distance* between two solutions  $\mathcal{U}_1$  and  $\mathcal{U}_2$  can then be defined,

$$D(\mathcal{U}_1, \mathcal{U}_2) = \frac{|P_{\mathcal{U}_1} \cup P_{\mathcal{U}_2}| - |P_{\mathcal{U}_1} \cap P_{\mathcal{U}_2}|}{|P_{\mathcal{U}_1} \cup P_{\mathcal{U}_2}|}. \quad (63.6)$$

This measure gives the proportion of vertex pairings (assigned to the same color) that exist in just one of the two solutions. Consequently, if  $\mathcal{U}_1$

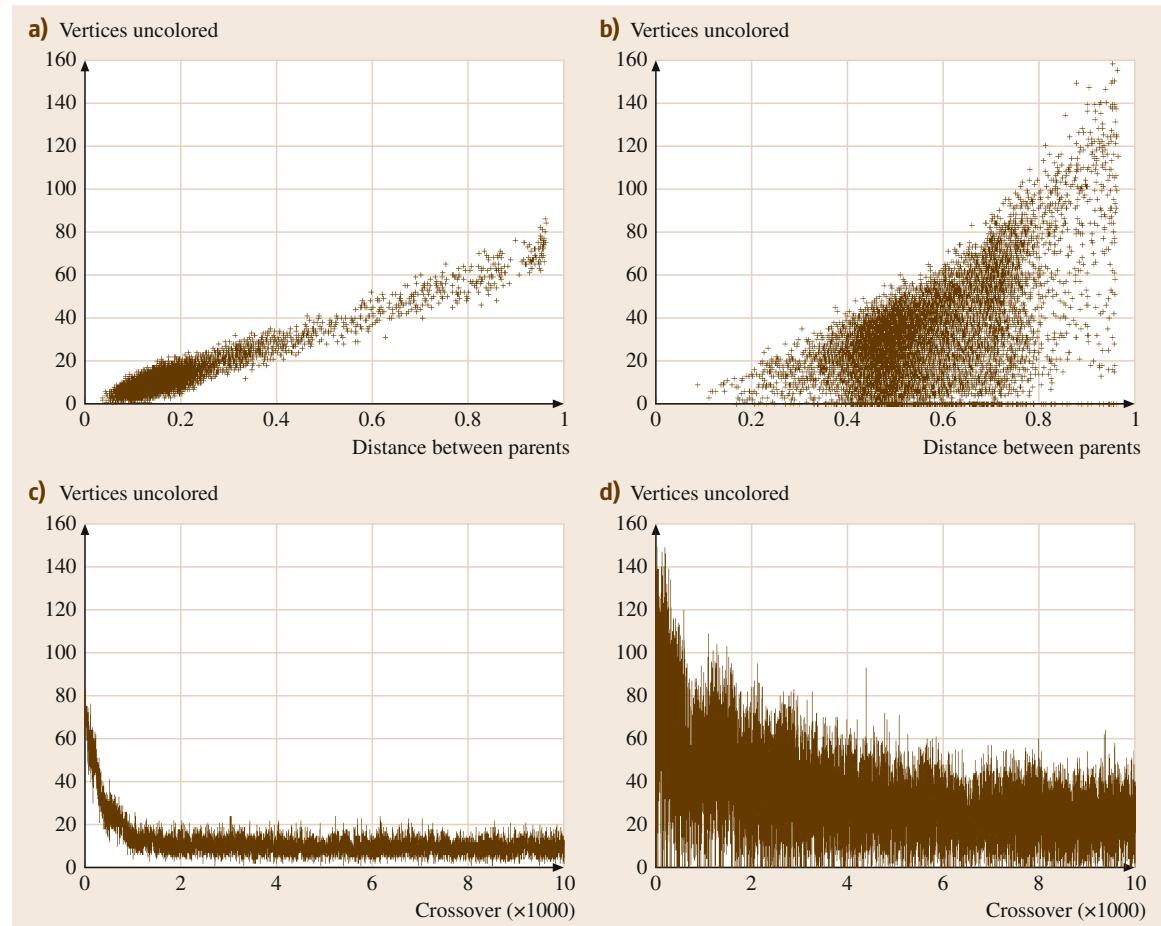

and  $\mathcal{U}_2$  are identical, then  $P_{\mathcal{U}_1} \cup P_{\mathcal{U}_2} = P_{\mathcal{U}_1} \cap P_{\mathcal{U}_2}$ , giving  $D(\mathcal{U}_1, \mathcal{U}_2) = 0$ . Conversely, if no vertex pair is assigned the same color,  $P_{\mathcal{U}_1} \cap P_{\mathcal{U}_2} = \emptyset$ , implying  $D(\mathcal{U}_1, \mathcal{U}_2) = 1$ . Population diversity can also be defined as the mean distance between each pair of solutions in the population. That is, given a set of  $m$  individuals  $\mathbf{U} = \{\mathcal{U}_1, \mathcal{U}_2, \dots, \mathcal{U}_m\}$

$$\text{Diversity}(\mathbf{U}) = \frac{1}{\binom{m}{2}} \sum_{\forall \mathcal{U}_i, \mathcal{U}_j \in \mathbf{U}: i < j} D(\mathcal{U}_i, \mathcal{U}_j). \quad (63.7)$$

Considering our results, the two scatter plots of Fig. 63.6 demonstrate the positive correlation that exists between parental distance and the number of uncolored vertices that result in applications of the **GPX** and **GGA** operators. This data was derived from graph #4, though similar patterns were observed for the other instances. Note that the correlation is weaker for **GGA** due to two reasons. First, unlike **GPX**, which requires half of the color classes to be inherited from each parent, with **GGA** this proportion can vary. Thus if the majority of color classes are inherited from just one par-

**Table 63.2** Number of colors in the best feasible solution achieved at the cut-off point (mean (min; median; max) of 20 runs)

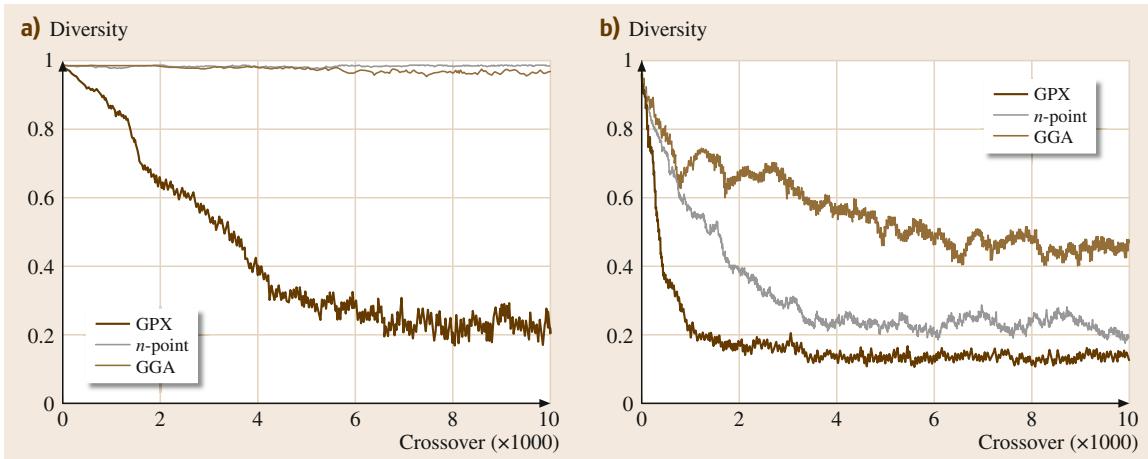

**Fig. 63.6a–d** Relationship between parental distance and number of uncolored vertices with the **GPX** (a) and **GGA** (b) operators. Also shown is the number of uncolored vertices in the first 10 000 applications of **GPX** (c) and **GGA** (d)

ent, it is possible to have two very different parents, but only a small number of uncolored vertices. Second, as mentioned earlier **GGA** shows no bias towards inheriting larger color classes, meaning that the number of uncolored vertices can also be higher than **GPX**, particularly when inheriting around half of the color classes from each parent. An effect of these patterns is shown in the lower graphs of Fig. 63.6, where throughout the evolutionary process, the number of uncolored vertices occurring during recombination is fewer and less varied with **GPX**. In comparison to **GGA**, this behavior leads to a more rapid loss of diversity, as is demonstrated in Fig. 63.7 for two example graphs.

Whether sustained diversity is a help or hindrance with these **EAs** thus seems to depend on the type of graph being tackled. As can be seen in Fig. 63.7, for

graph #1 **GPX** is the only recombination operator that leads to any sort of population convergence, and it is also the algorithm that produces the best solutions given sufficient time, suggesting that it suitably *homing in* on high-quality regions of the search space. On the other hand, for graphs #3 and #4, **GGA**'s more sustained diversity (caused and perpetuated by the greater number of uncolored vertices that occur during recombination) causes the operator to be more disruptive. However, in these cases this factor also seems to provide a useful diversification mechanism, allowing the algorithm to sample wider areas of the search space, leading to better results. An extreme case of diversity loss occurs with graph #5, which we recall has a low density and high degree variance. In this case, when using **GPX** large color classes of low-degree vertices that are formed in

**Fig. 63.7a,b** Population diversity during the first 10 000 recombinations with (a) the random (#1) and (b) TT(A) (#4) instances

early stages of the algorithm quickly come to dominate the population limiting the exploration that then takes place – indeed, in many runs the algorithm was actually unable to improve on costs achieved in the initial population.

Figure 63.7 also shows that *n*-point crossover tends to maintain diversity for longer periods than **GPX** in this case, allowing it to produce superior results for graphs #3 and #4. However, the sustained diversity is not due

to uncolored vertices (which do not occur with this operator); rather, it seems due to the naturally occurring disruption that results from the color labeling issues mentioned in Sect. 63.2.1.

Finally, we also mention that during our runs with these EA's, the local search element was observed to be by far the most expensive part of the algorithm, with none of the recombination operators consuming more than 1.8% of the available run time.

## 63.5 Experiment 2

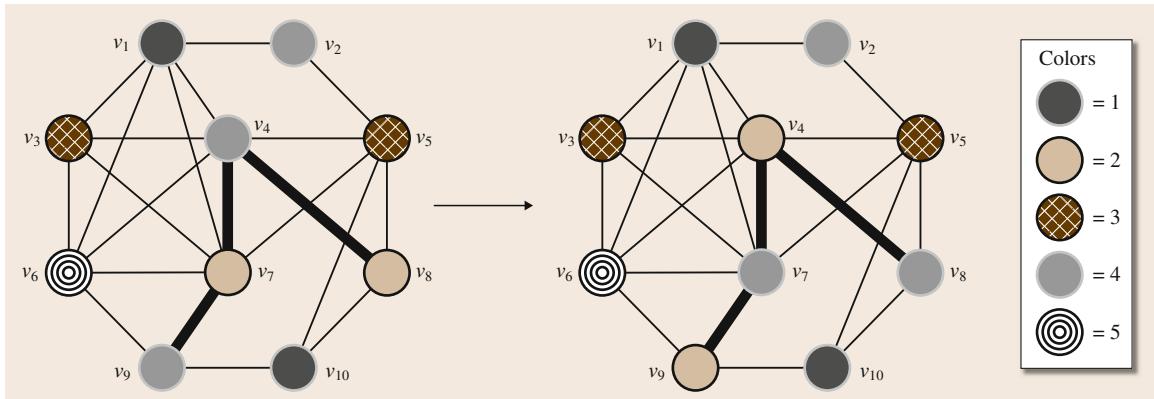

In this section we now consider ways in which the results of the **GPX** operator might be improved, particularly looking at how we might encourage diversity to be sustained in the population.

As mentioned in Sect. 63.2.1, *Lü* and *Hao* [63.34] previously proposed extending the **GPX** operator to allow offspring to be produced using  $m \geq 2$  parents. In this operator, which we call **MULTIX**, offspring are constructed in the same manner as **GPX**, except that at each stage the largest color class from *multiple parents* is chosen to be copied into the offspring. The intention behind this increased choice is that larger color classes will be identified, resulting in fewer uncolored vertices once the  $k$  color classes have been constructed. In order to prohibit too many colors being inherited from one particular parent, *Lü* and *Hao* also make use of a parameter  $q$ , specifying that if the  $i$ -th color class in an offspring is copied from a particular parent, then this

parent should not be considered for further  $q$  colors. In our application of **MULTIX** we follow the recommendations of the *Lü* and *Hao*, choosing  $m$  randomly from the set  $\{2, \dots, 6\}$  in each application and using  $q = \lfloor m/2 \rfloor$ . Note also that **GPX** is simply an application of **MULTIX** using  $m = 2$  and  $q = 1$ .

Though having the potential to produce good results [63.34], an issue with **MULTIX** is that it could result in diversity being lost even more rapidly than with **GPX**, particularly if fewer vertices need to be randomly recolored at the end of each application. In [63.34], *Lü* and *Hao* attempt to deal with this using a mechanism whereby offspring are only inserted into the population if they are seen to be sufficiently different or better than existing members. However, in our case, we suggest two alternative methods.

The first of these involves altering the **MULTIX** operator so that it works exclusively with proper col-

**Fig. 63.8** Example Kempe chain involving, e.g., vertex  $v_7$  and color 4 (left), and the resultant coloring due to a color interchange (right)

orings. As noted, **GPX** and **MULTIX** currently operate on colorings in which clashes are permitted; however, this could in theory result in large color classes that feature many clashes being unduly promoted in the population, when perhaps the real emphasis should be on the promotion of large color classes that are *independent sets*. The **ISETS** approach thus operates by first iteratively removing clashing vertices from each parent (in a random order, until proper colorings are achieved), and then using the **MULTIX** operator to produce an offspring as before. This implies that, before recoloring missing vertices, offspring will also be proper, since subsets of independent sets are themselves independent sets. A further effect is that a greater number of vertices might need to be recolored, since vertices originally removed from the parents could also be missing in the resultant offspring.

Our second proposal for prolonging diversity is to make changes directly to an offspring to try to increase its distance from its parents before reinsertion into the population. One way of doing this would be to increase the iteration limit of the local search procedure, as demonstrated by *Galinier and Hao* [63.33]. However, we find that such an approach can slow the algorithm unnecessarily, particularly because as the procedure progresses, movements in the search space (due to improving or sideways moves) become less frequent. An alternative in this case is to exploit the structure of the graph coloring problem via the use of a Kempe chain interchange operator. Kempe chains define connected sub-graphs that involve exactly two colors, and can be generated by taking an arbitrary vertex  $v$  and color  $i$ , such that  $c(v) \neq i$ . An example is given in Fig. 63.8. Note that when interchanging the colors of vertices in

a Kempe chain, if the original coloring is proper, then so is the new coloring. Thus we have the opportunity to quickly alter colorings without compromising their quality.

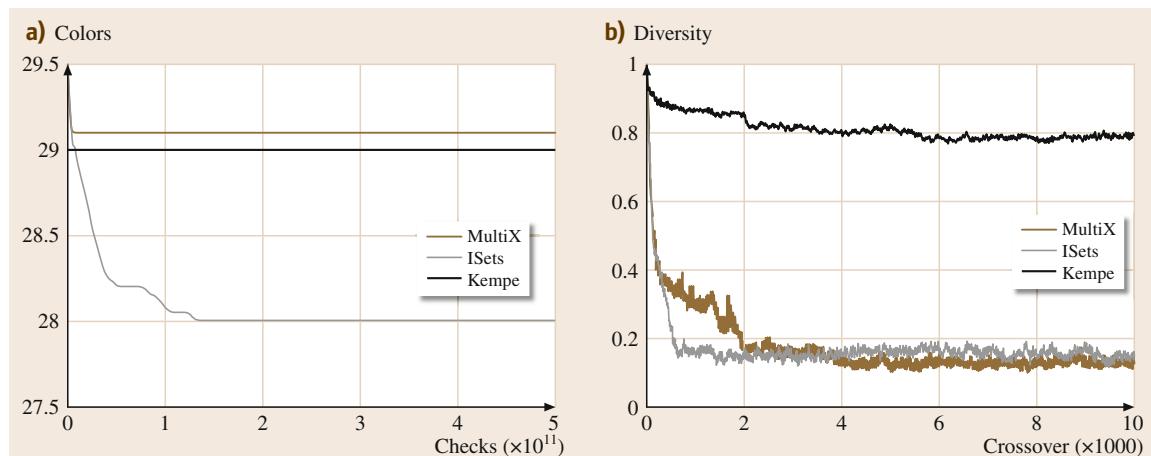

Our **KEMPE** approach operates in the same manner as **ISETS**, except that before reassigning uncolored vertices, a series of randomly selected Kempe chain interchanges are performed on the existing proper coloring. In our case,  $2k$  such moves are applied.

The results achieved by our three modifications are summarized in Table 63.3, where bold entries signify samples that are significantly different to **GPX** at significance level 0.01. We see that improvements over **GPX** were only obtained on graph #1, where all three variants were successful, and graph #4 using the **KEMPE** variant. In practice, we found that **MULTIX** causes diversity to be lost more quickly than **GPX** with these graphs – however, the **ISETS** mechanism did not seem to alter this behavior a great deal, usually because the number of clashing vertices needing to be removed was quite small (less than 10).

Surprisingly, we also found that the **KEMPE** variant was only able to maintain higher levels of diversity with instances #4 and #5. For graphs #1, #2, and #3, it turns out that when using a suitably low number of colors  $k$ , the bipartite graphs induced by most pairs of color classes in a solution are connected. In these cases, all of the vertices belonging to the two color classes are included in the Kempe chain, meaning that a color interchange does not alter the structure of the solution, but merely produces a relabeling of the two color classes. (An example of such a Kempe chain would occur in Fig. 63.8 using vertex  $v_3$  and color 2.) This is not the case for the less structured graphs #4 and #5, where we

**Fig. 63.9** (a) Run profile for TT(A) (graph #4, left), and (b) its diversity over the first 10 000 recombinations

found that diversity could be maintained for longer periods. However, this only led to significant improvements in the results for graph #4, whose run profiles are shown

in Fig. 63.9. Also note that these enhanced results still fail to beat those of the GGA and  $n$ -point operators, as shown in Table 63.2.

## 63.6 Conclusions and Discussion

In this chapter we have examined the relative performance of a number of different graph coloring recombination operators. Using a common evolutionary framework, we have seen that this performance varies, particularly due to the underlying structures of the graphs being tackled.

A desirable property of recombination is that it should be able to combine meaningful substructures of existing candidate solutions (parents) in the production of new, hopefully fitter, offspring. However, does that process actually occur with any of these operators? Or, by involving the random reassignment of some vertices, do the operators simply provide a mechanism by which large random perturbations are periodically applied to a solution, helping to re-invigorate the search process?

Again, the answer to such a question seems to depend on the problem instance at hand. In Table 63.4 we compare the costs of solutions achieved by the best available recombination operator for each instance, together with those produced by a corresponding random perturbation operator. Specifically, for each graph we identified the best run from the EA's sample of 20 and recorded the number of uncolored vertices that resulted in each application of recombination. We then used these figures, together with the same  $k$ -value, to specify the number of vertices that would be randomly selected and reassigned in each corresponding application of our random perturbation operator. In each iteration this algorithm then operated by selecting two parents, making a copy of parent 1, randomly perturbing this copy, ap-

**Table 63.4** Comparison of the best EA and corresponding random perturbation operator. (Cost of best solutions using  $f_2$  (63.2); (mean, (min; median; max) from 20 runs), and proportion of runs where  $f_2 = 0$  (feasibility) was achieved)

|    | $k$ | Type       | EA          |           |             | Random |               |       |
|----|-----|------------|-------------|-----------|-------------|--------|---------------|-------|
|    |     |            | Cost        | (0; 0; 0) | Feas.       | Cost   | (4; 17.5; 31) | Feas. |
| #1 | 85  | MULTIX     | <b>0.00</b> | (0; 0; 0) | <b>1.00</b> | 16.80  | (4; 17.5; 31) | 0.00  |
| #2 | 12  | <b>GPX</b> | <b>2.40</b> | (0; 2; 4) | 0.05        | 7.60   | (5; 8; 10)    | 0.00  |
| #3 | 105 | <b>GPX</b> | 0.90        | (0; 1; 2) | 0.40        | 1.75   | (0; 2; 3)     | 0.15  |
| #4 | 27  | <b>GGA</b> | 1.10        | (0; 1; 2) | 0.15        | 1.35   | (0; 1; 2)     | 0.05  |
| #5 | 32  | <b>GGA</b> | 1.75        | (0; 2; 3) | 0.05        | 1.50   | (0; 1.5; 3)   | 0.15  |

plying local search, and finally replacing the weaker of the two parents.

The results in Table 63.4 indicate that, for graph #1, recombination is clearly doing more than just randomly perturbing solutions since all runs have resulted in feasible 85-colorings. However, although recombination has achieved significantly lower *costs* with graph #2, the proportion of runs where feasibility has been achieved shows no significant difference for any of the graphs #2 to #5 (according to McNemar's test at significance level 0.01). We find this observation compelling as it might suggest that better results might ultimately be achieved using schemes that make more informed decisions about the size and frequency of perturbations. Indeed, currently the size of random perturbations tends to fall as the run progresses (Fig. 63.6); however, it may be useful to allow this trend to be reversed, particularly if improvements are not achieved for a lengthy period of time. In addition, the way in which vertices are chosen for random reassignment might also influence performance – for example, we might target those belonging to a specific color, those that are causing clashes, those that have been assigned to a particular color for the longest, and so on. This requires further research.

An interesting point regarding the structure of solutions was raised previously by Porumbel et al. [63.35], who considered the sizes of the color classes. Specifically, they propose that when solutions involve a small

number of large color classes (such as graph #2 in our case), good quality colorings tend to result through the identification of large independent sets. On the other hand, if a solution involves many small color classes, quality is determined more by the *productive interaction* between classes. In other words, the proposal is that small independent sets in isolation do not constitute good features in these cases; rather, quality results from appropriate combinations of these sets. Such an observation might provide evidence as to why the **GGA** recombination has outperformed **GPX** with graph #3 because, unlike **GPX**, it does not require half of the color classes to be inherited from each parent, thus potentially allowing more class-combinations to be considered. However, this argument is countered by the fact that, according to Table 63.4, **GGA** has not outperformed the random perturbation operator, suggesting that it is actually this mechanism that influences the search. Clearly, further research in this area is also required.

Given such observations, another important avenue of future research will be to increase our understanding of the links between a graph's structure and the best algorithms that can then be used to color it. This might, for example, be derived by increasing our understanding of the behavior, strengths, and weaknesses of the various algorithmic operators available for graph coloring, and also via more empirical means such as data mining, as discussed by Smith-Miles and Lopes [63.55].

# 64. Metaheuristic Algorithms and Tree Decomposition

# Metaheuristi

Thomas Hammerl, Nysret Musliu, Werner Schafhauser

This chapter deals with the application of evolutionary approaches and other metaheuristic techniques for generating tree decompositions. Tree decomposition is a concept introduced by Robertson and Seymour [64.1] and it is used to characterize the difficulty of constraint satisfaction and NP-hard problems that can be represented as a graph. Although, in general, no polynomial algorithms have been found for such problems, particular instances can be solved in polynomial time if the treewidth of their corresponding graph is bounded by a constant. The process of solving problems based on tree decomposition comprises two phases. First, a decomposition with small width is generated. Basically in this phase the problem is divided into several subproblems, each included in one of the nodes of the tree decomposition. The second phase includes solving a problem (based on the generated tree decomposition) with a particular algorithm such as dynamic programming. The main idea is that by decomposing a problem into subproblems of limited size, the whole problem can be solved more efficiently. The time for solving the problem based on its tree decomposition usually depends on the width of the tree decomposition. Thus, it is of high interest to generate tree decompositions having small widths.

Finding the treewidth of a graph is an NP-hard problem [64.2]. In order to solve this problem, different algorithms have been proposed in the literature. Exact methods such as branch and bound techniques can be used only for small graphs. Therefore, metaheuristic algorithms based on genetic algorithms [64.3], simulated annealing [64.4], tabu search [64.5], iterated local search [64.6], and ant colony optimization

(ACO) [64.7, 8] have been proposed in the literature to generate good upper bounds for larger graphs. Such techniques have been applied very successfully and they are able to find the best existing upper bounds for many benchmark problems in the literature.

In this chapter, we will first introduce the concept of tree decomposition, and then give a survey on metaheuristic techniques used to generate tree decompositions. Three approaches based on genetic algorithms, iterated local search, and ACO that were proposed in the literature will be described in detail. Finally, we will also mention briefly two recent approaches that exploit tree decompositions within metaheuristic search.

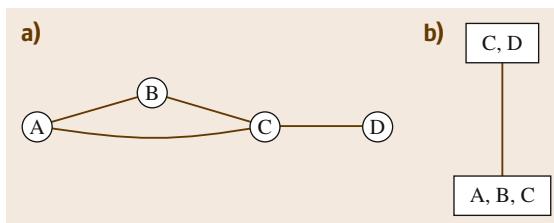

## 64.1 Tree Decompositions

We start with an informal description of tree decomposition. Suppose that we have to find solutions for the graph coloring problem (**GCP**), which is a well-known constraint satisfaction problem (**CSP**) in the literature. For this problem, we have to find a coloring of vertices of a given graph in such a way that no two vertices connected by an edge share the same color. An instance of the **GCP** is shown on the left-hand side of Fig. 64.1. The task is now to find a valid coloring just using the colors red, green, and blue.

A naive approach to solve this problem might be to try out all possible combinations of variable assignments and see which ones are valid. In general, there are  $d^n$  possible combinations, where  $d$  is the number of available colors and  $n$  is the number of vertices.

To solve this problem by tree decomposition, first we generate the tree decomposition of the corresponding problem graph. Informally, a tree decomposition is a tree containing a group of graph vertices where each tree node fulfills the following conditions: each vertex of the graph appears in one of the nodes of the tree; if two vertices are connected in the graph, they must appear together in some of the tree nodes; connectedness condition must be fulfilled, i.e., if a vertex appears in two different nodes of the tree, it must appear also in other nodes between these two nodes. The formal definition of tree decomposition is given in the next section.

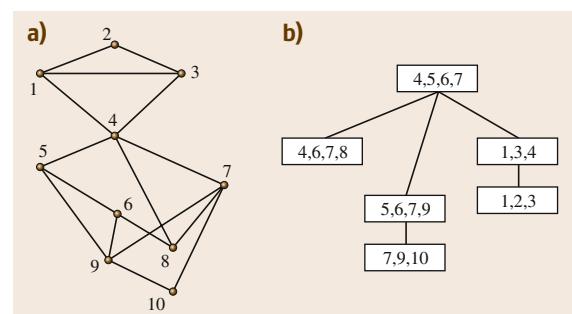

The corresponding constraint graph of a coloring problem and a possible tree decomposition is shown in Fig. 64.1a,b. If we want to solve the graph coloring problem based on this tree decomposition, we can start out by solving the subproblems given by each node in the tree decomposition. Using a naive approach of trying out all possible combinations of variable assignments, one has to generate  $3^3$  (27) different solution candidates for the vertex containing  $A, B$ , and  $C$ . Because of the constraints  $A \neq B, A \neq C$ , and  $B \neq C$  only six of them are valid. For the subproblem containing the

**Fig. 64.1a,b** Instance of the graph coloring problem and a possible tree decomposition

vertices  $C$  and  $D$  we generate  $3^2$  (9) solution candidates and rule out three of them because of the constraint  $C \neq D$ . We can now get all solutions to the whole problem by joining the subproblem solutions. Therefore, we will take a look at the variables that both subproblems have in common. In this case, that is the variable  $C$ . Each solution for the subproblem  $A, B, C$  is joined with the solutions for the subproblem  $C, D$  sharing the same color for the vertex  $C$ . By using the tree decomposition, we have to generate 36 combinations of variable assignments in order to determine all solutions compared to the 81 combinations we would have to generate without the tree decomposition. This difference increases very quickly with the size of the graph coloring problem and constraint satisfaction problems in general. The smaller the subproblems in the tree decomposition the more efficiently we can solve a particular problem. This motivates our interest in finding tree decompositions of small width.

Note that tree decompositions have been applied for several applications, like combinatorial optimization problems, expert systems, computational biology etc. The use of tree decomposition for inference problems in probabilistic networks is shown in [64.9]. Koster et al. [64.10] propose the application of tree decompositions for frequency assignment problem. Tree decomposition has also been applied for the vertex cover problem on planar graphs [64.11]. Furthermore, solving partial constraint satisfaction problems (e.g. **MAX-SAT**) with tree-decomposition-based method has been investigated in [64.12]. In computational biology tree decompositions has been used for protein structure prediction [64.13]. Recently, the application of tree decomposition in Answer-Set Programming has been investigated in [64.14].

**Fig. 64.2a,b** A graph  $G$  (a) and a tree decomposition of  $G$  (b)

### 64.1.1 Formal Definitions

The concept of tree decompositions has been first introduced by *Robertson and Seymour* [64.1]. The formal definition of tree decomposition is given as follows [64.1, 15].

#### Definition 64.1

Let  $G = (V, E)$  be a graph. A tree decomposition of  $G$  is a pair  $(T, \chi)$ , where  $T = (I, F)$  is a tree with node set  $I$  and edge set  $F$ , and  $\chi = \{\chi_i : i \in I\}$  is a family of subsets of  $V$ , one for each node of  $T$ , such that:

1.  $\bigcup_{i \in I} \chi_i = V$ ,
2. for every edge  $(v, w) \in E$ , there is an  $i \in I$  with  $v \in \chi_i$  and  $w \in \chi_i$ , and
3. for all  $i, j, k \in I$ , if  $j$  is on the path from  $i$  to  $k$  in  $T$ , then  $\chi_i \cap \chi_k \subseteq \chi_j$ .

The width of a tree decomposition is  $\max_{i \in I} |\chi_i| - 1$ . The treewidth of a graph  $G$ , denoted by  $tw(G)$ , is the minimum width over all possible tree decompositions of  $G$ .

Figure 64.2 shows a graph  $G$  and a possible tree decomposition of  $G$ . The width of shown tree decomposition is 3.

For the given graph  $G$ , the treewidth can be found from its triangulation. In the following, we will give basic definitions, explain how the triangulation of graph can be constructed, and give lemmas which give relation between the treewidth and the triangulated graph.

Two vertices  $u$  and  $v$  of graph  $G(V, E)$  are neighbors, if they are connected by an edge  $e \in E$ . The neighborhood of a vertex  $v$  is defined as  $N(v) := \{w | w \in V, (v, w) \in E\}$ . A set of vertices is clique if they are fully connected. An edge connecting two nonadjacent vertices in the cycle is called chord. The graph is triangulated if there exists a chord in every cycle of length larger than 3.

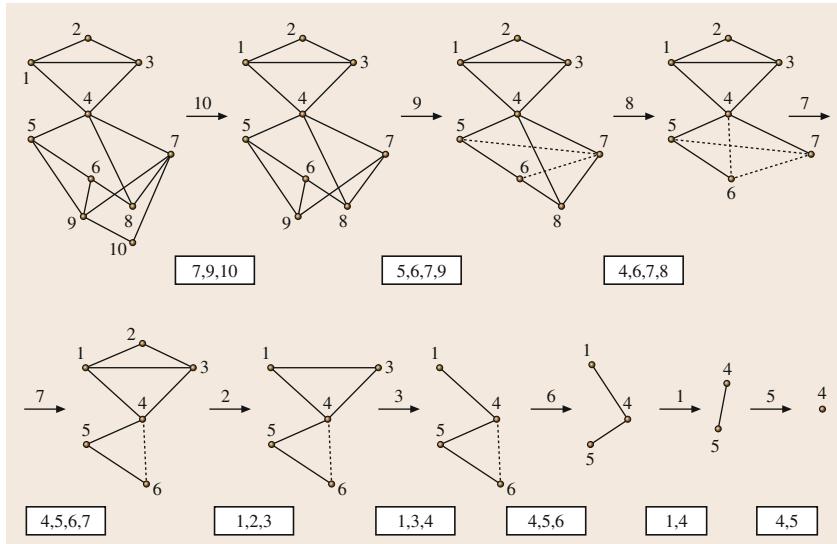

A vertex of a graph is simplicial if its neighbors form a clique. An ordering of nodes  $\sigma(1, 2, \dots, n)$  of  $V$  is called a perfect elimination ordering for  $G$  if for any  $i \in \{1, 2, \dots, n\}$ ,  $\sigma(i)$  is a simplicial vertex in  $G[\sigma(i), \dots, \sigma(n)]$  [64.16]. In [64.17] it is proved that the graph  $G$  is triangulated if and only if it has a perfect elimination ordering. Given an elimination ordering of nodes the triangulation  $H$  of graph  $G$  can be constructed as following. Initially  $H = G$ , then in the process of elimination of vertices, the next vertex in order to be eliminated is made simplicial vertex by adding of new

edges to connect all its neighbors in current  $G$  and  $H$ . The vertex is then eliminated from  $G$ . This process is repeated for all vertices in the ordering.

The treewidth of a triangulated graph can be calculated based on its cliques. For the given triangulated graph, the treewidth is equal to its largest clique minus 1 [64.18]. Moreover, the largest clique of a triangulated graph can be calculated in polynomial time. The complexity of calculating the largest clique for the triangulated graphs is  $O(|V| + |E|)$  [64.18]. For every graph  $G = (V, E)$ , there exists a triangulation of  $G$ ,  $\bar{G} = (V, E \cup E_t)$ , with  $tw(\bar{G}) = tw(G)$ . Thus, finding the treewidth of a graph  $G$  is equivalent to finding a triangulation  $\bar{G}$  of  $G$  with the minimum clique size (for more information see [64.15]).

The process of elimination of nodes from the given graph  $G$  is illustrated in Fig. 64.3. Suppose that we have given the following elimination ordering: 10, 9, 8, 7, 2, 3, 6, 1, 5, 4. The vertex 10 is first eliminated from  $G$ . When this vertex is eliminated no new edges are added to the graph  $G$  and  $H$  (graph  $H$  is not shown in the figure), as all neighbors of node 10 are connected. From the remained graph  $G$  the vertex 9 is eliminated. To connect all neighbors of vertex 9, two new edges are added in  $G$  and  $H$  (edges (5, 7) and (6, 7)). The process of elimination continues until the triangulation  $H$  is obtained. A more detailed description of the algorithm for constructing a graph's triangulation for a given elimination ordering is found in [64.15].

For generating the tree decomposition during the vertex elimination process, first the nodes of the tree decomposition are created. This is illustrated in Fig. 64.3. When vertex 10 is eliminated a new tree decomposition node is created. This node contains the vertex 10 and all other vertices which are connected with this vertex in the current graph  $G$ . Further, the next tree node with vertices  $\{5, 6, 7, 9\}$  is created when the vertex 9 is eliminated. To the end of elimination process all tree decomposition nodes will be created. The created tree nodes should be connected, such that the connectedness condition for vertices is fulfilled. This is the third condition in the tree decomposition definition. To fulfil this condition, the tree decomposition nodes are connected as following. The tree decomposition node with vertices  $\{7, 9, 10\}$  that is created when vertex 10 is eliminated, is connected with the tree decomposition node which will be created when the next vertex which appears in  $\{7, 9, 10\}$  is eliminated. In this case, the node  $\{7, 9, 10\}$  should be connected with the node created when vertex 9 is eliminated, because this is the next vertex in the ordering that is contained in

**Fig. 64.3** Elimination of vertices 10, 9, 8, 7, 2, 3, 6, 1, 5, 4. When a vertex is eliminated a tree node containing eliminated vertex and its neighbors is created

$\{7, 9, 10\}$ . This rule is further applied for connection of other tree decomposition nodes, and from the graph the tree decomposition in Fig. 64.2 will be constructed. Note that some of tree nodes that are created in the elimination process are not presented in the tree decomposition, because they are contained in larger tree

nodes. For example, the node  $\{4, 5, 6\}$  which is created by eliminating vertex 6 is already contained in the node  $\{4, 5, 6, 7\}$  which is created by eliminating vertex 7. Moreover, tree nodes which are created by eliminating vertices 1, 5, 4 are also contained in other larger tree nodes.

## 64.2 Generating Tree Decompositions by Metaheuristic Techniques

As described in the previous section, the width of the tree decomposition depends on the elimination ordering of vertices. Therefore, the task of finding tree decomposition with minimal width consists of finding the best permutation of graph vertices. This problem is similar to the traveling salesman problem, but with a different objective function.

In the last two decades, researchers have been proposing different techniques to find tree decompositions for different benchmark examples. This includes the exact techniques based on tree search and branch and bound, the simple greedy techniques and metaheuristic techniques. In this chapter, we focus on metaheuristic techniques. At the end of this section, we will also shortly describe other approaches used for tree decompositions.

The metaheuristic techniques applied for tree decomposition can be divided in two groups: population based/nature inspired techniques, and local search techniques. Regarding nature inspired techniques the ap-

plication of genetic algorithms has been investigated in [64.19, 20], and ACO has been used in [64.21]. Examples of local search techniques for tree decompositions are [64.16, 22, 23].

### 64.2.1 Genetic Algorithms for Tree Decomposition

Application of genetic algorithm for tree decompositions has been first investigated in [64.19]. This algorithm tried to minimize a weight associated with the decompositions of Bayesian networks which is not exactly the same as the width of the tree decomposition. In [64.20], this algorithm has been extended for generating hypertree decompositions and with some changes in fitness function (the width of tree decompositions has been used as a objective function) has been tested on different problems from the literature. The following description of genetic algorithm for tree decomposition is based on our previous work in [64.20].

*Genetic algorithms* (**GAs**) were developed by [64.3]. They try to find a good solution for an optimization problem by imitating the principle of evolution. Genetic algorithms alter and select individuals from a population of solutions for the optimization problem. In the following, we describe frequently used terms within the field of genetic algorithms:

*Population* ... set of candidate solutions.

*Individual* ... a single candidate solution.

*Chromosome* ... set of parameters determining the properties of a solution.

*Gene* ... single parameter.

A genetic algorithm tends to optimize the value of an objective function of an optimization problem, in terms of genetic algorithms also called *fitness function*. At the beginning a genetic algorithm creates an initial population containing randomly or heuristically created individuals. These individuals are evaluated and assigned a *fitness* value, which is the value of the fitness function for the solution represented by the individual. The population is evolved over a number of generations until a halting criterion is satisfied. At each generation, the population undergoes *selection* and *recombination*, also called *crossover* and *mutation*.

During the selection process, the genetic algorithm decides which individuals from the current population are allowed to enter the next population. This decision is based on the fitness value of the individuals and individuals of better fitness should enter the next population with higher probability than individuals of lower fitness. Not selected individuals are discarded and will not be evolved further.

The recombination process or crossover combines different properties of several parent solutions within one or more children solutions, also denoted as *offspring*. Crossover exchanges properties between the individuals with the aim of increasing the average quality of the population.

During the mutation process, individuals are slightly altered. Mutation is used to explore new regions of the search space and to avoid early convergence to local optima.

In practice, parameters are used in order to control the behavior of a genetic algorithm. Typical *control parameters* are mutation rate, crossover rate, population size, and parameters for selection techniques. The choice of the control parameters has a crucial effect on the quality of the best solution found by a genetic algorithm.

The genetic algorithm for tree decomposition presented below is named *GA-tw* and was implemented

in [64.20]. Algorithm 64.1 presents algorithm *GA-tw* in pseudo code notation.

The algorithm takes as input a graph and several control parameters. Individual solutions are vertex orderings. Each individual is assigned the width of the tree decomposition returned from the corresponding vertex ordering as its fitness value.

Initially *GA-tw* generates a population consisting of randomly created individuals. Tournament selection was chosen as the selection technique. Tournament selection selects an individual by randomly choosing a group of several individuals from the former population. The individual of highest fitness (smallest width) within this group is selected to join the next population. This process is applied until enough individuals have entered the next population. Finally, after a certain number of generations, algorithm *GA-tw* will return the best fitness (smallest width) of an individual found during the search process.

### Crossover and Mutation Operators

Within the genetic algorithms in [64.20] nearly all types of crossover operators and all mutation operators were implemented. The same operators were also applied in [64.19] for decomposing the moral graph of Bayesian networks.

#### Algorithm 64.1 Genetic Algorithm for Tree Decompositions – *GA-tw*

```

Input: a graph  $G = (V, E)$ 
        control parameters for the GA  $n, p_m, p_c, s$ 
        and max_iterations
Output: an upper bound on the treewidth
        of the graph
 $t = 0$ 
initialize  $(population(t), n)$ 
evaluate  $population(t)$ 
while  $t < max\_iterations$  do
     $t = t + 1$ 
     $population(t) = tournament\_selection$ 
     $(population(t - 1), s)$ 
    recombine  $(population(t), p_c)$ 
    mutate  $(population(t), p_m)$ 
    evaluate  $population(t)$ 
end while
return the smallest width found during the search

```

### Crossover Operators

- Partially mapped crossover (**PMX**)
- Cycle crossover (**CX**)

- Order crossover (**OX1**)
- Order-based crossover (**OX2**)
- Position-based crossover (**POS**)
- Alternating-position crossover (**AP**).

### Mutation Operators

- Displacement mutation operator (**DM**)
- Exchange mutation operator (**EM**)
- Insertion mutation operator (**ISM**)
- Simple-inversion mutation operator (**SIM**)
- Inversion mutation operator (**IVM**)
- Scramble mutation operator (**SM**).

We will describe the crossover and mutation operators which returned the best results of algorithm *GA-tw* in more detail.

#### Order Crossover (**OX1**)

The order crossover operator determines a crossover area within the parents by randomly selecting two positions within the ordering. The elements in the crossover area of the first parent are copied to the offspring. Starting at the end of the crossover area all elements outside the area are inserted in the same order in which they occur in the second parent.

#### Order-Based Crossover (**OX2**)

The order-based crossover operator selects at random several positions in the parent orderings by tossing a coin for each position. The elements of the first parent at these positions are deleted in the second parent. Afterward they are reinserted in the order of the second parent.

#### Position-Based Crossover (**POS**)

The position-based crossover operator also starts with selecting a random set of positions in the parent strings by tossing a coin for each position. The elements at the selected positions are exchanged between the parents in order to create the offsprings. The elements missing after the exchange are reinserted in the order of the second parent.

#### Exchange Mutation Operator (**EM**)

The exchange mutation operator randomly selects two elements in the solution and exchanges them.

#### Insertion Mutation Operator (**ISM**)

The insertion mutation operator randomly chooses an element in the solution and moves it to a randomly selected position (Fig. 64.5).

The genetic algorithm implemented in [64.19] was applied to two artificial graphs. This genetic approach returned competitive results when compared to results obtained by simulated annealing [64.22]. The algorithm implemented in [64.20] was evaluated on 62 graphs of the second DIMACS graph coloring challenge [64.24]. Different experiments were performed to find the best parameter values for parameters of the genetic algorithm and it turned out that the position-based crossover operator(**POS**) and the insertion mutation operator(**ISM**) were best suited for finding tree decompositions of small width. Existing upper bounds for treewidth for several DIMACS instances could be improved.

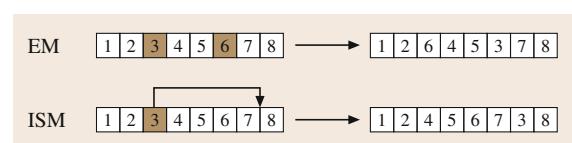

#### 64.2.2 Ant Colony Optimization for Tree Decomposition

*Ant colony optimization* (**ACO**) has been applied for tree decompositions in [64.21, 25]. The current section is based on [64.21] and describes different ant colony optimization variants applied for tree decomposition.

**ACO** is a population-based metaheuristic introduced by Dorigo et al. [64.7, 8]. As the name suggests, the technique was inspired by the behavior of *real* ants. Ant colonies are able to find the shortest path between their nest and a food source just by depositing and reacting to pheromones while they are exploring their environment. The basic principles driving this system can also be applied to many combina-

|     | Parents                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | Offsprings |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |   |  |

torial optimization problems. For a detailed description of different ACO algorithms and their applications the reader is referred to the book *ant colony optimization* [64.26].

The following variants of ACO algorithms for finding good upper bounds for tree decompositions were investigated in [64.21, 25]: simple ant system [64.7, 8], elitist ant system [64.7, 8], rank-based ant system [64.27], max-min ant system [64.28, 29], and ant colony system [64.30]. Two different pheromone update strategies were proposed and two stagnation measures were implemented that indicate the degree of diversity of the solutions constructed by the ants. Furthermore, two constructive heuristics (Min-Degree, Min-Fill) were implemented and incorporated alternatively into every ACO variant as a guiding function, and the combination of ACO with two existing local search methods: Hill Climbing and Iterated Local Search [64.23] were investigated.

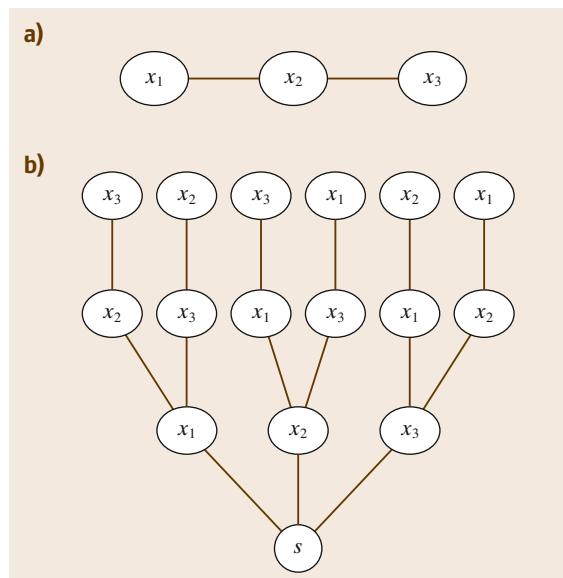

A simple constraint graph and the corresponding ACO construction tree are shown in Fig. 64.6. The construction tree can be obtained from the constraint graph as follows:

1. Create a root node  $s$  that will be the starting point of every ant in the colony.
2. For every vertex of the constraint graph append a child node to the root node  $s$ .
3. To every leaf node append a child node for every vertex of the constraint graph that is neither represented by the leaf node itself nor by an ancestor of this node.
4. Repeat step 3 until there are no nodes left to append.

All possible elimination orderings for the constraint graph can now be represented as a path from the root node  $s$  to one of the leaf nodes in the construction tree. Therefore, each of the ants finds such a path and at each node on its way the ant decides where to move next probabilistically based on the pheromone trails and a heuristic value both associated with the outgoing edges.

### Pheromone Trails

A pheromone trail gives information how favorable it is to eliminate a certain vertex  $x$  after another vertex  $y$ . The more pheromone is located on a trail the more likely the corresponding vertex will be chosen by the ant. A way to represent the pheromone trails of the construction tree in Fig. 64.6 is the matrix as shown in the

**Fig. 64.6a,b** Constraint graph  $G$  and the ACO construction tree

following,

$$\mathcal{T} = \begin{pmatrix} \tau_{x_1 x_1} & \tau_{x_1 x_2} & \tau_{x_1 x_3} \\ \tau_{x_2 x_1} & \tau_{x_2 x_2} & \tau_{x_2 x_3} \\ \tau_{x_3 x_1} & \tau_{x_3 x_2} & \tau_{x_3 x_3} \\ \tau_{s x_1} & \tau_{s x_2} & \tau_{s x_3} \end{pmatrix}. \quad (64.1)$$

In this matrix, each row contains the amounts of pheromone located on the trails connecting a certain node with all the other nodes. For example, the first row contains the pheromone levels related to the node  $x_1$  describing the desirability of eliminating  $x_2(\tau_{x_1 x_2})$ , respectively,  $x_3(\tau_{x_1 x_3})$  immediately after  $x_1$ . The last row is related to the root node  $s$  that is the starting point for every ant.

All pheromone trails are initialized to the same value in the beginning of the algorithm that is computed according to the following equation,

$$\tau_{ij} = \frac{m}{W_\eta}, \quad \forall \tau_{ij} \in \mathcal{T}. \quad (64.2)$$

where  $W_\eta$  is the width of the decomposition obtained using the guiding heuristic (min-degree or min-fill) while  $m$  is the size of the ant colony.

### Heuristic Information

The ants make their decision about which vertex to eliminate next not solely based on the pheromone ma-

trix but also consider a guiding heuristic. Two different heuristics have been implemented. In order to compute them, a separate graph in addition to the construction tree is maintained. This graph is called the *elimination graph* because it is obtained from the original constraint graph by successively eliminating the vertices traversed by the ant in the construction tree. Further, this graph is denoted as  $E(\mathcal{G}, \sigma)$  where  $\mathcal{G}$  is the original constraint graph and  $\sigma$  is a partial elimination ordering.

**Min-Degree.** The value for the min-degree heuristic is computed according to this equation

$$\eta_{ij} = \frac{1}{d(j, E(\mathcal{G}, \sigma)) + 1}. \quad (64.3)$$

The node  $i$  represents the last eliminated node, whereas  $j$  is a node which is not eliminated yet. The expression  $d(j, E(\mathcal{G}, \sigma))$  represents the degree of vertex  $j$  in the elimination graph  $E(\mathcal{G}, \sigma)$ .

**Min-Fill.** The value for the min-fill heuristic is computed according to this equation

$$\eta_{ij} = \frac{1}{f(j, E(\mathcal{G}, \sigma)) + 1}. \quad (64.4)$$

The expression  $f(j, E(\mathcal{G}, \sigma))$  represents the number of edges that would be added to the elimination graph due to the elimination of vertex  $j$ .

### Probabilistic Vertex Elimination

In the following it is shown how exactly the ants move from node to node on the construction tree. All of the ACO variants with the exception of ant colony system use (64.5) alone to compute the probability  $p_{ij}$  of moving from a node  $i$  to another node  $j$  where  $\alpha$  and  $\beta$  are parameters that can be passed to the algorithm in order to weight the pheromone trails and the heuristic values

$$p_{ij} = \frac{[\tau_{ij}]^\alpha [\eta_{ij}]^\beta}{\sum_{l \in E(\mathcal{G}, \sigma)} [\tau_{il}]^\alpha [\eta_{il}]^\beta}, \quad \text{if } j \in E(\mathcal{G}, \sigma). \quad (64.5)$$

This probability is computed for each vertex left in the elimination graph. According to these probabilities, the ant decides which vertex to eliminate next.

Ant colony system introduces an additional parameter  $q_0$  that constitutes the probability that the ant

makes a greedy move instead of making a probabilistic decision

$$j = \begin{cases} \arg \max_{l \in E(\mathcal{G}, \sigma)} \{[\tau_{il}]^\alpha [\eta_{il}]^\beta\}, & \text{if } q \leq q_0; \\ (64.5), & \text{otherwise.} \end{cases} \quad (64.6)$$

If a randomly generated number  $q$  in the interval of  $[0, 1]$  is less or equal  $q_0$  then the ant moves to the node that otherwise would have the highest probability to be chosen. Ties are broken randomly.

Ant colony system also introduces a so-called local pheromone update. After an ant has constructed its solution it removes pheromone from the trails belonging to its solution according to the following equation whereas  $\xi$  is a variant-specific parameter and  $\tau_0$  is the initial amount of pheromone

$$\tau_{ij} \leftarrow (1 - \xi)\tau_{ij} + \xi\tau_0. \quad (64.7)$$

The motivation is to diversify the search so that subsequent ants will more likely choose other branches of the construction tree.

### Pheromone Update

After each of the ants has constructed an elimination ordering (that optionally has been improved by a local search thereafter) the values in the pheromone matrix are updated reflecting the quality of the constructed solutions which will enable the subsequent ants in the following iteration to make decisions in a more informed manner. Moreover, pheromone is gradually removed from the pheromone trails so that solutions that might have been the best known solutions in earlier iterations of the algorithm can be forgotten.

### Pheromone Deposition

In this step for an elimination ordering  $\sigma_k$  that was constructed by an ant  $k$  the amount of pheromone that will be deposited for each  $(i, j)$  in  $\sigma_k$  is determined. An edge-independent and an edge-specific pheromone update strategy were considered. The first adds the same amount of pheromone to all trails belonging to  $\sigma_k$  while the latter adds more or less pheromone to individual trails depending on the quality of a certain elimination.

The edge-independent pheromone update strategy adds the reciprocal value of the tree decomposition's

width to all pheromone trails that are part of  $\sigma_k$

$$\Delta\tau_{ij}^k = \begin{cases} \frac{1}{W(\sigma_k)}, & \text{if } (i,j) \text{ belongs to } \sigma_k; \\ 0, & \text{otherwise.} \end{cases} \quad (64.8)$$

In contrast to the edge-independent update strategy the edge-specific update strategy deposits different amounts of pheromone onto the trails belonging to the same elimination ordering

$$\Delta\tau_{ij}^k = \begin{cases} \frac{1}{d(j, E(G, \sigma_{kj})) / |E(G, \sigma_{kj})|} \cdot \frac{1}{W(\sigma_k)}, & \text{if } (i,j) \text{ belongs to } \sigma_k; \\ 0, & \text{otherwise.} \end{cases} \quad (64.9)$$

This amount depends on the ratio between the degree of the vertex  $j$  when it was eliminated  $d(j, E(G, \sigma_{kj}))$  and the number of vertices left in the elimination graph  $|E(G, \sigma_{kj})|$  at that time ( $\sigma_{kj}$  is the partial elimination ordering that is obtained from  $\sigma_k$  by omitting  $j$  and all vertices that are eliminated after  $j$ ).

The selection of ants that deposit pheromone and the weighting of this pheromone varies between the different ACO variants. The reader is referred to [64.26] for description of these variants.

### Pheromone Evaporation

After the pheromone has been added to the trails, a certain amount of pheromone is removed. This amount is determined based on the pheromone evaporation rate  $\rho$

$$\tau_{ij} = (1 - \rho)\tau_{ij}, \quad \forall \tau_{ij} \in \mathcal{T}. \quad (64.10)$$

Ant colony system only removes pheromone from the trails belonging to the best known elimination ordering  $\sigma_{bs}$

$$\tau_{ij} = (1 - \rho)\tau_{ij}, \quad \forall (i,j) \in \sigma_{bs}. \quad (64.11)$$

### Hybridization with Local Search

All ACO variants were extended with two local search methods for tree decompositions. Both of these algorithms try to improve the quality of the solutions that were constructed by the ant colony by changing the positions of certain vertices in the elimination orderings. Two local search techniques were used: an hill climbing algorithm and an iterated local search similar to the algorithm proposed in [64.23].

### Stagnation Measures

If the distribution of the pheromone on the trails becomes too unbalanced due to the pheromone depositions, the ants will generate very similar solutions causing the search to stagnate. In order to enable the algorithm to detect such situations two stagnation measures were implemented (variation coefficient and  $\bar{\lambda}$  branching factor) proposed by Dorigo and Stützle [64.26] that indicate how explorative the search behavior of the ants is. A detailed description of stagnation measures is given in [64.25, page 67].

All described ACO variants in [64.21] were evaluated experimentally with DIMACS Graph Coloring Challenge instances. Max-Min ant system and ant colony system performed slightly better than the other variants. Although the ant colony optimization in general could not compete with iterated local search and genetic algorithms, it could improve the upper bound for one of problems.

### 64.2.3 Iterated Local Search for Tree Decomposition

The application of iterated local search for generating tree decompositions has been investigated in [64.23, 31]. In this section, we give the description of this algorithm based on these references.

The algorithm is based on the iterated local search framework and it includes a simple local search heuristic to generate good orderings, and an iterative process in which the algorithm calls a local search technique with the initial solution produced in the previous iteration. The algorithm also includes a mechanism for acceptance of a candidate solution for the next iteration. Although the constructing phase is very important, choosing the appropriate perturbation at each iteration as well as the mechanism for acceptance of solution are also crucial to obtain good results for an iterative local search algorithm. The iterated local search algorithm for tree decomposition is presented below.

#### Algorithm 64.2 Iterative Heuristic Algorithm – IHA

```

Generate initial solution S1
BestSolution = S1
while Termination Criteria is not fulfilled do
    S2 = ConstructionPhase(S1)
    if Solution S2 fulfils the acceptance criteria then
        S1 = S2
    else
        S1 = BestSolution
    end if

```

```

    Apply perturbation in solution S1
    Update BestSolution if solution S2 has better
        (or equal) width than the current best solution
end while
return BestSolution

```

The algorithm starts with an initial solution which takes an order of nodes as they appear in the input. Better initial solutions can also be constructed by using other heuristics which run in polynomial time, such as maximum cardinality search, min-fill heuristic, etc. However, as the proposed method usually finds a solution produced by these heuristics in a very short time, the algorithm starts with an ordering of nodes given in the input.

After constructing the initial solution the iterative phase starts. In this phase, the local search method is called iteratively, and then the selected solution is perturbed. Two different local search techniques that can be used in the construction phase were proposed. The solution returned from the construction phase is accepted for the next iteration if it fulfils the specific criteria determined by the solution acceptance mechanism. Experiments with different possibilities for the acceptance of the solution returned from the construction phase were performed. If the solution does not fulfil the acceptance criteria this solution is discarded and the currently best solution is selected. In the selected solution, the perturbation mechanism is applied. Different possibilities are used for perturbation. The perturbed solution is given as an input solution in the next call of the construction phase. This process continues until the termination criterion is fulfilled.

Two local search methods were proposed for generating a good solution which is used as an initial solution with some perturbation in the next call of the same local search algorithm. Both techniques are based on the idea of moving only vertices in the ordering which cause the largest clique during the elimination process. The motivation for using this method is to reduce the number of solutions that should be evaluated. The first proposed technique named **LS1** is presented below.

#### **Algorithm 64.3 Local Search Algorithm 1 – LS1 (InputSolution)**

```

BestLSSolution = InputSolution
NrNotImprovements = 0
while NrNotImprovements < MAXNotImprovements
    do

```

In the current solution (*InputSolution*) select a vertex in the elimination ordering which causes the

largest clique when eliminated – ties are broken randomly if there are several vertices which cause the clique equal with the largest clique

Swap this vertex with another vertex located in a randomly chosen position

**if** the current solution is better than *BestLSSolution* **then**

```
    BestLSSolution = InputSolution
```

```
    NrNotImprovements = 0
```

**else**

```
    NrNotImprovements = NrNotImprovements + 1
```

**end if**

**end while**

**return** *BestLSSolution*

The proposed algorithm applies a simple heuristic. In the current solution a vertex is chosen randomly among the vertices that produce the largest clique in the elimination process. Then the selected vertex is moved from its position. Two types of moves were used. In the first variant, the vertex is inserted in a random position in the elimination ordering, while in the second variant the vertex is swapped with another vertex located in a randomly selected position, i.e., the two chosen vertices change their position in the elimination ordering. The swap move was shown to give better results. The heuristic stops if the solution does not improve for a certain number of iterations. Experiments with different *MAXNotImprovements* were performed. **LS1** alone is a simple heuristic and usually cannot produce good results for tree decompositions. However, by using this heuristic as a local search heuristic in the iterated local search algorithm good results for tree decompositions are obtained.

The second proposed heuristic (**LS2**) is similar to algorithm **LS1**. However, this technique differs from **LS1** regarding the exploration of the neighborhood. In **LS2** in some of iterations the neighborhood of solution consists of only one solution which is generated by swapping a vertex (that causes the largest clique) in the elimination ordering with another vertex located in the randomly chosen position. This neighborhood is used in a particular iteration with probability  $p$ . Experiments with different values for parameter  $p$  were performed. With probability  $1 - p$ , the other type of neighborhood will be explored. The neighborhood of current solution in this case consists of all solutions which can be obtained by swapping of a vertex (which causes the largest clique) in the elimination ordering with its neighbors. The best solution from the generated neighborhood is selected for the next iteration in the **LS2**. Note that

in this technique the number of solutions that have to be evaluated is much larger than in LS1. In particular, in the first phase of search the node which causes the largest clique usually has many neighbors and therefore the number of solutions to be evaluated when the second type of neighborhood is used is equal to the size of the largest clique produced during the elimination process.

### Perturbation

During the perturbation phase the solution obtained by local search procedure is perturbed and the newly obtained solution is used as an initial solution for the new call of the local search technique. The main idea is to avoid the random restart. Instead of random restart the solution is perturbed with a bigger move(s) as those applied in the local search technique. This enables some diversification that helps to escape from the local optimum, but avoids beginning from scratch (as in the case of random restart), which is very time consuming. Three perturbation mechanisms were proposed:

- *RandPert*:  $N$  vertices are chosen randomly and they are moved into new random positions in the ordering.
- *MaxCliquePer*: All nodes that produce the maximal clique in the elimination ordering are inserted in a new randomly chosen positions in the ordering.
- *DestroyPartPert*: All nodes between two positions (selected randomly) in the ordering are inserted in the new randomly chosen positions in the ordering.

The perturbation RandPert just perturbs the solution with a larger random move and would be kind or random restart if  $N$  is very large. Keeping  $N$  smaller avoids restarting from completely new solution, and the perturbed solution does not differ much from the previous solution. MaxCliquePer concentrates on moving only vertices which produce maximal clique in the elimination ordering. The basic idea for this perturbation is to apply a technique similar to min-conflict heuristic, by moving only the vertices that cause large treewidth. DestroyPartPert is similar to RandPert, except that the selected nodes to be moved are located near each other in the elimination ordering.

Determining the number of nodes  $N$  that will be moved is complex and may be dependent on the prob-

lem. To avoid this problem an adaptive perturbation mechanism was proposed that takes into consideration the feedback from the search process. The number of nodes  $N$  varies from 2 to some number  $y$  (determined experimentally), and the algorithm begins with small perturbation ( $N = 2$ ). If during the iterative process (for a determined number of iterations) the local search technique produces solutions with same tree width for more than 20% of cases, the size of perturbation is increased by 1, otherwise the size of  $N$  will be decreased by 1. This enables an automatic change of perturbation size based on the repetition of solutions with the same width.

The combination of two perturbations was considered. The mixed perturbation applies two perturbations: RandPert and MaxCliquePer. The algorithm starts with RandPert, and switches alternatively between two perturbations if the solution is not improved for a determined number of iterations. Experiments with different sizes of perturbation sizes for each type of perturbation were performed.

### Acceptance Criterion

Different techniques can be applied for accepting the solution obtained by the local search technique. Following variants for acceptance of solution for the next iteration were used:

- Solution returned from the construction phase is accepted only if it has a better width than the best current existing solution.
- Solution returned from the construction phase is always accepted.
- Solution is accepted if its treewidth is smaller than the treewidth of the best yet found solution plus  $x$ , where  $x$  is an integer.

The first variant for accepting a solution is very restrictive. In this variant, the solution from the construction phase is accepted only if it improves the best existing solution. Otherwise, the best existing solution is perturbed and it is used as input solution for next call of the construction phase. In the second variant, the iterated local search applies the perturbation in a solution returned from the construction phase, independently from the quality of produced solution. The third variant is between the first and the second variant, and in this case the solution which does not improve the best existing solution can be accepted for the next iteration, if its width is smaller than the best found width plus some bound.

#### 64.2.4 Other Techniques for Tree Decomposition

This section gives a short overview on other approaches applied for tree decomposition. Examples of complete algorithms for tree decompositions are [64.32–34]. *Gogate and Dechter* [64.33] reported good results for tree decompositions by using branch and bound algorithms. They showed that their algorithm is superior compared to the algorithm proposed in [64.32]. The branch and bound algorithm proposed in [64.33] applies different pruning techniques, and provides anytime solutions, which are good upper bounds for tree decompositions. The algorithm proposed in [64.34] includes several other pruning and reduction rules and is successful on small graphs. The complete techniques described earlier have exponential running time in the worst case and can only be used to find the optimal width for not too large graphs.

To generate good upper bounds (which can be sufficient for many applications) for treewidth several greedy heuristic techniques that run in polynomial time have been proposed. These heuristics select the ordering of nodes step by step based on different criteria, such as the degree of the nodes, the number of edges to be added to make the node simplicial etc. Most popular techniques are maximum cardinality search (**MCS**), min-fill heuristic and minimum degree heuristic.

**MCS** [64.35] initially selects a random vertex of the graph to be the first vertex in the elimination ordering (the elimination ordering is constructed from right to left). The next vertex will be picked such that it has the highest connectivity with the vertices previously selected in the elimination ordering. Ties are broken randomly. **MCS** repeats this process iteratively until all vertices are selected.

The min-fill heuristic first picks the vertex which adds the smallest number of edges when eliminated (ties are broken randomly). The selected vertex is made simplicial (a vertex of a graph is simplicial if its neighbors form a clique) and it is eliminated from the graph. The next vertex in the ordering will be any vertex that adds the minimum number of edges when eliminated from the graph. This process is repeated iteratively until the whole elimination ordering is constructed.

The minimum degree heuristic picks first the vertex with the minimum degree. The selected vertex is made simplicial and it is removed from the graph. Further, the vertex that has the minimum number of unselected neighbors will be chosen as the next node in the elimination ordering. This process is repeated iteratively.

**MCS**, min-fill, and min-degree heuristics run in polynomial time and usually produce tree decompositions in a reasonable amount of time. According to [64.33], the min-fill heuristic performs better than **MCS** and min-degree heuristic. Although these heuristics sometimes give good upper bounds for tree decompositions, more advanced techniques usually provide better upper bounds for most problems. Min-degree heuristic has been improved by *Claudiaux et al.* [64.16] by adding a new criterion based on the lower bound of the treewidth for the graph obtained when the node is eliminated. Recently, *Kask et al.* [64.36] proposed an iterative greedy variable ordering algorithm to improve the greedy heuristics given earlier. We refer to [64.15, 37] for a survey of different upper bounds algorithms.

#### 64.2.5 Comparison of Algorithms for Tree Decomposition

In this section, we compare results obtained with metaheuristic approaches described in this chapter and other existing methods in the literature. The results of these methods for 62 DIMACS vertex coloring instances are given. These instances have been used for testing several methods for tree decompositions proposed in the literature. The compared methods have been executed in different computers and we give here only results regarding the width of the tree decomposition. The reader is referred to [64.15, 16, 20, 23, 25, 33], for the information about the computers used and the time needed to generate solutions.

In Tables 64.1 and 64.2, the results for DIMACS graph coloring instances are presented. First and second columns of the tables present the instances and the number of nodes and edges for each instance. In column KBH are shown the best results obtained by algorithms in [64.15]. The TabuS column presents the results reported in [64.16], and column BB shows the results obtained with the branch and bound algorithm proposed in [64.33]. Finally, columns **GA**, **IHA**, and **ACO** represent, respectively, results obtained with a genetic algorithm [64.20], iterated local search [64.23], and ant colony optimization [64.21, 25].

Based on the results given in Tables 64.1 and 64.2 we conclude that regarding the width of tree decomposition, the metaheuristic techniques described in this paper give very good results and for many instances the best existing upper bounds for the treewidth.

#### 64.2.6 Application of Tree Decomposition in Metaheuristic Techniques

Traditionally, tree decompositions have been used to solve constraint satisfaction problems exactly by dynamic programming algorithms. Recently, researchers have been investigating the incorporation of tree decomposition within metaheuristics techniques. The work in this direction is just in the starting phase and to the best of our knowledge only two papers investigated

yet the application of tree decomposition in metaheuristic search.

In [64.38] tree-decomposition-based heuristics have been developed for the two-dimensional bin packing problem with conflicts. The aim is to find a conflict-free packing of given items by using minimal number of bins. Tree decomposition is applied to decompose a problem instance into subproblems which can be solved independently. First a tree decomposition is obtained, and then each item is assigned to a specific

cluster (this phase is called cluster separation). Then these clusters are considered as subproblems which are solved iteratively. Finally, the partial solutions from subproblems are merged to obtain solutions for the whole problem.

Another application of tree decomposition includes the approach introduced by *Fontaine* et al. [64.39] where tree decomposition is used to guide the explo-

ration for the search space. Authors propose a method called decomposition guided **VNS** (variable neighborhood search) that exploits the graph of clusters to build neighborhood structures. By using clusters better intensification and diversification is achieved. For example, the moves are favored in regions that are closely linked and the search is diversified by selecting new clusters and therefore exploring new regions of the search space.

### 64.3 Conclusion

Several metaheuristic approaches based on nature inspired strategies and local search have been used successfully in the literature for generating tree decompositions. Among these approaches, genetic algorithms and iterated local search-based algorithms provide best upper bounds for many benchmark instances.

Although metaheuristic techniques currently provide state-of-the-art upper bounds for most problems, the runtime of such algorithms for large graphs is still high. Greedy heuristic approaches generate slightly worse upper bounds, but are more efficient. Therefore, developing more efficient metaheuristics for tree de-

compositions is still a challenging task. Moreover, for many problems the treewidth is still not known, and the question is if the current metaheuristics can still be improved to find new upper bounds for such problems. To obtain better upper bounds, it would be interesting to investigate some other approaches such as memetic algorithms, large neighborhood search, and other hybrid techniques. Furthermore, the iterative improvement of the initial generated tree decomposition (based on vertex ordering) is an interesting question.

Finally, in some applications, the treewidth is not the only important parameter for solving problems

based on tree decompositions efficiently. Therefore, the development of metaheuristics for generating tree

decompositions which optimize other features of tree decomposition would be of interest in the future.

# Evolutionary Computation and Constraint Satisfaction

Jano I. van Hemert

In this chapter we will focus on the combination of *evolutionary computation (EC)* techniques and *constraint satisfaction problems (CSPs)*. *Constraint programming (CP)* is another approach to deal with constraint satisfaction problems. In fact, it is an important prelude to the work covered here as it advocates itself as an alternative approach to programming [65.1]. The first step is to formulate a problem as a *CSP* such that techniques from *CP*, *EC*, combinations of the two, often referred to as hybrids [65.2,3], or other approaches can be deployed to solve the problem. The formulation of a problem has an impact on its complexity in terms of effort required to either find a solution or that proof no solution exists. It is, therefore, vital to spend time on getting this right.

*CP* defines search as iterative steps over a search tree where nodes are partial solutions to the problem where not all variables are assigned values. The search then maintains a partial solution that satisfies all variables with assigned values. Instead, in *EC* algorithms sample a space of candidate solutions where for each sample point variables are all assigned values. None of these candidate solutions will satisfy all constraints in the problem until a solution is found. Such algorithms are often classified as Davis–Putnam–Logemann–Loveland (*DPLL*) algorithms, after the first backtracking algorithm for solving *CSP* [65.4].

Another major difference is that many constraint solvers from *CP* are sound, whereas *EC* solvers are not. A solver is sound if it always finds

a solution if it exists. Furthermore, most constraint solvers from *CP* can easily be made complete, although this is often not a desired property for a constraint solver. A constraint solver is complete if it can find every solution to a problem.

## 65.1 Informal Introduction to CSP

For a formal definition please skip to the next section. A constraint satisfaction problem consists of a set of variables and each variable must be assigned one value from its finite set of values, called its domain.

A set of constraints restricts certain simultaneous assignments. In most *CSPs*, the objective is to search for a simultaneous assignment of all the variables such that all constraints are satisfied, i.e., no forbidden si-

multaneous assignment from the set of constraints is used.

A famous example is the SEND MORE MONEY puzzle, where each letter must be replaced by a unique number such that the following sum holds [65.5]

$$\begin{array}{r} \text{S} & \text{E} & \text{N} & \text{D} \\ + & \text{M} & \text{O} & \text{R} & \text{E} \\ = & \text{M} & \text{O} & \text{N} & \text{E} & \text{Y}. \end{array}$$

In this **CSP**, the variables are  $S, E, N, D, M, O, R, Y$  and the domains are  $\{1, \dots, 9\}$  for  $S, M$  and  $\{0, \dots, 9\}$  for  $E, N, D, O, R, Y$ . The constraint can be also written as  $1000 \times S + 100 \times E + 10 \times N + D + 1000 \times M + 100 \times O + 10 \times R + E = 10000 \times M + 1000 \times O + 100 \times N + 10 \times E + Y$ . Every **CSP**  $A$  can be rewritten into another **CSP**  $B$  where a bijective mapping exists between the solutions of  $A$  and  $B$ , which follows

from the reducibility theorem from complexity theory [65.6]. The solution to this **CSP** is the assignment  $S = 9, E = 5, N = 6, D = 7, M = 1, O = 0, R = 8, Y = 2$ , which uniquely satisfies the constraint.

Other very well-known constraint satisfaction problems are map coloring, more commonly known as vertex coloring (Sect. 65.5.2), and the recreational game Sudoku, which is equivalent to completing a graph 9-coloring problem on a given specific graph with 81 vertices. A specific **EC** solution is provided by Lewis [65.7]. Quite a lot of constraint satisfaction problems exist; we will first look at **CSP** in general within the context of **EC** as problem solvers. Then we will discuss several specific constraint satisfaction problems and the particular **EC** approaches applied to these problems. Last, we will provide a brief overview on using **EC** for generating problem instances for **CSP**.

## 65.2 Formal Definitions

Slightly different, but equivalent, formal definitions of **CSP** exist. The most common definition is:

**Definition 65.1 (Constraint Satisfaction Problem)** is a triple  $\langle V, D, C \rangle$ :

- $V$  is an  $n$ -tuple of *variables*  $V = \langle v_1, v_2, \dots, v_n \rangle$ ,
- Each  $v \in V$  has a corresponding  $m$ -tuple of values called its *domains*,  $D_v = \langle d_1, d_2, \dots, d_m \rangle$  of which it can be assigned one and
- $C = \langle C_1, \dots, C_t \rangle$  is a  $t$ -tuple of *constraints* where each  $c \in C$  restricts certain simultaneous variable assignments to occur.

The definition of a constraint is often reversed in the literature, where generic **CSP** is discussed in that constraints are defined as the set of assignments that are *allowed* rather than restricted. Note, in generic **CSP** literature, variables are often denoted with  $X$ , whereas in graph-oriented problem domains such as graph coloring and maximum clique,  $V$  is adopted.

**Definition 65.2 (Solution to a CSP)**

is an assignment of variables  $(d_1, \dots, d_n) \in D_1 \times \dots \times D_n$  such that for every constraint  $c \in C$  on  $x_{i_1}, \dots, x_{i_m}$ :  $(d_{i_1}, \dots, d_{i_m}) \notin c$ .

In the context of one constraint  $c$ , we say an assignment of variables *satisfies* the constraint  $c$  if the

assignment is in  $c$  or *violates* the constraint  $c$  if the assignment is *not* in  $c$ . A **CSP** can be *insoluble* – more commonly written as *insolvable*, which means every assignment of variables will violate at least one constraint.

A *constraint solver* is an algorithm that takes as input a **CSP** and produces as output either a solution or a proof that no solution exists or a notification of failure. The input is often referred to as a *problem instance*, as a **CSP** is often defined to cover a class of problems such as, 3-satisfiability. The output can be more than one solution, in fact it could be every solution. However, as **EC** techniques are based on sampling, in principle they cannot proof that every solution has been found, which is referred to as not complete. Moreover, they cannot proof no solution exists, which is referred to as not sound. Therefore, constraint solvers based on **EC** and other heuristic approaches often terminate after a certain criterion is met, e.g., a predefined elapsed time is reached in terms of the number of solutions evaluated, the computation time spent, or a certain convergence of the population reached.

We recommend the following books for further reading on constraint satisfaction. For the foundations of the problem and basic algorithms, Tsang [65.8]; for an introduction with comprehensive overview of constraint programming techniques, Dechter [65.9] and Lecoutre [65.10]; and for a more theoretical approach Apt [65.1] and Chen [65.11].

## 65.3 Solving CSP with Evolutionary Algorithms

In this chapter we will restrict ourselves to covering the conceptual mapping required to solve a [CSP](#) with an evolutionary algorithm. This mapping will consist of choosing a representation for the problem and a corresponding fitness function to determine the quality of a solution. Once this mapping is complete, the evolutionary algorithm will require other components, such as appropriate variation operators, selection mechanisms, and a suitable initialization method for the population and termination criteria. All these, and other optional variants can be found elsewhere in the handbook.

We will explain the two most common mappings using the well-known  $n$ -queens on an  $n \times n$ -chessboard problem. These mappings are *direct encoding* and *indirect encoding*. First we introduce a conceptual definition of the problem.

The  $n$ -queens problem requires the placing of  $n$  queens on an  $n \times n$  chessboard such that no queen attacks any of the other  $n - 1$  queens. Thus, a solution requires that no two queens share the same row, column, or diagonal. Several common formal definitions of the problem exist. The most common is to define  $n$  variables  $\{q_1, \dots, q_n\}$ , where each variable  $q$  has a domain that consists of the row position the queen will be placed on in its corresponding unique column, i.e.,  $q \in \{1, \dots, n\} \forall i = 1, \dots, n$ . The set of constraints consists of  $q_i \neq q_j$  (i.e., not in the same row) and  $|q_i - q_j| \neq |i - j| \forall i, j = 1, \dots, n$  (i.e., not in the same diagonal).

The  $n$ -queens problem is no longer considered a challenging problem as it has a structure that can be exploited to solve very large problems of over 9 million queens by repeating a pattern [65.12]. It is, however, an excellent problem for explaining characteristics of constraint satisfaction problems and their solvers due to the simple 2-D spatial nature of the problem. For instance, to explain symmetry in [CSP](#), the 8-queens problem can be used to show it has 12 unique solutions, as shown in Fig. 65.1 out of the 92 distinct solutions when removing variants due to rotational and reflection symmetry.

### 65.3.1 Direct Encoding

With a direct encoding the genotype consists of a vector  $\vec{g}$  where each element corresponds uniquely to one variable of the [CSP](#); an element  $g_i$  contains values directly from the domain of its corresponding variable  $D_i$ . A wide variety of genetic operators both for mutation and recombination are applicable to this encoding and

can be found in [65.13]. Most of these operators will be called discrete or mixed-integer operations.

The genotype is mapped to the phenotype by taking into consideration the constraints; it requires a measurement for determining the quality of candidate solutions. Thus, we need to introduce a fitness function. The most common fitness function takes the sum of all constraints violated by a candidate solution

$$\text{fitness}(\vec{g}) = \sum_{c \in C} \text{violated}(c),$$

$$\text{where } \text{violated}(c) = \begin{cases} 1 & \text{if } c \text{ violated by } \vec{g} \\ 0 & \text{if } c \text{ satisfied by } \vec{g} \end{cases}.$$

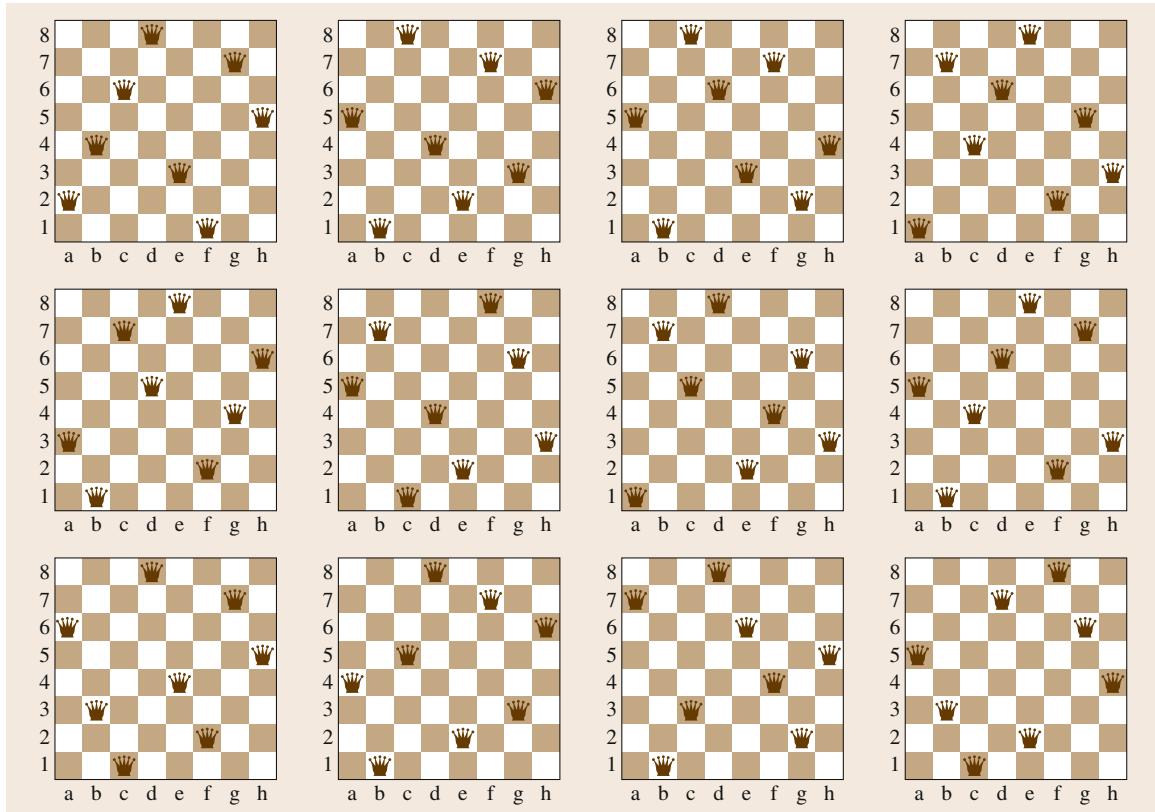

The fitness should be minimized and once it reaches zero, a solution has been found.

### 65.3.2 Indirect Encoding

With an indirect encoding the genotype first needs to be transformed into a full or partial assignment of the variables of the [CSP](#). It is also referred to as local search depending on the level of sophistication; these transformations range from as simple as a greedy assignment all the way to sound search algorithms evaluating a small part of the [CSP](#).

The most common approach for this representation takes as a genotype the permutation of variables of the [CSP](#). Many genetic operators are designed to maintain a permutation and several are explained in the Handbook of Evolutionary Computation [65.13]. The permutation is the input to the local search and determines the order in which variables are processed; processing a variable involves trying to assign a value such that no constraint is violated and perhaps further steps if no value can be assigned without violating at least one constraint.

More advanced encodings may also include the ordering in which to consider values from each variable's domain. From constraint programming we know that the order in which variables and values are considered has a huge impact on the efficiency of search algorithms [65.14]; more often it is the search method that determines the order using a particular heuristics such as choosing the next vertex with the *maximum saturation degree*, as is used in DSatur [65.15]. The saturation degree for a vertex is defined as the total number of colors used for coloring its neighbors. The principle

**Fig. 65.1** The 12 unique solutions under symmetry via rotations and reflections for the 8-queens problem

has been used in many algorithms since its introduction in 1979.

The most common fitness function used with indirect encoding simply counts the number of unassigned variables after the local search terminates. Note that two different strategies will influence the resolution of this function. If the local search terminates after it first encounters a variable it cannot assign, then many candidate solutions will have the same fitness but can still be very different. On the other hand, terminating after all variables have been considered will give a richer landscape to consider but may incur more computational effort. See [65.16] for a comprehensive theoretical and empirical analysis of sampling in **EC**.

### 65.3.3 General Techniques to Improve Performance

Over the past two decades, many techniques were developed to improve the efficiency and/or the effectiveness of **EC** for solving constraint satisfaction problems.

Only a handful of these techniques were evaluated on more than one problem. Hence, we cannot draw any general conclusions about the success of these techniques. Even worse is that many studies will show improvement only compared to their previous results or compare their results with an algorithm that has already been superseded in terms of performance by many other techniques. Often the set of competitor algorithms is chosen to fall within **EC**, which severely limits the strength of the competition. Therefore, we will discuss techniques for improving performance in the context of the problems they were developed for. Section 65.5 reviews several popular **CSPs** used for developing more efficient and effective evolutionary algorithms.

One approach that has been applied to several **CSPs** with varying success is that of assigning weights to constraints to allow biasing the search towards satisfying certain constraints; in the first experiments this approach was referred to as penalty functions [65.17]. Moreover, the search can be influenced dynamically

by adapting weights according to heuristics, such as increasing the weight of the constraint that has been satisfied the least number of times recently [65.18]. The origin of this idea can be found in the self-adaptation used in evolution strategies [65.19].

With penalty functions, the optimization objectives replacing the constraints are traditionally viewed as penalties for constraint violation, hence to be minimized [65.20]. There are two basic types of penalties:

1. Penalty for violated constraints
2. Penalty for wrongly instantiated variables.

Formally, let us assume that we have constraints  $c_i$  ( $i = \{1, \dots, m\}$ ) and variables  $v_j$  ( $j = \{1, \dots, n\}$ ). Let  $C^j$  be the set of constraints involving variable  $v_j$ . Then the penalties relative to the two options described above can be expressed as follows:

$$1. f_1(s) = \sum_{i=1}^m w_i \times \chi(s, c_i), \text{ where}$$

$$\chi(s, c_i) = \begin{cases} 1 & \text{if } s \text{ violates } c_i \\ 0 & \text{otherwise} \end{cases},$$

$$2. f_2(s) = \sum_{j=1}^n w_j \times \chi(s, C^j), \text{ where}$$

$$\chi(s, C^j) = \begin{cases} 1 & \text{if } s \text{ violates at least one } c \in C^j \\ 0 & \text{otherwise,} \end{cases}$$

where the  $w_i$  and  $w_j$  are weights that correspond to a constraint and a variable, respectively. These will be important later on, for now we assume all these weights equal to 1.

Obviously, for each of the above functions  $f \in \{f_1, f_2\}$  and for each  $s \in S$  we have that  $\phi(s) = \text{true}$  if and only if  $f(s) = 0$ . For instance, in the graph 3-coloring problem the vertices of a given graph  $G = (V, E)$ ,  $E \subseteq V \times V$ , have to be colored by three colors in such a way that no neighboring vertices, i. e., graph nodes connected by an edge, have the same color. This problem can be formalized by means of a **CSP** with  $n = |V|$  variables, each with the same domain  $D = \{1, 2, 3\}$ . Furthermore, we have  $m = |E|$  constraints, one for each edge  $e = (k, l) \in E$ , with  $c_e(s) = \text{true}$  if and only if  $s_k \neq s_l$ . Then the corresponding **CSP** is  $\langle S, \phi \rangle$ , where  $S = D^n$  and  $\phi(s) = \bigwedge_{e \in E} c_e$ . Using the constraint-oriented penalty function  $f_1$  with  $w_i = 1$  for all  $i = \{1, \dots, m\}$  we count the incorrect edges that connect two vertices with the same color. The variable-oriented penalty function  $f_2$  with  $w_i = 1$  for all  $i = \{1, \dots, m\}$  amounts to counting the incorrect vertices that have a neighbor with the same color.

Advantages of indirect encoding:

- Introduces in general, e.g.,  $f_1, f_2$  are problem-independent penalty functions
- Reduces problem to *simple* optimization
- Allows user preferences by weights.

Disadvantages of indirect encoding:

- Loss of information by packing everything in a single number
- In the case of constrained optimization (as opposed to **CSP** as we are handling here)  $f_1, f_2$  are reported to be weak [65.21].

## 65.4 Performance Indicators

An understanding of the efficiency and effectiveness is vital when choosing which solver to use or when developing an algorithm to deal with a specific **CSP**. In this section we briefly explain measures for determining these properties in the context of solving **CSP**. However, these properties must be measured using a suite of benchmark instances and, as EAs are generally randomized algorithms, with multiple independent runs of the algorithm on each instance. Choosing an appropriate suite of benchmark instances is paramount to making decisions on which algorithm, parameter setting, or next algorithmic feature to add.

In a sense, the search for a good algorithm is in itself an optimization problem. The suite of benchmark instances represents only the problem, just like training data in a machine learning problem represents all data possibly encountered. Changing an algorithm and tuning its parameters on the same small suite of instances could lead to over-fitting [65.22, 23], which in turn means the algorithm will have a poorer performance in the general case. Therefore, the first step should be to characterize the problem well and have a good representation, e.g., spread, of the instances possibly encountered when deployed.

### 65.4.1 Efficiency

The time taken by an algorithm to provide a solution is an important factor. Even more so in situations where solutions are required in real time. Much research is devoted to speeding up algorithms, either by cleverly exploiting properties of the problem, by parallelization, or by balancing aspects of the quality of the solution.

The most common approach to measuring the efficiency of evolutionary algorithms is by counting the number of evaluations, i.e., the number of times the fitness function is executed. This approach has several drawbacks. First, the approach allows comparison only with algorithms that use the exact same fitness function and spend the most significant part of their time on computing that function. Second, the computational complexity of the evolutionary algorithm may not be dependent on the fitness function. For instance, with the indirect encoding described in Sect. 65.3.2, much computational effort will go into the local search, whereas the computation of the fitness is trivial.

Another common approach is to measure time spent as reported by the operating system. This has even more drawbacks as the reported numbers will depend on the computer programming language used for implementing the algorithm, the compiler and its setting for translating the implementation into machine code, the architecture of the computer for executing the machine code, and the operating system for hosting the execution environment. Variations of these will have an affect on the reported results and, moreover, as these environments themselves change over time, future studies will find it hard to reproduce results accurately or even create meaningful comparisons to reported results.

A more meaningful solution is to count all the atomic operations that are directly related to the problem. The operations that must be included should be those that in theory increase exponentially in numbers with larger problems, as **CSP** fall under the class of non-polynomial deterministic problems. The most common operation will be a *conflict check*; this is also referred to as a constraint check, but in the strictest sense, a constraint check consists of multiple conflict checks [65.8]. For example, when solving the *n*-queens problem, every time the algorithm checks  $q_i \neq q_j$  for any  $q_i$  and  $q_j$ , this should be recorded as one check. The same proce-

dure should be followed for the constraint concerning diagonal attacks  $|q_i - q_j| \neq |i - j|$ . The sum of all checks when the algorithm terminates is the computational effort spent.

By reporting the number of conflict checks we assure future studies can compare with current results as this measurement will not be affected by future changes in hardware and software environments. We are measuring a property of the algorithm here as opposed to a property of one implementation of the algorithm running in one particular environment.

It is important to note that there are subtle differences in the reporting used in different studies. Some studies report the average number of operations over all independent runs, including runs that are unsuccessful, i.e., where no solution was found. Other studies report the average number of operations to a solution, where only the runs that yield a solution are taken into account. The former method will produce higher averages than the latter if the success rate is less than 1.

### 65.4.2 Effectiveness

Efficiency is only one aspect of which to measure the success of a constraint solver. The other most important aspect is that of effectiveness, which measures how successful an algorithm is in finding or approximating a solution. The easiest and most commonly used measurement is that of the *success rate*, which is defined for an experiment as the number of runs in which an algorithm finds a solution divided by the total of number of runs of the same algorithm in that experiment. As no prior knowledge is required about whether problem instances are insolvable, this measurement is straightforward to implement.

Another popular measurement in combinatorial optimization is *distance to the optimal solution*. This measurement poses two challenges in the context of constraint satisfaction. Unlike a combinatorial optimization problem, which has the function to optimize, a **CSP** has no such function. As an alternative we could use the fitness function, but that is not an inherent property of the problem. Also, we often do not know whether a **CSP** has a solution and when it does not, then we do not know the optimal fitness function. Distance to the optimal solution is rarely used when solving **CSP** due to these impracticalities.

## 65.5 Specific Constraint Satisfaction Problems

Many specific constraint satisfaction problems have been addressed in the literature. A full overview of these would not provide much benefit, as the most likely scenario is that one is looking for papers that provide descriptions of algorithms and results with those algorithms on a certain problem. The exceptions to this are several problems that in the literature are used to drive the development of algorithms in terms of efficiency and effectiveness. These *core* problems are used over and over to test whether new algorithms are better than existing algorithms.

Several reasons exist for the choice of these problems. Their compact definition means that the problem is easy to replicate by everyone and quick to introduce in papers. The most popular problems were used in the 1970s when the theory on non-polynomial deterministic problems was developed, which were consequently seen as important intelligent building blocks. Also, test sets and later problem generators were released in the public domain, thereby providing easy access to test suites.

We will use several of these *core* problems to describe the progress of development in evolutionary computation for constraint satisfaction problems. For each problem we will provide a quick introduction, a justification of its importance in terms of practical applications, and a set of pointers to problem suites before describing the approaches used.

### 65.5.1 Boolean Satisfiability Problem

Given a Boolean formula  $\phi$  determine whether an assignment of the variables in  $\phi$  exists that makes it TRUE. It is often referred to as satisfiability and abbreviated to **SAT** [65.24]. In **SAT** variables are often referred to as literals. Most often the problem is studied in conjunctive normal form (**CNF**) where  $\phi$  is a conjunction of clauses where each clause is a disjunction of variables. Every **SAT** problem can be reduced to a **3-CNF-SAT** (three variables/clause-conjunctive normal form-satisfiability) [65.25], where each clause has three literals.

**3-CNF-SAT** was the first problem to be shown to be NP-complete [65.26]. It serves as an important basis to proving that other problems are NP-complete, such as the maximal clique problem. Such a proof involves a polynomial-time reduction from **3-CNF-SAT** to the other problem [65.6].

The following is an example of **3-CNF-SAT**:

- $\phi = (x_1 \vee \neg x_3 \vee x_4) \wedge (\neg x_2 \vee x_1 \vee \neg x_6) \wedge (x_3 \vee x_2 \vee \neg x_5)$
- A solution:  $x_1 = 1, x_2 = 0, x_3 = 1, x_4 = 0, x_5 = 0, x_6 = 0$ .

Important practical applications of **SAT** are model checking [65.27], for example, in mathematical proof planning [65.28], generic planning problems, especially using the planning domain definition language (**PDDL**) [65.29], test pattern generation [65.30], and haplotyping in the scientific field of bioinformatics [65.31].

As far as the development of efficient and effective **CSP** solvers go, **SAT** is the most active field. It has an annual conference – The International Conference on Theory and Applications of Satisfiability Testing, which also hosts an annual competition to determine the current best solvers. The latter also ensures that new problem instances are continuously added, which prevents what is called *overfitting* [65.32] of the solvers to an existing set of problem instances.

The general approach to solve satisfiability with **EC** is to directly represent the variables in  $\phi$  and assign these either TRUE or FALSE, i. e., these form the domain. The fitness function used is the number of clauses violated, which should be minimized.

The earliest evolutionary algorithm for **SAT** was reported in 1994 by [65.33] and was soon followed by the work of Gottlieb and Voss [65.34, 35], who were looking to improve its performance. Soon after, independent efforts led to parallelized algorithms [65.36, 37]. In 2000, the first adaptive evolutionary algorithms were applied [65.38], which was 3 years after they were applied to graph coloring (Sect. 65.5.2).

The introduction of hybrid evolutionary algorithms with local search created a real boost of research activity [65.39–43]. However, a major issue remains with research on solving satisfiability with **EC**, as all studies include only local search and evolutionary algorithms without comparing to the state-of-art **DPLL** and heuristic solvers from the annual satisfiability community. This holds true even for recent studies such as [65.44]. Due to this major gap between the two communities of **EC** and **CP**, we do not comment on the comparison in terms of effectiveness and efficiency.

New research [65.45] focusses on using **EC** to evolve parameter settings for existing sound **SAT**

solvers, mostly ones based on the Davis–Putnam–Logemann–Loveland algorithm [65.46]. All modern **SAT** solvers have many parameters to tune how the search is organized. These parameters are often tuned manually, which allows for only a small exploration. Using **EC**, a much larger space can be explored in order to create fast **SAT** solvers for a given benchmark.

### 65.5.2 Graph Coloring

Graph coloring has several variants. The most commonly used definition is that of graph  $k$ -coloring, also known as the vertex coloring problem. Given a graph of vertices and edges  $(V, E)$  the goal is to find a coloring of the vertices  $V$  of the graph such that no two adjacent vertices have the same coloring. If  $c(v)$  provides the color assigned to  $v$ , then  $\forall v, w \in V : c(v) \neq c(w)$  iff  $(v, w) \in E$ . The objective is to make use of  $k$  or less colors. The problem is known to be NP-complete for  $k \geq 3$  and to be decidable in linear time for  $k \leq 2$ .

Graph coloring is an abstract problem that lies at the core of many applications. Well-known applications are scheduling, most specifically timetabling [65.47], register allocation in compilers [65.48], and frequency assignment in wireless communication [65.49]. It is a well-studied problem as is shown by the number of entries in the best-kept bibliography source until April 2010 with over 450 publications contributing to vertex coloring [65.50].

The Second DIMACS Implementation Challenge in 1992–1993 focused on maximum clique, graph coloring, and satisfiability. The challenge provided not only a standard format for graph  $k$ -coloring problem instances, but also provided a set of problem instances that is still popular today. Soon after, in 1994, Culberson and Luo [65.51] created a problem instance generator, which can create problem instances with a known  $k$  and various other properties. Several other generators exist with specific goals, such as to hide cliques [65.52], to create register-interference graphs [65.53], and to create timetabling problems (Sect. 65.5.4).

The most straightforward approach to solving graph  $k$ -coloring with **EC** is to represent a genome as a vector of all variables of the problem. This vector can then undergo genetic operators suitable for integer representations. The fitness function is simply the number of violated constraints, which should be minimized until a solution is found when the fitness is equal to zero. Unfortunately, this approach leads to algorithms that are inefficient and ineffective [65.54].

To make **EC** more efficient and effective for solving graph  $k$ -coloring, new algorithms have been developed; these broadly fall into two categories. The first category consists of adding mechanisms that prevent the stagnation of search due to premature convergence. The second category consists of alternative representations that make use of decoders to map genotypes to phenotypes. The two categories are not mutually exclusive, and studies have included algorithms that combine mechanisms from both categories.

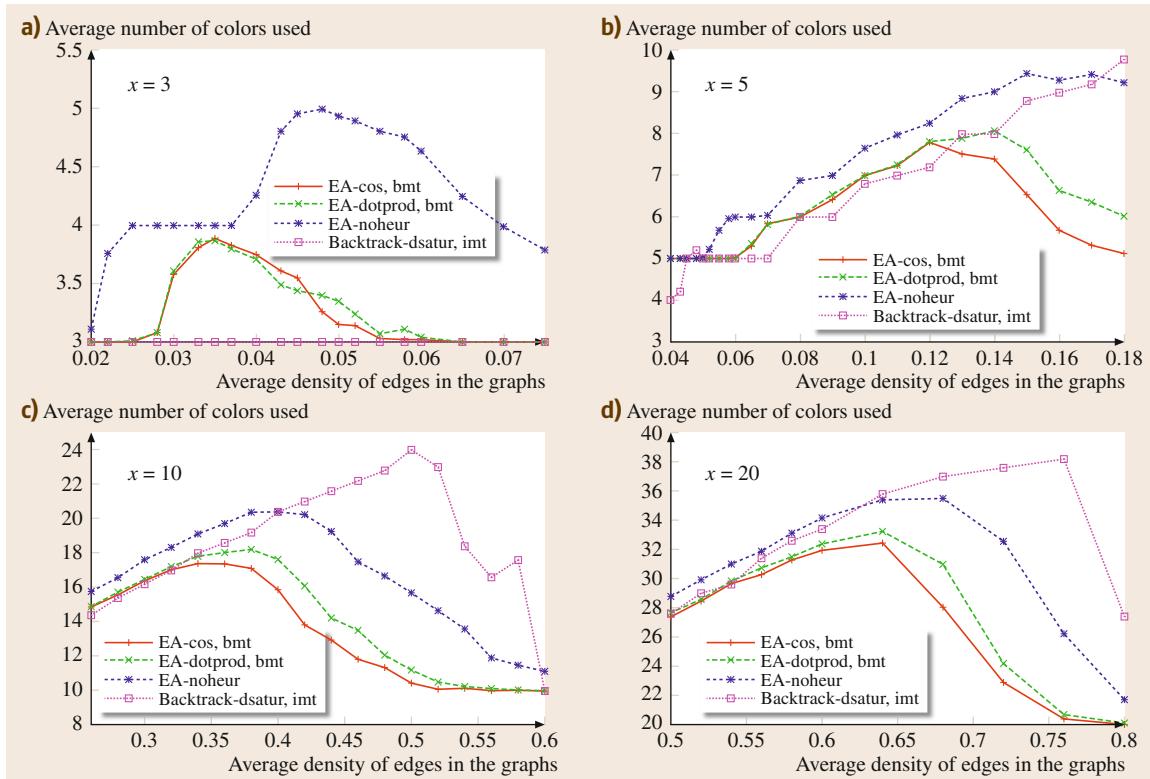

The earliest work on solving graph  $k$ -coloring with **EC** includes the following. *Fleurent* and *Ferland* successfully considered various hybrid evolutionary algorithms [65.55] with Tabu search and extended their work into a general implementation of heuristic search methods in [65.56]. *Von Laszewski* looked at structured operators and used adaption to improve the convergence rate of a genetic algorithm [65.57]. *Davis* designed an algorithm [65.58] to maximize the total of weights of nodes in a graph colored with a fixed number of colors. *Coll* et al. [65.59] discussed graph coloring and crossover operators in a more general context.

*Juhos* and *van Hemert* introduced several heuristics [65.60, 61] for guiding the search of an evolutionary algorithm. All these heuristics depend on their novel representation that collapses the graph by combining nodes assigned with the same color into one hypernode, which speeds up further constraint checking as edges are merged into hyperedges [65.62]. This representation benefits both complete and heuristic methods.

Moreover, as shown in the results in Fig. 65.2, the evolutionary algorithms developed by Juhos and van Hemert are able to outperform a complete method (Backtracking-DSatur) on very difficult problem instances where the chromatic number is 10 or 20. These algorithms are unable to compete with the complete method for smaller chromatic numbers of 3 and 5.

### 65.5.3 Binary Constraint Satisfaction Problems

A *binary constraint satisfaction problem* (**BIN CSP**) is a **CSP** where every constraint  $c \in C$  restricts at most two variables [65.63]. Often, network graphs are used to visualize (**CSP**) instances. In Fig. 65.3, we provide an example of a restricting hypergraph of a **BIN CSP**. It consists of three variables  $V = \{v_1, v_2, v_3\}$ , all of which have domain  $D = \{a, b\}$ . In a hypergraph every vertex corresponds to a possible variable assignment, i.e.,  $\langle v, d \rangle$ , where  $v \in V$  and  $d \in D_v$ . Every edge indicates the variable assignments that are forbidden by the

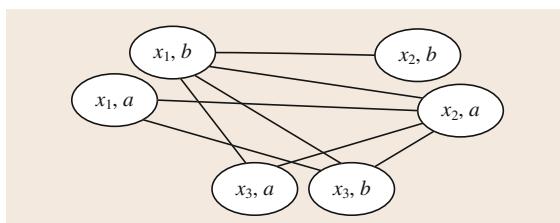

**Fig. 65.2a-d** Results of several evolutionary algorithms against the complete method Backtracking-DSat; average minimum number of colors used through the phase transition

set of constraints  $C$ . In the example, we show all the edges that correspond to the following set of forbidden value pairs  $C = \{ \langle v_1, a \rangle, \langle v_2, a \rangle, \langle v_1, a \rangle, \langle v_3, b \rangle, \langle v_1, b \rangle, \langle v_2, a \rangle, \langle v_1, b \rangle, \langle v_2, b \rangle, \langle v_1, b \rangle, \langle v_3, a \rangle, \langle v_1, b \rangle, \langle v_3, b \rangle, \langle v_2, a \rangle, \langle v_3, a \rangle, \langle v_2, a \rangle, \langle v_3, b \rangle \}$ .

For problem instances, studies on **BIN CSP** generally create large sets of instances using one of many problem instance generators. Several models to randomly create **BIN CSPs** have been designed and analyzed [65.63–65]. All of these incorporate a set of

parameters that may be used to control the size and difficulty of the problems. Often, these parameters can be used to create a set of problems that go through a *phase transition*. That is, we order the set on the parameters and observe how the algorithms behave when we move through the parameter space. In most constraint satisfaction problems we observe that the performance drops gradually until it reaches a minimum, after which it rises again. Most researchers test their algorithms in the region where the minimum is reached. Here the set of most difficult to solve problem instances is found. We will discuss these methods next.

The model most often used in empirical research on binary constraint satisfaction problems is one that uses four parameters to control, to some degree, the difficulty of an instance. By varying these global parameters one can characterize instances that are more likely to be either more or less difficult to solve. These parameters are: the number of variables  $n = |V|$ , the size of each variable's domain  $m = |D_{v_1}| = |D_{v_2}| = \dots = |D_{v_n}|$ , the density of constraints  $p_1$ , and the average tightness of

**Fig. 65.3** Example of a  $|V|$ -partite hypergraph of a (**BIN CSP**) with one solution:  $\{ \langle v_1, a \rangle, \langle v_2, b \rangle, \langle v_3, a \rangle \}$

all the constraints  $p_2$ . There are two ways of looking at parameters  $p_1$  and  $p_2$ . We will use the following definitions.

#### Definition 65.3 (Density)

The *density* of a **BIN CSP** is the ratio between the maximum number of constraints  $\binom{n}{2}$  and the actual number of constraints  $|C|$ ,

$$p_1 = \frac{|C|}{\binom{n}{2}}.$$

#### Definition 65.4 (Tightness)

The *tightness* of a constraint  $c \subset C$  over the variables  $v, w \in V$  of a **BIN CSP**  $\langle V, D, C \rangle$  is the ratio between the total number of forbidden variable assignments  $|c|$  and the total number of combinations of variable assignments possible  $m = |D_v||D_w|$ ,

$$p_2(c) = \frac{|c|}{m^2}.$$

#### Definition 65.5 (Average Tightness)

The *average tightness* of a **BIN CSP**  $\langle V, D, C \rangle$  is the sum of the tightness over all constraints divided by the number of constraints,

$$\bar{p}_2 = \frac{\sum_{c \in C} p_2(c)}{|C|}.$$

These definitions give the density and tightness in terms of a ratio, or in other words, as the percentages of the maximum. Another way of looking at these two properties uses probabilities [65.66]. We could define the density of a **BIN CSP** as the probability that a constraint exists between two variables. The tightness can be alternatively defined in an analogous way, as the probability that a conflict exists between two instantiations of two variables. The differences in these viewpoints becomes apparent in the different implementations of algorithms that generate **BIN CSPs**, as with uniform generation the ratio in an instance is determined beforehand, while with probability the ratio will vary according to a normal distribution. When comparing studies it is important to know when probabilities are used whether the results reported are against the probability set or the actual measured ratio in the whole instance.

**Table 65.1** Different models for the general method for generating binary constraint satisfaction problems

|             |             | Nogoods     |         |
|-------------|-------------|-------------|---------|
|             |             | Probability | Uniform |
| Constraints | Probability | Model A     | Model C |
|             | Uniform     | Model D     | Model B |

The simplest way to empirically test the performance of an algorithm on solving **CSPs** is by generating instances using different settings for the four main parameters,  $n$ ,  $m$ ,  $p_1$ , and  $\bar{p}_2$ . However, there are two ways of choosing where to put constraints in a constraint network. We can choose the number of constraints we want to have beforehand and then uniformly distribute them in the constraint network. Alternatively, we can choose for each *possible* edge in the constraint network with the probability  $p_1$  if this edge is inserted, i.e., a constraint is added. We will call the first model the *uniform model* and the second the *probability model*. The same categorization holds for nogoods. Given a constraint we can either distribute  $\bar{p}_2 m^2$  nogoods uniformly or with probability  $\bar{p}_2$  decide which value pairs become nogoods. Now we can define four different models and we will name them according to the models in [65.63, 65]. The models are shown in Table 65.1.

#### Definition 65.6 (Parameter Vector of a **BIN CSP**)

A *parameter vector* of a binary constraint satisfaction problem (**BIN CSP**) with  $n$  variables and  $m$  as each variable's domain size is a 4-tuple  $\langle n, m, p_1, \bar{p}_2 \rangle$  of four parameters: the number of variables  $n$ , the domain size of each variable  $m$ , the density  $p_1$ , and the average tightness  $\bar{p}_2$ .

We can also characterize a set of binary constraints satisfaction problems using the parameter vector as a set  $B$  of **BIN CSP** instances where

$$\begin{aligned} & \forall \langle n, m, p_1, \bar{p}_2 \rangle, \langle n', m', p'_1, \bar{p}'_2 \rangle \in B \\ & \Leftrightarrow n = n' \wedge m = m' \wedge p_1 = p'_1 \wedge \bar{p}_2 = \bar{p}'_2. \end{aligned}$$

Such a set we call a *suite of problem instances*.

Achlioptas et al. proves in [65.64] that as the number of variables becomes large almost all instances created by Models A–D become unsolvable. The reason lies in the existence of *flawed variables*. Whenever a variable  $v$  is involved in a constraint and has all its values incompatible with a value of an adjacent variable  $w$ , this variable is called *flawed*. In terms of compound labels using the constraint  $c$  over variables  $v$  and  $w$  this is

written as,

$$\forall v \in D_v : \exists w \in D_w : \\ \text{satisfies}((\langle v, v \rangle, \langle w, w \rangle), c) \wedge c \in C .$$

When the number of variables is increased without changing the other parameters, the number of flawed variables will increase, thus making it easy to prove instances have no solution. To overcome the problems a new model is proposed [65.64]:

#### **Definition 65.7 (Model E)**

The graph  $C^{\Pi}$  is a random  $n$ -partite graph with  $m$  nodes in each part that is constructed by uniformly, independently, and with repetitions selecting  $p_e \binom{n}{2} m^2$  edges out of the  $\binom{n}{2} m^2$  possible ones.

The idea behind this model is that the difficulty is controlled by the tightness and not influenced by the structure of the constraint network. The parameter  $p_e$  is responsible for the average tightness of the **BIN CSP**. However, it is not the same parameter as the average tightness  $\bar{p}_2$ . Because we allow repetitions in the process we end up with an average tightness smaller than or at most equal to  $p_e$ .

Parameter  $p_e$  also influences the value of  $p_1$ . In [65.65] we find the proof that using Model E with fairly small values ( $p_e < 0.05$ ) will result in a fully connected constraint network ( $p_1 = 1$ ). This is seen as a flaw in Model E, as many problems do not require a fully connected constraint network. This has led to yet another model.

*MacIntyre* et al. propose a more generalized version of Model E called *Model F* [65.65]. This model starts out the same way as Model E by generating  $p_1 \bar{p}_2 m \binom{n}{2}$  nogoods. Afterwards, a constraint network is generated with exactly  $p_1 \binom{n}{2}$  edges in the uniform way. All nogoods that are not in a constraint in the constraint network are removed from the problem instance. Model E is the special case of Model F where  $p_1 = 1$ . The benefit of Model F is the ability to generate problems where  $p_1 < 1$ , which is more realistic towards real-world problems.

*Craenen* et al. [65.67] present the largest comparison study of **EC** and **CP** approaches for the **BIN CSP**. In this study they compare the success rate and average number of conflict checks to a solution of 11 evolutionary algorithms. The best four evolutionary algorithms are compared with forward checking with conflict-directed backjumping [65.68], and the authors

concluded the latter has a superior performance on every problem instance in the benchmark.

The following heuristic approaches are included in the study. In [65.69, 70], *Eiben* et al. propose to incorporate existing **CSP** heuristics into genetic operators. A study on the performance of these heuristic-based operators when solving binary **CSPs** was published in [65.71]. Two heuristic-based genetic operators are specified: an asexual operator that transforms one individual into a new one and a multi-parent operator that generates one offspring using a number of parents. In [65.72–74], *Riff-Rojas* introduced an EA for solving **CSPs** that uses information about the constraint network in the fitness function and in the genetic operators (crossover and mutation). The fitness function is based on the notion of the *error evaluation* of a constraint. *Marchiori* et al. introduced and investigated EAs for solving **CSPs** based on pre-processing and post-processing techniques [65.75–77]. Included in the comparison is the variant form [65.75, 78] that transforms constraints into a canonical form in such a way that there is only one single (type of) primitive constraint; we call this algorithm glass-box. This approach is used in constraint programming, where **CSPs** are given in implicit form by means of formulas of a given specification language. In [65.79, 80] *Handa* et al. formulate a coevolutionary algorithm where a population of schemata are parasitic on the host population. Schemata in this algorithm are individuals where a portion of variables in the individual has values while all other variables have do-not-care symbols represented by asterisks.

The following approaches with emphasis on adaptive features are included in the comparison; a co-evolutionary approach invented by *Paredis* and evaluated on different problems, such as neural net learning [65.81], constraint satisfaction [65.81, 82], and searching for cellular automata that solve the density classification task [65.83]. Furthermore, results on the performance of the co-evolutionary approach when facing the task of solving binary **CSPs** are reported in [65.84, 85]. In the co-evolutionary approach for **CSPs** two populations evolve according to a predator-prey model: a population of candidate solutions and a population of constraints. In the approach proposed by *Dozier* et al. in [65.86] and further refined and applied in [65.87–89], information about the constraints is incorporated both in the genetic operators and in the fitness function. In the microgenetic iterative descent algorithm the fitness function is adaptive and employs *Morris'* breakout creating

mechanism [65.90] to escape from local optima. The stepwise adaptation of weights mechanism was introduced by *Eiben* and *van der Hauw* [65.91, 92] as an improved version of the weight adaptation mechanism of *Eiben* et al. [65.93, 94]. The approach has been studied in several comparisons and often proved to be a robust technique for solving several specific CSPs [65.95–97]. A comprehensive study of different parameters and genetic operators can be found in [65.98]. The basic idea is that constraints that are not satisfied or variables causing constraint violations after a certain number of steps must be hard, thus must be given a high weight (penalty) in the fitness function.

#### 65.5.4 Examination Timetabling

Examination timetabling has been studied for many years as it is a common problem in many organizations. Already in 1986, *Carter* gave an extended survey of work on automated timetabling [65.99]. He is also responsible for providing problem instances, which are still available and popular today [65.100], although a more diverse benchmark is used in the annual timetabling competition [65.101]. *Burke* et al. provide the most extensive recent surveys of automated timetabling in [65.102, 103]. Examination timetabling is just one of many problems under the topic of timetabling [65.104].

Timetabling as a problem has many different definitions due to different kinds of constraints and objectives. The definition that is most relevant for constraint satisfaction is often referred to as examination timetabling. The most abstract definition simply consists of a matrix  $C$  where  $C_{i,j} = 1$  if exam  $i$  conflicts with exam  $j$  by having common students that must take both exams,  $C_{i,j} = 0$  otherwise. This definition is equivalent to a graph coloring problem if the objective is to minimize the number of exam slots required, where the number of slots equals the number of colors required for coloring the graph with incidence matrix  $C$ . Hence, an appropriate approach to performance testing is via graph coloring instances based on examination timetabling, such as the problem instances labeled **SCH** (school) in the graph coloring instances suite provided by *Lewandowski* [65.105].

Many problem instances and problem instance generators exist. Infrequently, an International Timetabling Competition is organized by The International Series of Conferences on the Practice and Theory of Automated Timetabling. At each event, another definition of timetabling problems is tackled. The differences between definitions are in the objectives and the soft and hard constraints used. Hard constraints are treated the same as in constraint satisfaction, whereas soft constraints may be violated but will either incur an additional penalty on the objective function or be used to prioritize solutions otherwise, for instance, using a Pareto front. *Corne* et al. [65.106] identified five categories of constraints, unary, binary, capacity, event spread, and agent preference.

Three approaches exist to solving timetabling problems. The first approach is called *one-stage optimization*. It aggregates all types of constraints of one problem, often by summation, into one objective function where each type is assigned a weight. The advantage is that, in principle, the approach can be applied to any set of constraints. In practice, it may prove difficult to optimize such a function. Representations of the problem fall into the two main categories direct encoding (Sect. 65.3.1) [65.107] and indirect encoding (Sect. 65.3.2) [65.106, 108].

The second approach is called *two-stage optimization*. It first solves the problem of finding a feasible solution where all the hard constraints are satisfied. In the second stage it searches within the space set with these hard constraints and optimizes only against the soft constraints. The benefits are that during search we do not have to distinguish between feasible and infeasible constraints and, therefore, are not in danger of the search wandering off into an infeasible part of the search space. *Thompson* and *Dowsland* [65.109] were the first to report on this approach using simulated annealing, closely followed by the first EA by *Yu* and *Sung* [65.110].

The third approach uses *relaxation of constraints*. Typically, relaxation in timetabling is achieved by not assigning events to slots or by adding additional time slots. An early example of an EA is by *Burke* et al. [65.111], where an indirect encoding is used and additional time slots are used to relax the problem.

## 65.6 Creating Rather than Solving Problems

So far we have covered evolutionary computation for solving **CSP**. A contrasting idea proposed first for constraint satisfaction in [65.112] is to use evolutionary computation to generate problem instances. Such an approach allows a search for problem instances that adhere to certain properties as long as these can be measured efficiently by a fitness function.

A straightforward use for such an approach is to evolve problem instances that are difficult to solve for a particular algorithm. By measuring the efficiency of an algorithm to solve instances of a certain problem we can then change the instances with the aim of decreasing the efficiency. Measurements for efficiency of **EC** for **CSP** are discussed in Sect. 65.4.1. It is important to note that the algorithm we are evolving problem instances for can be of any kind, as long as we can execute it on problem instances generated and we can measure its efficiency.

Such hard problem instances identify the weak spots in the algorithm that tries to solve it. Moreover, if we can characterize a set of problem instances where all members of the set are hard for an algorithm, then we can use that characterization to decide what algorithm is suitable for solving a new problem instance. That is, if the work required to obtain the characteristics of one instance takes less effort than solving the actual problem instance itself [65.113].

### 65.6.1 Evolving Binary Constraint Satisfaction Problem Instances

The first application to constrained problems was for the binary constraint satisfaction problem (Sect. 65.5.3), where problem instances are represented as a binary vector with each element corresponding to the element of a conflict matrix between two variables [65.114]. Even the small instances investigated in the study led to large vectors, i.e., with 15 variables each with a domain of size 15, the corresponding vector has  $\binom{15}{2} \cdot 15^2 = 23\,625$  elements. Results with problem instances of this size show problem instances can be created that are far more difficult to solve than when creating a much larger set of randomly generated instances [65.112]. Furthermore, analysis of these instances provides an insight as to what structure is responsible for making instances difficult for the algorithm; two well-known algorithms from constraint programming were tested: chronological backtracking [65.115] and

forward checking with conflict-directed backjumping [65.116].

### 65.6.2 Evolving Boolean Satisfiability Problem Instances

In [65.114] an evolutionary algorithm is used to evolve solvable Boolean satisfiability problem instances that are in conjunctive normal form and have three variables per clause. A 3-SAT problem is represented by a list of natural numbers. A number in the list, i.e., a gene, corresponds to a unique clause with three different literals. The number of possible unique clauses depends on the number of variables and the size of the clause. Here, the number of variables is set to 100 and the size of the clause is 3, hence there are 1 313 400 unique clauses. This representation has strong advantages over a simple *one gene for every literal* approach. Most importantly, it prevents duplicate variables in clauses, which reduces the state space and could otherwise introduce trivial clauses, e.g.,  $(x \vee \neg x \vee y)$ , or 2-SAT clauses, e.g.,  $(x \vee x \vee y)$ . Also, the variation operators now simply become mutation and uniform crossover for lists of natural numbers over a fixed domain.

Two problem solvers are used from the annual **SAT** competition [65.117]; both are based on the *Davis–Putnam* procedure [65.4]. zChaff [65.118] is based on Chaff [65.119], a **SAT** solver that employs a particularly efficient implementation of Boolean constraint propagation and a novel low overhead decision strategy. Relsat [65.120] is explained in [65.121, 122]. In both solvers, the number of states of instantiations are enumerated to determine the search effort required.

The change of certain structural properties over the duration of evolution was analyzed. Two established properties were used: the number of solutions [65.123, 124] and the backbone size [65.125]. No clear relationship was identified with these properties.

However, a new relationship was identified: when problem instances are becoming more difficult to solve, the variance in the frequency in variable usage decreases. In other words, the distribution of variables throughout the instances is more uniform when problems are more difficult to solve.

### 65.6.3 Further Investigations

The application of evolutionary computation in problem generation is widespread. *Smith-Miles* and

Lopes [65.126] provide an extensive review in terms of measuring instance difficulty in combinatorial optimization problems, which also discusses studies that evolve problem instances for constrained optimization as well as for constraint satisfaction problems.

The maximization of the effort required to solve a problem instance highlights only one aspect of the problem difficulty. Another aspect that looks at the ef-

fectiveness is to maximize the distance a solver is able to reach to the optimal solution. To compute this distance, we require the fitness of the optimal solution a priori. Note, however, we do not need to know what the optimal solution is, only its fitness. Another approach is to directly compare solvers by maximizing the difference in some aspect, e.g., efficiency or effectiveness, between two solvers.

## 65.7 Conclusions and Future Directions

Research on solving constraint satisfaction problems with evolutionary computation has produced a rich set of research papers that contribute solvers, insights into solvers and their performance, and heuristic subroutines. One major flaw in this research has remained consistent over the past 20 years: most studies compare performance results only to other evolutionary or closely associated techniques. Even recent studies, such as [65.127–129], restrict themselves to comparing only results from other heuristic methods or have not included alternative techniques at all.

Many studies report on the promising performance of a particular evolutionary algorithm over another existing heuristic technique. The few systematic studies that do compare evolutionary and constraint programming techniques conclude that constraint programming

is superior in terms of efficiency [65.60, 67]. Also, constraint programming techniques are generally sound and, therefore, given sufficient time, always find a solution or proof that none exists. Hence, these solvers are more effective unless they are bounded by time. Recent efforts have shown success in speeding up modern DPLL-based techniques using heuristics for guiding the search [65.130, 131].

In Sect. 65.5 we reviewed many techniques that were developed and studied for the purpose of improving EC in terms of efficiency and effectiveness. The vast majority of these techniques was applied to one problem only. A huge benefit would come from studies that show the success of a technique across several CSPs. Such studies would be especially opportune for the SAT problem, which is still the most actively used CSP for benchmarking algorithms [65.132].

# 66. Swarm Intelligence in Optimization and Robotics

# Swarm Intelligence

Christian Blum, Roderich Groß

Swarm intelligence is an artificial intelligence discipline, which was created on the basis of the laws that govern the behavior of, for example, social insects, fish schools, and flocks of birds. The organization of these animal societies has always mesmerized humans. Therefore, it is surprising that it has only been in the second half of the last century that some of the most important principles of swarm intelligent behavior have been unraveled. A prime example is stigmergy, which refers to a self-organization of the animal society via changes applied to the environment.

In this chapter, we provide a concise introduction to swarm intelligence, with two main research lines in mind: optimization and robotics. Popular examples of optimization algorithms based on swarm intelligence principles are ant colony optimization and particle swarm optimization. On the other side, the field of robotics has adopted var-

ious swarm intelligent behaviors for problem solving and organizing groups of robots. This has resulted in a separate research field nowadays known as swarm robotics.

## 66.1 Overview

Swarm intelligence (SI) [66.1–3] is a subfield of the more general field of artificial intelligence [66.4]. The term *swarm intelligence* was introduced and used for the first time by Beni et al. [66.5–7] in the context of cellular robotic systems. Nowadays, SI research is generally concerned with the design of intelligent multiagent systems whose inspiration is taken from the collective behavior of social – or even eusocial – insects and other animal populations. Examples include ant colonies, bee hives, wasp colonies, frog populations, flocks of birds, and fish schools. Among these, social insects have always played a prominent role in the inspiration of SI techniques. Even though their intrinsic ways of functioning have fascinated researchers for many years, the mechanisms that govern their behavior remained unknown for a long time. In colonies of social insects, for example, single colony members are

unsophisticated individuals, yet they are able to achieve complex tasks in cooperation. Essential colony behaviors emerge from relatively simple interactions between the colony's individual members.

An important aspect of any SI system is *self-organization* [66.8]. Originally, the term *self-organization* was introduced by the German philosopher Immanuel Kant [66.9] in an attempt to characterize what makes organisms so different from other objects. Nowadays, the term self-organization refers to a process where some form of global order or coordination emerges from rather simple interactions between low-level components of an initially unordered system. Self-organizing processes are neither directed nor controlled by any agent or component, neither from inside nor from outside the system. They are often triggered by random fluctuations that are amplified by *positive feedback* and

**Fig. 66.1** Ants cooperate for retrieving a heavy prey (photo courtesy of M. J. Blesa)

possibly counterbalanced by *negative feedback*, which generally aids in stabilizing the system. The global properties exhibited by self-organizing systems are thus the result of this distributed interplay of their components. As such, self-organization is typically robust and able to survive and self-repair damage or perturbations. Historically, self-organization processes have been studied in physical, chemical, biological, social, and cognitive systems. Well known examples are crys-

tallization, molecular self-assembly, and the way in which neural networks learn to recognize complex patterns.

During the last 50 years or so, biologists discovered that many aspects of the collective activities of social insects are self-organized as well, that is, they function without a central control. For example, the African weaver ant constructs nests by pulling leaves together. Where the gap between leaves exceeds the body length of an individual ant, multiple ants organize into pulling chains. Once the leaves are in contact, they are glued together using silk from larvae, which are carried to the site by other workers of the colony [66.10]. Other examples concern the recruitment of fellow colony members for prey retrieval (Fig. 66.1), the capabilities of termites and wasps to build sophisticated nests, or the ability of bees and ants to orient themselves in their environment. For more examples, we refer the interested reader to [66.1, 2].

In the meantime, some of the above mentioned behaviors have been used as inspiration for the resolution of technical problems, especially in the context of optimization and in robotics. This chapter is dedicated to reviewing some of the – in the opinion of the authors – most interesting algorithms/systems from these two fields.

## 66.2 SI in Optimization

The use of SI techniques for solving optimization problems has already a rather extensive history. SI techniques have been used for both solving combinatorial and continuous optimization problems in static and in distributed settings. Two of the most well-known SI techniques for solving optimization problems are ant colony optimization (ACO) and particle swarm optimization (PSO). More recently, other techniques such as the artificial bee colony algorithm have been developed. Apart from solving optimization problems, SI techniques are being used for management tasks, for example, in distributed settings or in online optimization. The following sections will give a brief overview of this application field of SI.

### 66.2.1 Ant Colony Optimization

ACO [66.11] is one of the earliest SI techniques for optimization. Dorigo and colleagues developed the first ACO algorithms in the early 1990s [66.12–14]. The

development of these algorithms was inspired by the observation of ant colonies. Ants are social insects. They live in colonies and their behavior is governed by the goal of colony survival rather than being focused on the survival of individuals. The behavior that provided the inspiration for ACO is the ants' foraging behavior, and in particular, how ants of many species can find shortest paths between food sources and their nest. In order to search for food, ants initially explore the area around their nest by means of random walks. While moving, ants leave tiny drops of a pheromone substance on the ground. Ants are also able to scent these pheromones. When choosing their way, they are attracted by paths marked by strong pheromone concentrations. When having identified a food source, ants evaluate the quantity and the quality of the food and carry some of it back to their nest. During the return trip, the quantity of pheromone that ants leave on the ground may depend on the quantity and quality of the food. The pheromone trails will guide other

ants to the food source. It has been shown in [66.15] that the indirect communication between the ants via pheromone trails – known as *stigmergy* [66.16] – enables them to find the shortest paths between their nest and food sources. Initially, **ACO** algorithms were developed with the aim of solving discrete optimization problems. It should be mentioned, however, that nowadays the class of **ACO** algorithms also comprise methods for the application to problems arising in networks, such as routing and load balancing [66.17], and for the application to continuous optimization problems [66.18].

**ACO** algorithms may be regarded from different perspectives. First of all, as mentioned above, they are **SI** techniques. However, seen from an operations research perspective, **ACO** algorithms belong to the class of metaheuristics [66.19–21]. The term *metaheuristic*, first introduced in [66.22], has been derived from the composition of two Greek words. *Heuristic* derives from the verb *heuriskein* ( $\epsilon\nu\rho\sigma\kappa\epsilon\iota\upsilon$ ) which means *to find*, while the prefix *meta* means *beyond, in an upper level*. Before this term was widely adopted, metaheuristics were often called *modern heuristics* [66.23]. In addition to **ACO**, other algorithms such as evolutionary computation, iterated local search, simulated annealing, and tabu search, are often regarded as metaheuristics. For books and surveys on metaheuristics, we refer the reader to [66.19–21, 23].

#### Algorithm 66.1 Ant colony optimization (ACO)

```

1: while termination conditions not met do
2:   ScheduleActivities
3:   AntBasedSolutionConstruction()
4:   PheromoneUpdate()
5:   DaemonActions(){optional}
6: end ScheduleActivities
7: end while
```

From a technical perspective, **ACO** algorithms work as follows. Given a combinatorial optimization problem to be solved, first a finite set  $C$  of the so-called solution components, used for assembling solutions to the problem, must be defined. Second, a set  $\mathcal{T}$  of *pheromone values* must be defined. This set of values is commonly called the *pheromone model*, which is – from a mathematical point of view – a parameterized probabilistic model. The pheromone model is one of the central components of any **ACO** algorithm. The pheromone values  $\tau_i \in \mathcal{T}$  are commonly associated with solution components. The pheromone model is used to probabilistically generate solutions to the problem under

consideration by assembling them from the set of solution components. In general, **ACO** algorithms attempt to solve an optimization problem by iterating the following two steps:

- Candidate solutions are constructed using a pheromone model, that is, a parameterized probability distribution over the search space.
- The candidate solutions are used to update the pheromone values in a way that is deemed to bias future sampling toward high-quality solutions.

The pheromone update aims to concentrate the search in regions of the search space containing high-quality solutions. In particular, the reinforcement of solution components depending on the solution quality is an important ingredient of **ACO** algorithms. It implicitly assumes that good solutions consist of good solution components. To learn which components contribute to good solutions can help assemble them into better solutions. The main steps of any **ACO** algorithm are shown in Algorithm 66.1. **DaemonActions** (see line 5 of Algorithm 66.1) may include, for example, the application of local search to solutions constructed in function **AntBasedSolutionConstruction()**.

The class of **ACO** algorithms comprises several variants. Among the most popular ones are **MAX-MIN** Ant System (**MMAS**) [66.24] and ant colony system (**ACS**) [66.25]. For more comprehensive information, we refer the interested reader to [66.26].

#### 66.2.2 Particle Swarm Optimization

**PSO** [66.2, 27] is an **SI** technique for optimization that is inspired by the collective behavior of flocks of birds and/or fish schools. The first **PSO** algorithm was introduced in 1995 by *Kennedy and Eberhart* [66.28] for the purpose of optimizing the weights of a neural network, that is, for continuous optimization. In the meantime, **PSO** has also been adapted for its application to discrete optimization problems [66.29].

In **PSO**, solutions to the problem under consideration are labeled *particles*. The algorithm works on a whole set of particles at the same time, the so-called *swarm*. Therefore, **PSO** can be seen as a population-based optimization technique. During the run time of the algorithm, particles move through the search space on the search for an optimal, or good enough, solution. Moreover, particles communicate their current positions to neighboring particles. The position of each particle is updated according to three terms: its so-

called *velocity*, the difference between its current position and the best position it has found so far, and that from the best position found by its neighbors. This has the effect that, during the execution of the algorithm, the swarm increasingly focuses on areas of the search space containing high-quality solutions. The term *particle swarm* was chosen by Kennedy and Eberhart for the following reason. Their initial intention was to model the movements of flocks of birds and fish schools. As their model further evolved toward an algorithm for optimization, the visual plots produced from the results of the algorithm rather resembled swarms of mosquitoes. The term *particle* was used due to making use of the term *velocity*, and *particle* seemed to be the most appropriate term in this context.

**PSO** is closely related to *artificial life* models. Early works by *Reynolds* on the flocking model known as *boids* [66.30], and *Heppner* and *Grenander*'s studies on rules governing large numbers of birds flocking synchronously [66.31], suggested that bird flocking is an emergent behavior resulting from local interactions between the birds. These studies laid the foundation for the development of **PSO** for solving optimization problems. **PSO** is – in some way – similar to *cellular automata* (**CA**), which are often used for generating astonishing self-replicating patterns based on simple local rules. **CAs** may be characterized by the following three main attributes:

1. Cells are updated in parallel.
2. The value of each new cell depends only on the old values of the cell and its neighbors.
3. There is no difference in rules for updating different cells [66.32].

These three attributes also hold for the particles in **PSO**.

Henceforth,  $v_i$  denotes the velocity of the  $i$ th particle in the swarm,  $x_i$  denotes its position,  $p_i$  denotes the *personal best* position, and  $p_g$  is the best position found by particles in its neighborhood. In the original **PSO** algorithm,  $v_i$  and  $x_i$ , for  $i = 1, \dots, n$ , are updated according to the following two equations [66.28]:

$$v_i \leftarrow v_i + c_1 R_1 \otimes (p_i - x_i) + c_2 R_2 \otimes (p_g - x_i), \quad (66.1)$$

$$x_i \leftarrow x_i + v_i, \quad (66.2)$$

where  $R_1$  and  $R_2$  are independent functions returning a vector of values, generated uniformly at random, from the range  $[0, 1]$ . Moreover,  $c_1$  and  $c_2$  are the so-called acceleration coefficients. The symbol  $\otimes$  refers to

point-wise vector multiplication. As shown in (66.1), the velocity term  $v_i$  of a particle is composed of three components: the *momentum*, the *cognitive* and the *social* terms. The *momentum* term  $v_i$  carries the particle toward the previous direction; the *cognitive* term,

$$c_1 R_1 \otimes (p_i - x_i),$$

represents a force that pulls the particle toward its personal-best position; finally, the *social* part,

$$c_2 R_2 \otimes (p_g - x_i),$$

represents a force that influences the new direction toward the best position of neighboring particles. Various different neighborhood topologies may be used for this purpose. Examples include ring, star, and *von Neumann*. The use of rather small neighborhood topologies – such as the one induced by the *von Neumann* neighborhood – has generally been shown to lead to better results when rather complex problems are addressed, whereas larger neighborhoods generally lead to a better performance for simpler problems [66.33]. Algorithm 66.2 summarizes the basic **PSO** algorithm.

---

#### Algorithm 66.2 Particle swarm optimization (**PSO**)

```

1: Randomly generate an initial swarm
2: while termination conditions not met do
3:   for each particle  $i$  do
4:     if  $f(x_i) < f(p_i)$  then  $p_i \leftarrow x_i$ 
5:      $p_g = \min(p_{\text{neighbors}})$ 
6:     Update velocity (66.1)
7:     Update position (66.2)
8:   end for
9: end while
```

---

The class of **PSO** algorithms is characterized by a multitude of different variants, rendering it impossible to mention all of them here. However, popular variants include the *Inertia Weight PSO* [66.34], *fully informed PSO* [66.33], and *adaptive hierarchical particle swarm optimizer* [66.35]. Moreover, *Frankenstein's PSO* [66.36] is a **PSO** variant that was created by analyzing the components of existing **PSO** variants and combining (some of) them in a beneficial way. For more information, the interested reader may consult [66.37].

#### 66.2.3 Artificial Bee Colony Algorithm

The artificial bee colony (**ABC**) algorithm was first proposed by *Karaboga* and *Basturk* in 2005 [66.38],

[39]. The inspiration for the **ABC** algorithm is to be found in the foraging behavior of honey bees, which essentially consists of three components: food source positions, amount of nectar and three types of honey bees, that is, *employed bees*, *onlookers*, and *scouts*. In short, the algorithm works as follows. Feasible solutions to the problem under consideration are modeled as *food source positions*. Moreover, the quality of a feasible solution is modeled as the *amount of nectar* present at the corresponding food source position. Each type of bee is responsible for one particular operation in the context of generating new candidate food source positions, that is, new candidate solutions. Specifically, employed bees will search in the vicinity of the food source position that is presently in their memory; meanwhile they pass information about good food source positions to onlooker bees. Onlooker bees tend to select good food source positions from those found by the employed bees, and then further search for better food source positions around the selected food source position. In case the employed bee and the onlookers associated with a food source position are not able to find a better food source position, their current food source position is abandoned and the employed bee associated with this food source becomes a scout bee that performs a search for discovering new food source positions. If a scout identifies a new food source position, it turns into an employed bee again.

Essentially, the difference between the **ABC** algorithm and other population-based optimization techniques is to be found in the specific way of managing the resources of the algorithm, as suggested by the foraging behavior of honey bees. Due to its simplicity and ease of implementation, the **ABC** algorithm has captured much attention recently. It should also be mentioned that, although the algorithm has initially been introduced for continuous optimization, in the meantime it has been adapted for its application to combinatorial optimization problems as well [66.40, 41]. For a recent survey, we refer to [66.42].

#### 66.2.4 Other SI Techniques for Optimization and Management Tasks

In the following, we briefly mention other applications of SI techniques for optimization and management tasks, the latter especially for what concerns distributed environments. They are grouped with respect to their natural inspiration.

#### Division of Labor (Ants/Wasps)

In colonies of ants and wasps, for example, there are various tasks to be dealt with by the colony members. However, the urgency to engage in certain tasks may change over time. In 1984, Wilson [66.43] showed that the concept of *division of labor* in colonies of *Pheidole* genus ants allows the colony to adapt to these changing demands. Division of labor was later modeled in [66.44, 45] by means of response threshold models.

These models were later used in several technical applications. In the following, we mention a few of them. Nouyan et al. [66.46] consider static and dynamic task allocation problems in which trucks have to be painted in painting booths. Another application concerns media streaming in peer-to-peer networks [66.47]. A multiagent system for the scheduling of dynamic job shops with flexible routing and sequence-dependent setups is considered in [66.48]. Merkle et al. [66.49] made use of a response threshold model for self-organized task allocation in the context of computing systems with reconfigurable components. Finally, [66.50] present a system for task allocation in distributed environments.

#### Cemetery Formation (Ants)

The term *cemetery formation* refers to a behavior which has been observed in ant colonies of the species *Pheidole pallidula*, among others, which cluster the bodies of dead nest mates. This self-organized behavior has given rise to several applications, especially in the context of clustering and sorting. In 1991, a model for the clustering and sorting behavior of ants was published in [66.51]. Note that clustering refers in this context to the formation of piles, and sorting, on the other hand, refers to the spatial arrangement of objects according to their properties.

Mainly based on the model from [66.51], several algorithms for clustering and sorting were proposed in the literature. The first one was presented in [66.52], extending the original model to handle numerical data. More recent papers include [66.53] which deals with clustering and topographic mapping. Finally, the cemetery formation behavior of ants has also inspired an algorithm for dynamic load balancing [66.54].

#### Flashing in Fireflies

Fireflies are winged beetles that make use of bioluminescence to attract mates or prey. Moreover, tropical fireflies, in particular the ones from Southeast Asia, synchronize their light flashes in large groups of individuals. This is a self-organized phenomenon which is

mathematically described by the so-called *phase-coupled oscillator* models [66.55]. The benefits of this self-synchronization are not yet fully understood. Current hypotheses consider diet, social interaction, and altitude.

The literature contains, at least, two types of technical applications that are inspired by different aspects of the flashing of fireflies. First, there are applications that require some type of self-synchronization. Examples include, but are not limited to, a synchronization protocol in sensor networks [66.56], the synchronization in overlay networks [66.57], and dynamic pricing in online markets [66.58]. Second, the literature offers the so-called firefly algorithm (**FA**) [66.59], which is inspired by the way in which fireflies attract mates or prey. This algorithm was initially introduced for continuous optimization. It has, however, been adapted for the application to combinatorial optimization as well [66.60].

### Fish Schooling

A group of fish that have gathered are commonly called an *aggregation of fish*. Such a fish aggregation is called unstructured in the case in which the group consists of various species of fish having randomly gathered, for example, in the vicinity of a food source. If there is some social component to this gathering, the fish are said to be *shoaling*. Shoaling fish are aware of each other's presence, adjusting, for example, their swimming behavior to each other in order to stay together. However, their relation is rather loose. If, in contrast, an aggregation of fish is more tightly organized, for example, when all fish move at the same speed in the same direction, then the aggregation is said to be *schooling*. Schooling is a self-organized behavior that results from local interactions between the fish. This behavior comes with several advantages such as providing a means for social interactions, more successful foraging, and predator avoidance.

There are basically two different algorithms for optimization based on fish schooling to be found in the literature. The first algorithm is referred to as the *artificial fish swarm algorithm* (**AFSA**). It has, for example,

been applied to the training of feed-forward neural networks [66.61], multiuser detection [66.62], image segmentation [66.63], and generally to continuous optimization [66.64]. The second algorithm is known as *fish school search* [66.65].

### Self-Desynchronized Croaking (Japanese Tree Frogs)

Different biological studies – for example, [66.66] – have dealt with the croaking of Japanese tree frogs. The male individuals make use of their croaks in order to attract females. Moreover, females of this family of frogs can recognize the source of such a croak and are able to determine the current location of the corresponding male. However, this is only possible if no two frogs (that are close enough to the female) croak at the same time. In such a case, the female is not able to detect where the croaks came from. This is why, over time, male frogs evolved a self-organized way of desynchronizing their croaks. Aihara et al. [66.67] introduced a first formal model based on a set of pulse-coupled oscillators for capturing this behavior. So far, this model has only been applied to distributed graph coloring [66.68, 69]. However, the algorithm proposed in [66.69] is currently the state of the art for this problem.

### Nest Building (Termites/Wasps)

Both termites and wasps build highly complex nests in cooperation. The construction of such nests is well beyond the capabilities of an individual insect. The nests of both termites and wasps have a very complex internal structure. Moreover, termite nests are extremely large in comparison to individual insects. Scientists studying the nest-building behavior came up with probabilistic models for describing (parts of) the behavior [66.70]. It is nowadays generally accepted that stigmergy plays a central role in nest building.

Models for nest building based on stigmergy have been used mainly in software tools for simulating the automated building of certain structures. Examples can be found in [66.71–74].

## 66.3 SI in Robotics: Swarm Robotics

Swarm robotics refers to the study and use of **SI** techniques for the coordination of groups of robots. The following sections provide a brief overview of this field, with a focus on swarm robotic systems and the tasks they accomplish.

### 66.3.1 Systems

In the late 1940s, Walter [66.75] built two autonomous robots called *Machina speculatrix*, or simply tortoise, which exhibited behaviors resembling those of simple

animals. The robots had a driving/steering mechanism, a head light, a photoreceptor, and a bump sensor. They were designed to search for and approach light sources of moderate intensity. If a robot observed such a source, its head light was turned off, otherwise it was turned on. In an experiment, the robots were set up in a dark environment, where they approached each other exhibiting complex motion patterns. Such *mutual recognition* allowed *a population of machines* to form *a sort of community*, which broke up once an external light source was introduced [66.75, p. 129]. This two-robot system may be the first self-organizing multirobot system. Interestingly, even a single robot was reported to exhibit complex interactions when facing its mirror image – such a behavior, if *observed in an animal, might be accepted as evidence of some degree of self-awareness* [66.75, pp. 128–129].

In the 1950s, inspired by *von Neumann*'s kinematic model of machine replication [66.76], the first physical models of self-replication were built. Penrose and Penrose [66.77] studied a system in which passive mechanical parts move on a linear track when the latter is subjected to side-to-side agitation. In their default position, the parts do not link under the influence of shaking alone. If a seed object composed of two complementary parts, one hooked up to the other, is added, it replicates by interacting with the other parts on the track. Jacobson [66.78] implemented a system in which self-propelled electromechanical parts move on a circular track with several branches. A seed object composed of two parts could trigger other parts to assemble into identical objects without human intervention.

In the late 1980s, studies of Fukuda and Nakagawa [66.79–81], Beni [66.5], and Wang and Beni [66.82] provided an enormous impetus for the field that developed into *swarm robotics*. Fukuda and Nakagawa proposed a novel type of robotic system called *dynamically reconfigurable robotic system (DRRS)*, which can *dynamically reorganize its shape and structure [...] for a given task and strategic purpose*. DRRS is made of *several cells* with built-in intelligence and the ability to autonomously connect to and detach from one another [66.81, pp. 55–56]. The authors also presented a first prototype of this system, the **CEBOT** Mark I [66.80]. At the same time, Beni introduced the term *cellular robotic system*, referring to a system that can *encode information as patterns of its own structural units* [66.5, p. 59]; the units would be structural elements, each with built-in intelligence, able to move in space and act asynchronously under distributed control. Beni and Wang also used the terms

*swarm* and *swarm intelligence* in this context [66.83, 84].

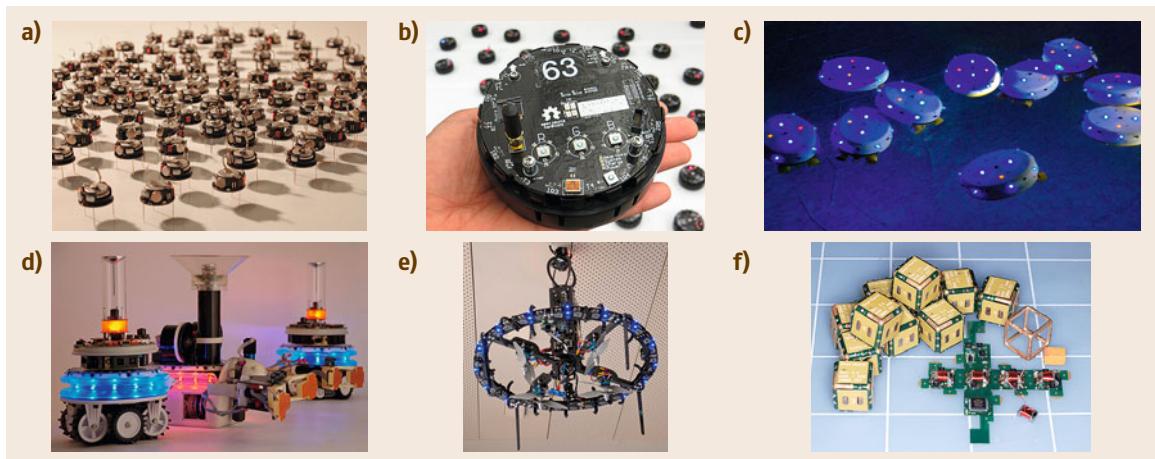

Other early physical implementations of distributed robotic systems include the **CEBOT** Mark II [66.85], ACTRESS [66.86], and GOFER [66.87].

### Hardware Architectures

Advances in technology, for example, in computers, manufacturing and mobile devices have made it affordable to study swarms of around 20–1000 physical robots [66.88] and up to around 1 000 000 robots in simulation [66.93–95]. At present, most swarm robotic systems consist of mobile robots that operate on the ground. An example is the Kilobot platform (Fig. 66.2a), which was designed to facilitate the fabrication and operation of thousands of robots – including their charging, programming and activation all at once [66.88]. Other state-of-the-art robotic systems include the r-one (Fig. 66.2b), which features, among others, a set of IR transmitters and receivers for communication and relative localization [66.89], and the Khepera I-IV [66.96] and e-puck [66.97], which feature a range of sensors including a camera. Increasingly, swarm robotic systems operate in spaces other than on the ground, such as underwater [66.90, 98] (Fig. 66.2c) or in the air [66.99, 100]. In some robotic systems, the swarms operate and collaborate across multiple spaces, such as on the ground and in the air [66.91, 101] (Fig. 66.2d,e).

According to their system architecture, most swarm robotic systems can be categorized into either *multirobot* systems or *modular reconfigurable robot* systems. Multirobot systems are composed of multiple distinct robots, which are typically mobile and able to perform (collectively) more than one task in parallel (Fig. 66.2a–c). Modular reconfigurable robot systems are composed of component modules that can be physically linked together to form a robot (Fig. 66.2f). A few *hybrid* systems exist, sharing properties of both multirobot and modular reconfigurable robot systems [66.91, 102–104] (Fig. 66.2d).

Of particular interest among systems of modular reconfigurable robots are those where the robots can build themselves [66.105, 106]. The term *self-reconfigurable* denotes the general ability of physical modules to reconfigure themselves, regardless of whether the process is centrally controlled, for example, by an external computer, or decentralized and autonomous. In the following, we use the term *self-assembly* to refer to processes by which pre-existing components (separate or distinct parts of a disordered structure) autonomously organize

**Fig. 66.2a–f** Examples of swarm robotic systems: (a) Kilobots developed by Harvard University [66.88]; (b) r-one (after [66.89], photo courtesy of J. McLurkin, Rice University); (c) Lily developed in the CoCoRo project (after [66.90], photo courtesy of T. Schmickl, University of Graz); (d,e) a heterogeneous system studied in the Swarmanoid project (after [66.91], photo courtesy of M. Dorigo, Université Libre de Bruxelles); (f) Pebbles (after [66.92], photo courtesy of D. Rus, MIT)

into patterns or structures without external intervention. Self-assembly is responsible for the generation of much of the order in nature [66.107] and has widely been applied in the synthesis of products from molecular components. Increasingly, the potential of self-assembly processes involving larger components – up to the centimeter-scale – is being recognized [66.108]. In robotic systems, two distinct classes of self-assembling systems exist [66.109]: (i) systems in which the components that self-assemble are externally propelled, and (ii) systems in which the components that self-assemble are self-propelled.

### Sensing and Communication

In most multirobot systems, robots interact with each other by using their sensors or some form of communication. Dudek et al. [66.110] presented a detailed taxonomy considering communication range, topology, and bandwidth. In the following, we adopt a simpler categorization proposed by Cao et al. [66.111]:

- *Interaction via environment* refers to the transfer of information that is mediated through the *memory* of the environment. In this case, robots leave persistent signs that stimulate the activity of other robots. This kind of indirect communication is also referred to as *stigmergy* [66.16]. Stigmergic communication is widely used in social insect societies, for example, during the construction of mounds by

termites of *Macrotermes bellicosus* [66.8], and has been implemented in several swarm robotic systems [66.112–116].

- *Interaction via sensing* refers to local interactions that occur between agents as a result of agents sensing one another, but without explicit communication [66.111, p. 12]. We include in this category interactions where agents sense each other indirectly, that is, where the current presence or motion of another agent can be inferred from changes in the environment. Note that the boundary to stigmergic communication is blurred; for example, consider the situation where multiple agents push an object simultaneously [66.117–119].

In some social animals, the members of a group observe a common leader individual. Their actions can be highly dependent on the observed behavior of the leader, as, for instance, during an attack of the group [66.120]. In other animals, no recognizable leader individual exists; instead, individuals observe nearby group members. The latter situation is typical for swarm systems. It is reported, for instance, for animal groups that exhibit herding, flocking, and schooling behavior [66.8]. Note that where the groups are not homogeneous, even a minority of individuals may be able to influence the rest of the group [66.121].

In principle, interaction via sensing can be considered an implicit form of communication, in par-

ticular, as an observed agent can change action and thereby influence the behavior of its observers. Arkin [66.122] referred to the interaction via sensing category as *cooperation without communication*, and showed that it is sufficient to accomplish tasks, that require the cooperation of multiple robots. Other examples of swarm robotic studies using interaction via sensing include [66.123–126].

- *Interaction via communication* refers to interactions involving explicit communication. Thereby, information is either broadcast or transferred to specific teammates. Information transfer can take place through direct physical interactions, such as touch. This latter form of communication can also be referred to as *direct interaction* [66.127]. Explicit communication can improve the performance of a multirobot system. This is typically the case where the system benefits from robots being recruited to certain areas of the environment. Balch and Arkin [66.128] studied such an environment and showed that it can be sufficient for each robot to signal its overall state. The transfer of more elaborate information however would not result in any significant increase in task performance. Explicit communication is commonly used in modular reconfigurable robot systems, for example, to exchange information between inter-connected modules or to support the docking process of separate modules [66.129].

### Control and Coordination

Over the last two decades, a range of design methods have been proposed for the control of swarm robotic systems. They can be broadly classified into behavior-based design methods and automated design methods [66.130].

In behavior-based design methods, the user approaches the problem in a bottom-up manner [66.131]. A repertoire of behaviors for individual robots is defined and often refined through a trial-and-error process. A common approach is the use of finite state machines. Each state defines a basic behavior. Transitions between states can be triggered by probability, external events, time-outs, and combinations of these [66.132–134]. A prominent example is the use of response threshold functions, for example,

$$1 - \exp^{-s_i/\theta_i} \text{ or } \frac{s_i^2}{s_i^2 + \theta_i^2},$$

which define the probability for an individual to engage in task  $i$  based on the perceived task stimulus  $s_i$  and

threshold  $\theta_i$ . The particular threshold value  $\theta_i$  can either be fixed for each individual from the outset [66.135] or learned during its lifetime [66.136, 137]. In both cases, the mechanism can facilitate the emergent allocation of tasks in groups of otherwise identical individuals (see also Sect. 66.2.4). In addition, *intentional* approaches to task allocation have been considered [66.138, 139]. These require the agents to cooperate explicitly with each other. For example, the decentralized ALLIANCE algorithm [66.140, 141] can be used for groups of heterogeneous robots to perform tasks and subtasks, which may have ordering dependencies, in a fault-tolerant way. It assumes that the robots detect with some probability the effect of their own actions as well as the actions of other team members.

Virtual potential fields [66.142, 143], and physicomimetics [66.144], is another widely used behavior-based design method. The robots mimic a physical particle under the influence of a potential field. The latter guides the particle toward a point of minimal potential energy. While the goal point, which the robot shall reach, would exert an attractive force on the particle, any obstacle would exert a repulsive force. Other robots can exert forces on the particle as well. Using this concept, a wide repertoire of behaviors can be realized, such as the collective movement of robots arranged in particular formations [66.145], or the tracking of multiple moving targets [66.146]. The properties of the resulting swarm systems, for example, the cohesion of the swarm, can also be formally analyzed [66.147].

Other design methods include the Growing Point Language [66.148], the Origami Shape Language [66.149], and Proto [66.150]. These languages were developed in the context of Amorphous Computing [66.151], which considers systems of massively distributed, disordered, asynchronous, and locally interacting computational devices. The Proto language has been extended for use on mobile devices. This extension was validated with a swarm of 40 iRobot robots [66.152]. Some amorphous computing approaches allow users to specify desired global system properties in the language. A compiler then produces the local rule set for the agents to achieve these properties [66.149].

Automated design methods can be grouped into reinforcement learning and evolutionary robotics. In reinforcement learning [66.153], an agent interacts with its environment by choosing actions and receiving rewards. Matarić [66.154, 155] applied reinforcement learning in a swarm robotic context. The robots had to learn how to collaborate in a foraging task. The robots

were provided with a set of hand-coded behaviors (as in a behavior-based approach) and were required to learn how to correlate appropriate conditions for each of these behaviors in order to optimize the higher-level behavior [66.155]. The difficulties of using reinforcement learning in a swarm robotic context are discussed in [66.130]. A recent survey of reinforcement learning in robotics is reported in [66.156].

Evolutionary robotics is an approach to designing robots, or aspects of them (e.g., morphology, control) using evolutionary algorithms [66.157, 158]. This approach can also be applied to the design of swarm robotic systems. In principle, evolution can bypass both the problem of decomposing a given task and the problem of identifying basic behaviors that achieve the subtasks [66.159, 160]. Early studies in evolutionary robotics developed collective behavior such as herding or flocking in simplistic simulation environments [66.161–163]. Simulation environments with physically embodied agents were considered in [66.159], where neural network controllers for aggregation were first evolved using a group of five robots in a simple simulation environment; the best of these controllers were subsequently validated using a more detailed simulation model of the robots. Quinn et al. [66.164] evolved neural network controllers for collective motion using a group of three simulated robots and subsequently tested the best-rated network in 100 trials with a group of three physical robots. Watson et al. [66.165] went a step further in that controllers for a simple phototaxis task were directly evolved on a group of eight physical robots. Working toward a distributed evolution of robot morphologies in hardware, Griffith et al. [66.166] demonstrated a system of template-replicating polymers, which were made of reconfigurable modules that slid passively on an air table and executed a finite state machine to control their connectivity. Recent work on evolutionary swarm robotics considers cultural evolution, for example, where behaviors that can be imitated (memes) are subject to an evolutionary process. In these, the robots engage as both teachers and learners to exchange memes [66.167].

Several design methods were developed specifically for, or mainly adopted in, the context of modular reconfigurable robot systems. One class of algorithms addresses the problem of how to adjust the relative positions of modules without changing their connection topology. Yim [66.168] proposed the use of *gait control tables* to produce a range of animal-like locomotion patterns, such as the walking gaits of hexapods. Each

gait control table specifies for each control cycle and module a basic action to be performed. The controller is executed either from a central place or in a distributed fashion. In the latter case, the modules synchronize their actions using internal timers. Shen et al. [66.169] proposed *hormone-inspired* communication and control, in which artificial hormones help modules to synchronize actions and discover changes in their topology. For example, a set of independent caterpillar-like robots could be connected into a single entity, which would adapt its gait to the new topology. In a similar experiment, a connected entity was manually split into smaller entities that continued to move as independent caterpillars. Stoy [66.170] proposed a *role-based control* algorithm to let modular robots display periodic locomotion patterns. A module's role specifies its actions and how to synchronize them with neighbor modules. For communication, a parent-child architecture is used; thus, modules need to be arranged in acyclic graphs. An extended version of the control algorithm can also cope with cycles.

Another class of algorithms addresses the problem of how to adjust the relative positions of modules by changing the connection topology [66.106]. One approach is to formulate the problem as a search problem. For example, in order to reconfigure a lattice-based robot from one topology to another, a graph search is performed, where the start node of the graph corresponds to the initial topology of the robot and the end node corresponds to the desired topology of the robot [66.171]. Due to the combinatorial explosion of possibilities, an exhaustive search of such graphs is impractical whenever the number of modules is not small. State-of-the-art approaches are thus heuristic and consider ways of reducing the problem complexity. For example, Yoshida et al. [66.172] proposed a two-level *motion planner*. A global planner ensures that the robot as a whole follows a predefined 3D trajectory. To do so, it specifies several candidate paths that bring individual modules from the tail to the head of the robot. A motion scheme selector chooses a feasible path for each module based on a rule database. Another example is to merge logically a group of nearby modules into *meta-modules*, which, typically, have more advanced locomotion abilities than the individual modules. The problem is then reduced to developing controllers for both meta-modules and modular robots composed of meta-modules [66.173]. In principle, modular robots can solve the search problem on the fly [66.174]. Other than by search, the reconfiguration problem can also be attempted by local movement strategies, for ex-

ample, random walks [66.175, 176], cellular automata rules [66.177], gradient rules [66.178, 179], or combinations of these [66.180]. These approaches naturally lead to decentralized implementations, as is desired in swarm robotics.

### 66.3.2 Tasks

A range of capabilities have already been demonstrated with swarm robotic systems. In the following, a brief overview is given. More detailed information is provided in Chaps. 71–74 of Part F of this handbook. Garnier et al. [66.189] demonstrated how a group of 20 Alice robots *aggregate* in a homogeneous environment. The robots mimic the aggregation behavior of cockroaches, which are reported to join and leave clusters with probabilities that depend on the sizes of clusters [66.190]. Such probabilistic algorithms have the advantage that, as long as the environment is bounded, it is not required that the robots initially form a connected graph in terms of their sensing and/or communication. A deterministic algorithm for aggregation is considered in [66.181]. It requires robots to have one binary sensor, which informs them whether or not there is another robot in their line of sight. The robots do not need memory and do not need to perform arithmetic computation. They rotate on the spot when they perceive another robot, and move backward along a circular trajectory otherwise. This algorithm was validated with groups of 40 e-puck robots (Fig. 66.3a).

Werfel et al. [66.116] developed a system of robots that can simultaneously *construct* and navigate structures from a supply of building blocks (Fig. 66.3b). The robots are inspired by termites, which use stigmergic rules to construct sophisticated structures, in particular, the mounds they inhabit. Given a desired target structure, it is possible to generate automatically a set of rules to be uploaded onto each robot. Using only local information, these rules allow the robots to coordinate their activities in a way that avoids conflict. A group of three robots constructed several structures, one resembling a castle.

Halloy et al. [66.182] showed that hybrid societies comprising both cockroaches and robots can collectively *decide* to aggregate under either of two shelters (Fig. 66.3c) and that it is possible for the robots to influence the decision-making process. In general, such interactive robots could be used to study and control animal groups [66.182, 191], including livestock [66.192, 193], and to inform ecological conservation policy.

Following the pioneering simulation works on *boids* [66.30], Turgut et al. [66.183] demonstrated how a group of robots can *flock* through a real environment using simple rules. To align with each other, the robots used *virtual heading sensors*, each comprising a digital compass and a wireless communication module. Flocking was demonstrated with 9 Kobot robots in a bounded environment (Fig. 66.3d).

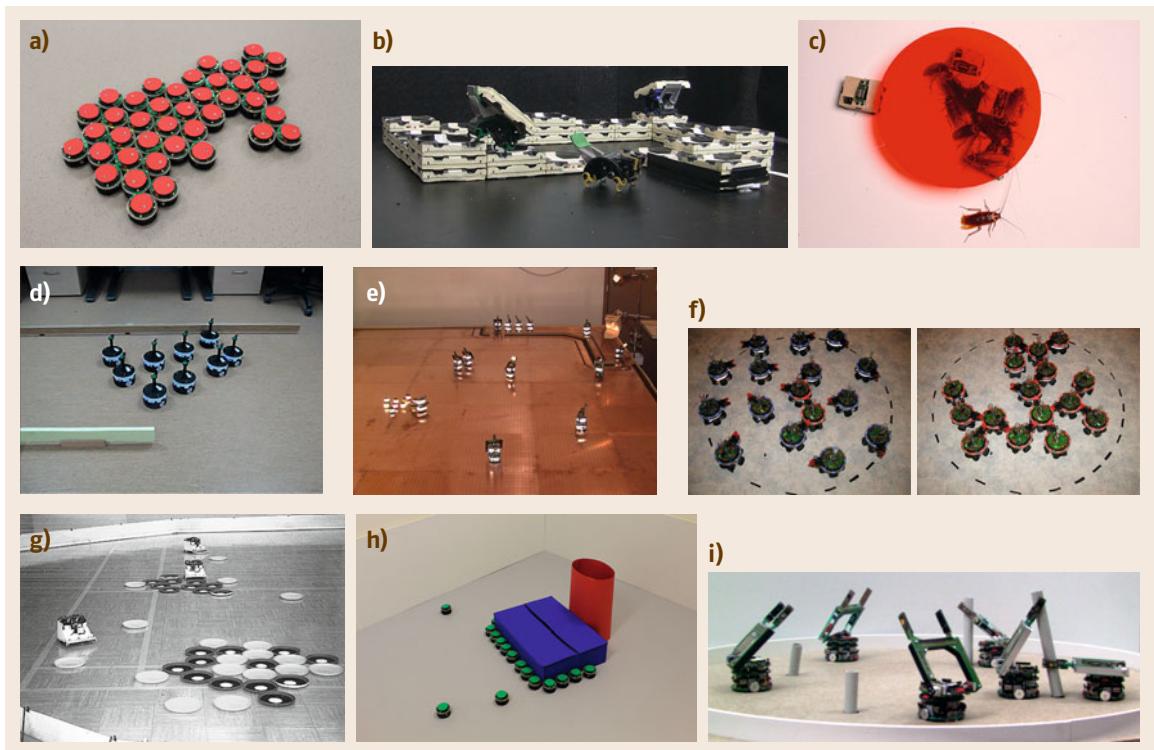

Krieger et al. [66.184] studied algorithms that allow a group of robots to *forage* (Fig. 66.3e). The robots rested in a central place, the nest. A robot would leave the nest if the total energy of the colony dropped below a threshold. Each robot had its own threshold, which effectively enabled the division of labor within the group. In addition, a robot would leave the nest when being recruited by another robot that had found a cluster of food. The pair of robots would then perform a tandem run to reach the cluster. The algorithms were tested on groups of up to 12 Khepera robots. The groups were reported to perform more efficiently when employing the division of labor and recruitment mechanisms than without such mechanisms.

Groß et al. demonstrated how a group of 16 s-bot robots *self-assemble* into a single composite entity [66.185]. The process was seeded by one of the robots activating its light emitting diode (**LED**) ring in red. Other robots activated their **LED** rings in blue. Once a robot would connect to the seed structure, it became red too, thereby attracting other robots to the structure as it grows (Fig. 66.3f). The problem of self-assembling into arbitrary morphologies of s-bot robots was considered in [66.194].

Holland and Melhuish [66.186] studied algorithms that allow groups of robots to *sort* (and cluster) objects of different types (Fig. 66.3g). Six robots were programmed using simple rules, which regulated the conditions under which objects of different types were picked up and deposited.

Following the pioneering work of Kube et al. [66.195, 196], Chen et al. [66.187] proposed an algorithm for a group of robots to *transport* objects larger than themselves toward a goal location (Fig. 66.3h). The robots were programmed to only push the object across the portion of its surface where the direct line of sight to the goal is occluded by the object. The algorithm was proven to work for objects of arbitrary convex shape and it was tested with 20 e-puck robots.

Ijspeert et al. [66.188] studied an algorithm that allows a group of robots to *pull sticks* out of the ground collaboratively (Fig. 66.3i). Upon encountering a stick,

**Fig. 66.3a–i** Examples of capabilities demonstrated by swarm robotic systems: (a) aggregation (after [66.181]); (b) construction (after [66.116]; reprinted with permission from AAAS); (c) decision making (after [66.182]; photo courtesy of J. Halloy, Université Libre de Bruxelles); (d) flocking (after [66.183]; photo courtesy of E. Şahin, Middle East Technical University); (e) foraging (after [66.184]; photo courtesy of L. Keller, University of Lausanne); (f) self-assembly (after [66.185]); (g) sorting of objects (after [66.186]; photo courtesy of C. Melhuish, Bristol Robotics Laboratory); (h) transport of objects (after [66.187]); (i) pulling sticks out of the ground (after [66.188]; reprinted with permission from Springer)

a robot would only be able to pull it partially out of the ground. It would then wait for a second robot to arrive and pull the stick out completely. The optimal

waiting time for the first robot was derived from an analytic model of the system. The algorithm was validated using a system of six Khepera robots.

## 66.4 Research Challenges

Research challenges concerning the use of swarm intelligence in optimization are mainly related to increasing their efficiency. More specifically, in addition to providing an innovative way of problem solving, swarm intelligence approaches must also be efficient concerning, for example, computation time in order to be able to compete with state-of-the-art optimization techniques. This may often be achieved by hybridizing swarm intelligence approaches with components taken from optimization algorithms in other fields such as,

for example, operations research. The interested reader may find various references to such kind of techniques in [66.197].

With regard to swarm robotics, a major challenge is the transition from systems operating in structured indoor environments, as typically found in laboratories, to the more complex environments found in the real world. Over the next decades, swarms of robots are expected to have impact in a range of application scenarios, including cognitive factories, deep sea ex-

ploration, disaster management, precision farming, and space systems. Working toward more complex environments also concerns the ability of swarms of robots to interact safely with humans. Another challenge concerns the miniaturization of swarm robotic systems. Most of the current systems comprise of centimeter-

sized robots. The swarm robotics approach, however, should be equally applicable to intelligent autonomous devices operating at scales from a millimeter down to a micrometer. This could have profound implications, for example, on advanced materials and healthcare technologies.

# 67. Preference-Based Multiobjective Particle Swarm Optimization for Airfoil Design

Robert Carrese, Xiaodong Li

A significant challenge to the application of evolutionary multiobjective optimization (**EMO**) for transonic airfoil design is the often excessive number of computational fluid dynamic (**CFD**) simulations required to ensure convergence. In this study, a multiobjective particle swarm optimization (**MOPSO**) framework is introduced, which incorporates designer preferences to provide further guidance in the search. A reference point is projected onto the Pareto landscape by the designer to guide the swarm towards solutions of interest. The framework is applied to a typical transonic airfoil design scenario for robust aerodynamic performance. Time-adaptive Kriging models are constructed based on a high-fidelity Reynolds-averaged Navier-Stokes (**RANS**) solver to assess the performance of the solutions. The successful integration of these design tools is facilitated through the reference point, which ensures that the swarm does not deviate from the preferred search trajectory. A comprehensive discussion on the proposed optimization framework is provided, highlighting its viability for the intended design application.

## 67.1 Airfoil Design

Airfoil design originates from an understanding of the fundamental physics of flight, where the aim is to identify or conform to the best possible shape for the given operating requirements. It has evolved from the use of wind tunnel catalogs and traditional *cut-and-try* methods to automated computational frameworks. While automated frameworks effectively simplify the design process, success is still largely dependent on the fidelity of the computational methods, as well as the experience of the designer in formulating the problem [67.1]. This section is devoted to a discussion

of airfoil design optimization architecture. The concepts that are especially applicable to this study are introduced, laying the foundations for the proposed methodology.

### 67.1.1 Airfoil Design Architecture

The direct method of airfoil design, pioneered by the work of *Hicks* and *Henne* [67.2], refers to the philosophy of using mathematical optimization methods to identify the optimal shape that achieves the prescribed

**Fig. 67.1** Generalized process flowchart for direct airfoil shape optimization

design criteria. The generalized framework for an aerodynamic shape optimization process is demonstrated in Fig. 67.1. The success of the direct approach is essentially dependent on three main components within the design loop:

- *Shape parameterization.* All design strategies share the common requirement that the geometry is represented by a finite number of design variables. A method to mathematically parameterize shapes is, therefore, required so that modifications can be made via direct manipulation of the design variables. The number of design variables is directly proportional to the geometrical degrees of freedom and, therefore, governs the dimensionality of the problem.
- *Computational flow solver.* The objective function is obtained from the flow solver and it is, therefore, up to the discretion of the designer to appropriately formulate the objective and constraint functions, such that they reflect the design and operating requirements. The choice of the flow solver ultimately governs the overall fidelity and efficiency of the optimization process, since repeated evaluations of the objective function are required for each candidate shape.
- *Optimization algorithm.* The responsibility of the optimizer is to iteratively determine the shape modifications required to satisfy the objective, whilst adhering to any shape or performance constraints. The optimizer should be robust and applicable to a wide operational spectrum, yet efficient to guarantee convergence with the least computational expense.

The integration of high-fidelity flow solvers and flexible parameterization methods for numerical op-

timization is still a computationally challenging and intensive undertaking. The extension to multiple objectives leads to a more generalized problem formulation, yet significantly increases the computational cost of convergence. While all elements of the design loop influence the efficiency of the process, arguably the most important element is the optimizer itself. The following section introduces the optimization paradigm adopted in this study, derived from the field of computational swarm intelligence.

### 67.1.2 Intelligent Optimization: PSO

The formation of hierarchies within groups of animals is a naturally occurring phenomenon and is simple to comprehend. Even humans have the intuitive tendency to appoint leaders (e.g., political leaders, military generals, etc.). Another interesting phenomenon, which is more difficult to perceive, is the self-organized behavior of groups where a leader *cannot* be identified. This is known as swarming and is evident from the flocking behavior of birds or fish moving in unison. The increasingly cited field of computational swarm intelligence focuses on the artificial simulation of swarming behavior to model a wide range of applications, including optimization [67.3].

Particle swarm optimization (PSO) is the stochastic population-based technique described by Kennedy and Eberhart [67.4] in accordance with the principles of swarm intelligence. The PSO architecture was derived from a synthesis of the fields of social psychology and engineering optimization. As was eloquently stated by the authors in their original paper [67.4]:

*Why is social behavior so ubiquitous in the animal kingdom? Because it optimizes. What is a good way*

to solve engineering optimization problems? Modeling social behavior.

The dynamics of the swarm are modeled on the social-psychological tendency of individuals to learn from previous experience and emulate the success of others. Similar to most evolutionary techniques, the swarm is initialized with a population of random individuals (particles) sampled over the design space. The particles navigate the multi-dimensional design space over a number of iterations or time steps. Each particle maintains knowledge of its current position in the design space. This is analogous to the *fitness* concept of conventional evolutionary algorithms (EAs). Each particle also records its personal best position, which is where the particle has experienced the greatest success. Aside from recording personal information, each particle also tracks the position of other members in the swarm. This level of social interaction between particles is coined the swarm *topology*. Particles may either be confined to share information only with their immediate neighbors, or they may be encouraged to share their experiences with the entire swarm. Utilizing this information, each particle adjusts its position in the design space by *accelerating* towards the successful areas of the design space. The absence of selection is compensated by this use of leaders to guide the swarm to converge to the most successful position. In this way, a solution which initially performs poorly may possibly be on the future road to success.

PSO has steadily gained popularity as a global optimization technique [67.3]. Its increasing use in the literature is due to its simple and straightforward implementation (despite its intricate origins) and its efficient and accurate convergence rates [67.5].

### 67.1.3 Multiobjective Optimization

Airfoil design problems are often characterized by several interacting or conflicting requirements, which must be satisfied simultaneously. In the case of an airfoil operating within the transonic regime, airfoil shape optimization is performed to limit shock and viscous drag ( $C_d$ ) losses, and reduce shock-induced boundary layer instability at the design Mach number ( $M$ ) and lift coefficient ( $C_l$ ). This often occurs at the expense of excessive pitching moments ( $C_m$ ) due to aft loading and performance degradation under off-design conditions. To facilitate adequate performance over a wide operational spectrum requires a search algorithm capable of handling multiple conflicting objectives.

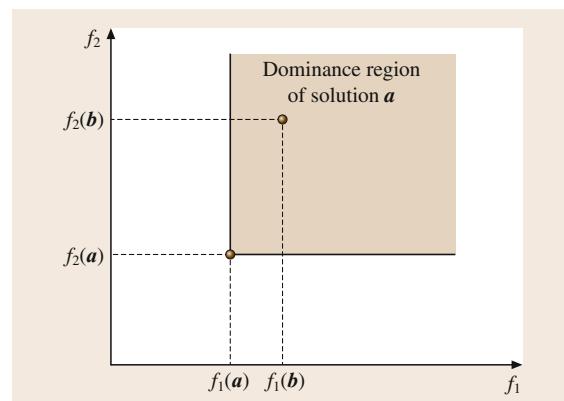

Let  $S \in \mathbb{R}^n$  denote the design space and let  $\mathbf{x} = \{x_1, x_2, \dots, x_n\} \in S$  denote the decision vector with lower and upper bounds  $\mathbf{x}_{\min}$  and  $\mathbf{x}_{\max}$ , respectively. The generic unconstrained multiobjective problem (MOP) is thus expressed as,

$$\min f(\mathbf{x}) = \{f_1(\mathbf{x}), \dots, f_m(\mathbf{x})\}, \quad (67.1)$$

where  $f_i(\mathbf{x}) : \mathbb{R}^n \rightarrow \mathbb{R}$  is the  $i$ -th component of the objective vector and  $m$  is the number of objectives. The definition of the optimum must be redefined since in the presence of conflicting objectives, improvement in one objective may cause a deterioration in another. It is often necessary to identify a set of trade-off solutions, which can all be considered equally optimal. A solution is termed non-dominated or Pareto optimal (after the nineteenth century Italian economist Vilfredo Pareto) if the value of any objective cannot be improved without deteriorating at least one other objective. The candidate solutions are defined as  $\mathbf{a}$  and  $\mathbf{b} \in S$ . The candidate  $\mathbf{a}$  dominates the candidate  $\mathbf{b}$  (denoted by  $\mathbf{a} \prec \mathbf{b}$ ) if,

$$\forall j = 1, \dots, m \quad f_j(\mathbf{a}) \leq f_j(\mathbf{b}) \wedge \exists j : f_j(\mathbf{a}) < f_j(\mathbf{b}). \quad (67.2)$$

The concept of dominance is illustrated in Fig. 67.2. The shaded area denotes the area of objective vectors dominated by  $\mathbf{a}$ . A decision vector  $\mathbf{a}^*$  is, therefore, non-dominated or Pareto optimal if there is no other feasible decision vector  $\mathbf{a} \neq \mathbf{a}^* \in S$  such that  $f(\mathbf{a}) \prec f(\mathbf{a}^*)$ . The Pareto front is the set of objective vectors which correspond to all non-dominated solutions. Multiobjective algorithms aim to identify the closest approximation to the true Pareto front, while ensuring a diverse Pareto optimal set.

**Fig. 67.2** Illustration of dominance on a two-objective landscape

### Techniques for Solving MOP

From a design perspective, the primary aim of multiobjective optimization is to obtain Pareto optimal solutions which are in the preferred interests of the designer, or best suit the intended application. Methods for solving MOPs are, therefore, characterized by how the designer preferences are articulated. As suggested by Fonseca and Fleming [67.6], there are three generic classes of methods for solving multiobjective problems:

- A priori methods. The preferences of the designer are expressed by aggregating the objective functions into a single scalar through weights or bias, ultimately making the problem single objective.
- A posteriori methods. The algorithm first identifies a set of non-dominated solutions, subsequently providing the designer greater flexibility in selecting the most appropriate solution.
- *Interactive* methods. The decision making and optimization processes occur at interleaved steps, and the preferences of the designer are interactively refined.

The a priori strategy requires the designer to indicate the relative importance of each objective before performing the optimization. A notable method that falls into this category is the weighted aggregation method, which is a fairly popular choice for airfoil design applications due to its simplicity and capability of handling many flight conditions [67.7–9]. Despite its popularity, there are recognized deficiencies with this strategy [67.10]. The prior selection of weights does not necessarily guarantee that the final solution will faithfully reflect the preferred interests of the designer, and varying the weights continuously will not necessarily result in an even distribution of Pareto optimal solutions, nor a complete representation of the Pareto front [67.11].

Alternatively the a posteriori methods provide maximum flexibility to the designer to identify the most preferred solution, at the expense of greater computational effort. Generally, these methods involve explicitly solving each objective to obtain a set of non-dominated solutions, a concept which is ideal for population-based evolutionary algorithms [67.12–14]. While these methods are computationally more complex, researchers in aerodynamic design are realizing the benefits of evolutionary multiobjective optimization (EMO), especially if there is a certain ambiguity in selecting the final design [67.15–17]. However, it poses the challenge of identifying and exploiting the entire Pareto front, which

may be impractical for design applications due to the excessive number of function evaluations.

While conventional EMO techniques may be computationally demanding, Fonseca and Fleming [67.12] argue that their most attractive aspect is the intermediate information generated, which can be exploited by the designer to refine preferences and improve convergence. These *interactive* methods involve the progressive articulation of preferences, which originates from the multicriteria decision making literature [67.18]. The optimization and decision making processes are interleaved, exploiting the intermediate information provided by the optimizer to refine preferences [67.6].

### Handling Multiple Objectives with PSO

PSO has been demonstrated to be an effective tool for single-objective optimization problems due to its fast convergence [67.5]. It has also gained rapid popularity in the field of multi-objective optimization (MOO) [67.19]. Since PSO is a population-based technique, it could ideally be tailored to identify a number of trade-off solutions to a MOP in one single run, similar to EMO techniques. Comprehensive surveys on extending PSO to handle multiple objectives have been provided by Engelbrecht [67.20], and more recently by Sierra and Coello Coello [67.19]. It was established that the primary ambiguity in specifically tailoring PSO to handle multiple objectives was the selection of guides for each particle to avoid convergence to a single solution. The selection process for particle leaders must, therefore, be restructured, to encourage search diversity and to ensure that non-dominated solutions found during the search are maintained.

Initial attempts to design a multiobjective particle swarm optimization (MOPSO) algorithm were motivated by the archive strategy by [67.21]. Coello Coello and Lechuga [67.22] incorporated the concept of Pareto dominance in PSO by maintaining two independent populations: the particle swarm and the elitist archive. Non-dominated solutions are stored in the archive and subsequently used as neighborhood leaders. The objective space is separated into hypercubes, which serve as a particle anti-clustering mechanism. Solutions in sparsely populated hypercubes have a higher selection pressure to be leaders, and solutions in densely populated hypercubes are removed if the archive limit is exceeded. This initial approach was later extended by Mostaghim and Teich [67.23], who studied the concept of  $\epsilon$ -dominance and compared it to existing clustering techniques for fixing the archive size, with favorable results.

*Fieldsend and Singh* [67.24] addressed the computational complexity of maintaining a restricted archive, by incorporating the *dominated tree* method. This data structure allows for an unrestricted archive size, which interacts with the population to define global leaders. A *turbulence* operator (similar to the concept of mutation in EA) was also implemented, where swarm members were randomly displaced on the design space to reduce the probability of premature stagnation. In the non-dominated sorting particle swarm optimization (NSPSO) algorithm of *Li* [67.25], the non-dominated sorting mechanisms of non-dominated sorting genetic algorithm (NSGA-II) are incorporated. The population and the personal best position of each particle are consolidated to form one single population, and the non-dominated sorting scheme is utilized to rank each solution. Global guides are selected based on particle clustering, where a niching or crowding distance metric is used to further classify non-dominated solutions. *Li* later proposed the maximinPSO algorithm [67.26], which does not use any niching method to maintain diversity.

*Sierra and Coello Coello* [67.27] proposed an elitist archive incorporating the  $\epsilon$ -dominance strategy to maintain global leaders for the swarm. A crowding distance operator is employed to classify non-dominated solutions and maintain uniformity. The crowding distance operator is also used to limit the number of candidate leaders after each population update, simplifying the mechanism to control the set of candidate leaders. A turbulence operator is implemented to encourage diversity, whereby particles are randomly mutated. A similar approach by [67.28] was developed in parallel (although this method does not implement  $\epsilon$ -dominance), where the crowding distance was used to both define the global guides and truncate the size of the archive. The proposed algorithm is primarily influenced by the two latter studies.

### Preference-Based Optimization

The concept of interactive optimization has led to an increasing interest in coupling classical interactive methods to EMO as an intuitive way of reflecting the designer preferences and identifying solutions of interest to the designer. This has led to the development of the preference-based optimization philosophy, which provides the motivation for the current study. Comprehensive surveys on preference-based optimization are provided by *Coello Coello* [67.29] and *Rachmawati and Srinivasan* [67.30]. The first recorded attempt at incorporating preferences within an evolutionary mul-

tiobjective optimization framework was made by *Fonseca and Fleming* [67.31] using the goal programming approach. Goal programming [67.11] is an ideal approach to indicate desired levels of performance for each objective, since they closely relate to the final solution of the problem. Goals may either represent target or ideal values. *Fonseca and Fleming* later extended the approach where an online decision making strategy was proposed based on goal and priority information [67.6]. A goal programming mechanism for identifying preferred solutions for MOP was also proposed by [67.32]. While the reported frameworks draw on the preferred interests of the designer to aid the optimization process, the goal programming approach is computationally complex, and there is no means of specifying any relation or trade-off between the objectives [67.30].

*Thiele et al.* [67.33] proposed another variant of interactive evolutionary multiobjective optimization. A coarse representation of the Pareto front is initially presented to the designer. The most interesting regions are subsequently isolated, on which the algorithm continues to focus on exclusively. This proposal effectively removes the necessity to predefine target values for each objective and provides the designer with a means of isolating the preferred trade-offs. However, it is a two-stage approach requiring an initial approximation to the Pareto front, which may be unnecessarily expensive. The integration of other classical preference articulation methods has also been proposed in the literature. A reference point-based evolutionary multiobjective optimization framework was proposed by [67.34]. The crowding distance operator of the NSGA-II algorithm was modified to include the reference point information and the extent of the preferred region was controlled by  $\epsilon$ -dominance. *Deb and Kumar* also experimented with the use of other classical preference methods, such as the reference direction method [67.35] and the light beam search method [67.36].

Recently, the use of interactive methods has also been integrated within PSO frameworks. *Wickramasinghe and Li* [67.37] integrated the reference point method to both the NSPSO [67.25] and maximinPSO [67.26] algorithms. Significant improvement in convergence efficiency was highlighted, and it was demonstrated that final solutions are of higher relevance to the designer. *Wickramasinghe and Li* [67.38] later extended their approach to handle MOP, by replacing the dominance criteria entirely with the simpler distance metric. It was conclusively demonstrated that without the use of the reference point, obtaining a final

set of preferred solutions solely through conventional dominance-based techniques is improbable.

#### 67.1.4 Surrogate Modeling

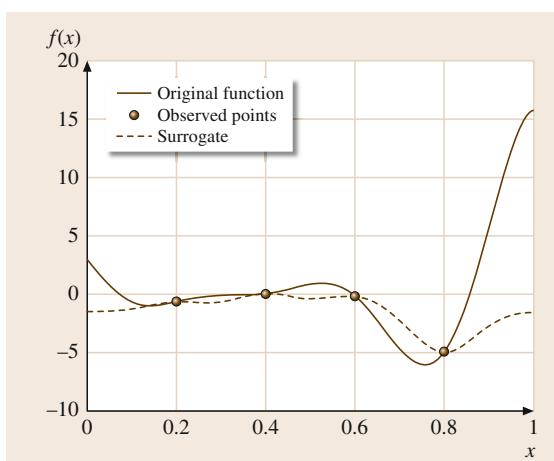

The most prohibiting factor of design optimization is the cost of evaluating the objective and constraint functions. For high-fidelity airfoil design, function evaluations may very well be measured in hours. This computational burden ultimately questions the practicality of performing an optimization study, and is often alleviated by simply reducing the level of sophistication of the solver. This consequently reduces the fidelity of the final design, which is undesirable. Another mitigating strategy which has steadily gained popularity in design is the use of inexpensive surrogates or metamodels [67.39]. These models emulate the response of the expensive function at an unobserved location, based on observations at other locations. Surrogate models are not specifically optimization methods, but rather they may ideally be used in lieu of the expensive function to extract information from the design space during the optimization process.

The insightful texts by *Keane and Nair* [67.39] and *Forrester et al.* [67.40] provide a detailed account of the use of surrogates in design. The most common use is to construct a *curve fit* of an expensive function landscape, which can be used to predict results without recourse to the original function. This is supported by the assumption that the inexpensive surrogate will still be usefully accurate when predicting sufficiently far from observed data points [67.40]. Figure 67.3 illustrates the use of

a surrogate to fit the one-dimensional multi-modal function, based on four sample observations. It is important to note, however, that the original function landscape could potentially represent any deterministic quantity of the design space. Rather than exactly emulating the response of a high-fidelity flow solver, the surrogate may, in fact, be used to bridge the gap between flow solvers of varying fidelity [67.40]. Alternatively, a surrogate may be used to interpret or filter noisy landscapes, so as to eliminate the adverse effects of flow solver convergence or grid discretization. Surrogates may also be used for data mining and design space visualization. Such methodologies are applied to extract useful information about the relationship between the design space and the objective space, allowing informed decisions to be made, which could simplify a seemingly complex problem.

For the aforementioned uses of surrogate modeling, the common requirement is to replicate the function relationship between the variable inputs and the output quantity of interest. This is typically achieved by sampling the design space using the exact function to sufficiently model the underlying relationship within the allowable computational budget. Whether the aim is to locally model the design space surrounding an existing design or tune a surrogate to replicate the global design space is entirely dependent on the formation of the sampling plan [67.39]. The construction of a surrogate model in either case should ideally make use of a parallel computing structure. A suitable surrogate model  $\hat{f}$  of the precise objective function  $f$  should then be constructed to fit the dataset.

There are a multitude of popular techniques for constructing surrogates in the literature. For a comprehensive review of different methods, the reader is referred to (among others) [67.39–42]. The selection of the surrogate model is dependent on the information that the designer is attempting to extract from the design space. Polynomial response surfaces and radial basis functions are fairly popular techniques for constructing local surrogates, especially if some level of regression is desirable. Techniques such as Kriging or support vector machines are more ideally suited to global optimization studies, since they offer greater flexibility in tuning model parameters and provide a confidence interval of the predicted output. Neural networks require extensive training and validation, yet have also been a popular technique for design applications, notably in aerodynamic modeling [67.43] and visualization techniques [67.44, 45].

## 67.2 Shape Parameterization and Flow Solver

It was established in Sect. 67.1.1 that the shape parameterization method essentially governs the dimensionality of the problem and the attainable shapes, whereas the objective flow solver dictates the overall fidelity of the optimum design. In this section, we present a discussion on these elements of the design loop to be used in conjunction with the developed optimizer for the subsequent design process.

### 67.2.1 The PARSEC Parameterization Method

Geometry manipulation is of particular importance in aerodynamic design. The selection of the shape parameterization method is an important contributing factor, since it will effectively define the objective landscape and the topology of the design space [67.46]. If the aim of the optimization process is to improve on an established design, then perhaps local parameterization methods, which offer a greater number of geometrical degrees of freedom, are desirable. However, the large number of variables may cause the convergence rate for global design applications to deteriorate. The development of efficient parameterization models has, therefore, been given significant attention, to increase the flexibility of geometrical control with a minimum number of design variables.

For certain applications, it is possible to make use of fundamental aerodynamic theory to refine the parameterization method, such that the design variables relate to important aerodynamic or geometric quantities. A common method for airfoil shape parameterization is the PARSEC method [67.47]. It has the advantage of strict control over important aerodynamic features, and it allows independent control over the airfoil geometry for imposing shape constraints. The methodology

**Fig. 67.4** Airfoil representation via the PARSEC method

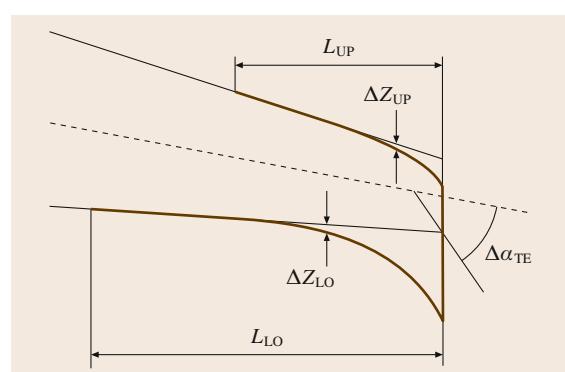

is characterized by 11 design variables (Fig. 67.4), including leading edge radius ( $r_{LE}$ ), upper and lower thickness locations ( $x_{UP}$ ,  $z_{UP}$ ,  $x_{LO}$ ,  $z_{LO}$ ) and curvatures ( $z_{xxUP}$ ,  $z_{xxLO}$ ), trailing edge direction ( $\alpha_{TE}$ ) and wedge angle ( $\beta_{TE}$ ), and trailing edge coordinate ( $z_{TE}$ ) and thickness ( $\Delta z_{TE}$ ). The shape function is modeled via a sixth-order polynomial function

$$z_k = \sum_{n=1}^6 a_{n,k} \cdot x_k^{n-\frac{1}{2}}, \quad (67.3)$$

where  $(x, z)$  are the shape coordinates and  $k$  denotes either the upper (suction) or lower (pressure) airfoil surface. The coefficients  $a_n$  are determined from the geometric parameters. A modification by *Jahangirian* and *Shahrokh* [67.48] was introduced to provide additional control over the trailing edge curvature. For supercritical transonic airfoils, this is beneficial to reduce the probability of downstream boundary layer separation, which results in increased drag values. A new variable  $\Delta\alpha_{TE}$  was introduced, which directly influences the additional curvature of the trailing edge. The modification decouples the trailing edge parameterization by first defining a smoother upper surface contour and then constraining the lower surface to intersect the trailing edge coordinate. Figure 67.5 illustrates the modification to the trailing edge curvature. The modification is applied to the upper and lower surfaces as follows

$$\delta_z = \frac{L \cdot \tan \Delta\alpha_{TE}}{2\mu\tau} \left[ 1 + \eta \cdot x^\tau - (1 - x^\tau)^\mu \right], \quad (67.4)$$

where the constants  $\eta$ ,  $\mu$ , and  $\tau$  are set to 0.8, 2, and 6, respectively. The modification is applied over the entire

**Fig. 67.5** Additional trailing edge curvature via the modified PARSEC method

| Description               | Variable               | Lower bound | Upper bound |
|---------------------------|------------------------|-------------|-------------|
| Leading edge radius       | $r_{LE}$               | 0.0063      | 0.0151      |
| Trailing edge direction   | $\alpha_{TE}$          | 0.2405(–)   | 0.0026(–)   |
| Trailing edge wedge angle | $\beta_{TE}$           | 0.0655      | 0.2618      |
| Upper-crest abscissa      | $x_{UP}$               | 0.3170      | 0.5250      |
| Upper-crest ordinate      | $z_{UP}$               | 0.0497      | 0.0683      |
| Upper-crest curvature     | $z_{xxUP}$             | 0.5135(–)   | 0.2393(–)   |
| Lower-crest abscissa      | $x_{LO}$               | 0.2835      | 0.3418      |
| Lower-crest ordinate      | $z_{LO}$               | 0.0603(–)   | 0.0478(–)   |
| Lower-crest curvature     | $z_{xxLO}$             | 0.2535      | 0.8405      |
| Trailing edge curvature   | $\delta_{\alpha_{TE}}$ | 0.0080(–)   | 0.3696      |

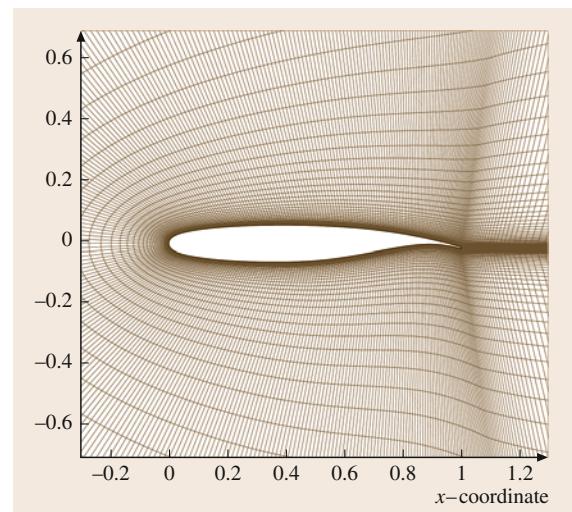

surface, such that  $L_{UP} = L_{LO} = c$ , where  $c$  is the airfoil chord length.

Table 67.1 presents the upper and lower boundaries for the subsequent optimization case study. These boundaries have been selected based on a thorough screening study involving a statistical sample of a number of benchmark airfoils.

## 67.2.2 Transonic Flow Solver

The optimization process is ultimately dependent on the selection of the flow solver, since it is the most computationally expensive component, and repeated evaluations of the objective and constraint functions are required for each candidate shape. However if the flow solver is not sufficiently accurate, the optimization process will converge to shapes that exploit the numerical errors or limitations, rather than the fundamental physics of the problem. For this reason, it is desirable to maintain the correct balance between solution accuracy and computational expense, which is dictated by the flow regime. For certain problems where the aerodynamic flow field is well behaved, it may be sufficient to consider more robust linear solvers. However for high-fidelity design it is prudent to consider non-linear and more computationally demanding solvers, to ensure that optimized shapes provide the anticipated performance requirements in flight.

The general purpose finite volume code ANSYS Fluent is adopted in this study. A pressure-based numerical procedure is adopted with third-order spatial discretization to capture the occurring flow phenomena. The momentum equations and pressure-based continuity equation are solved concurrently, with the Courant–Friedrichs–Lewy number set at 200. The one-equation

**Fig. 67.6** C-type grid for transonic simulation

Spalart–Allmaras turbulence model [67.49] is selected, and turbulent flow is modeled over the entire airfoil surface. The C-type grid (as represented in Fig. 67.6) stretches 25 chord lengths aft and normal of the airfoil section. Resolution of the C-grid is  $460 \times 65$ , providing an affordable mesh size of approximately 30 000 elements. The first grid point is located  $2.5 \times 10^{-4}$  units normal to the airfoil surface, resulting in an average  $y$ -plus value of 120. In the interest of robust and efficient convergence rates, a full multi-grid (FMG) initialization scheme is employed, with coarsening of the grid to 30 cells. In the FMG initialization process, the Euler equations are solved using a first-order discretization to obtain a flow field approximation before submission to the full iterative calculation.

## 67.3 Optimization Algorithm

The proposed algorithm was primarily motivated by the studies of *Wickramasinghe* and *Li* [67.38]. The principal argument is that for most design applications, to explore the entire Pareto front is often unnecessary, and the computational burden can be alleviated by considering the immediate interests of the designer. In Sect. 67.1.3, a discussion on the benefits of preference-based optimization was provided. Drawing on these concepts, a preference-based algorithm is proposed, where a designer-driven distance metric is used to scalar quantify the success of a solution. The multiobjective search effort is coordinated via a **MOPSO** algorithm. The swarm is guided by a reference point, which is an intuitive means of articulating the preferences of the designer and can ideally be based on an existing or target design. This section provides a comprehensive discussion on the proposed algorithm, highlighting its viability for the intended domain of application.

### 67.3.1 The Reference Point Method

In this research, the swarm is guided by a reference point to confine its search focus exclusively on the preferred region of the Pareto front as dictated by the preferences of the designer. Introducing the preferred region provides the designer flexibility to explore other interesting alternatives. This hybrid methodology is advantageous for navigating high-dimensional and multimodal landscapes, which are typical of aerodynamic design problems. Furthermore, inherently considering the preferences of the designer provides a feasible means of quantifying the practicality of a design.

#### The Reference Point Distance Metric

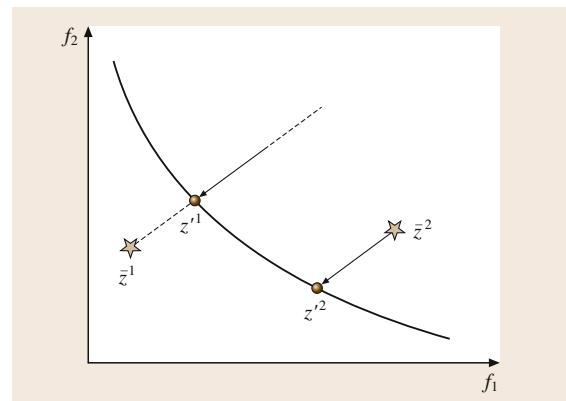

The reference point method has been integrated into **MOO** algorithms, notably by *Deb* and *Sundar* [67.34] and *Wickramasinghe* and *Li* [67.37, 38]. These studies highlight the benefits of incorporating preference information via the reference point in terms of convergence. Guided by the information provided by the reference point, the swarm can simultaneously identify multiple solutions in the preferred region. This provides the designer flexibility to explore several *preferred* designs, while alleviating the computational burden of identifying the entire Pareto front. A reference point distance metric following the work of *Wickramasinghe* and *Li* [67.37] is proposed. This metric provides an intuitive criterion to select global leaders and assists the swarm to identify only solutions of interest to the de-

signer. The distance of a particle  $\mathbf{x}$  to the reference point  $\bar{\mathbf{z}}$  is defined as

$$d_z(\mathbf{x}) = \max_{i=1:m} \{f_i(\mathbf{x}) - \bar{z}_i\}. \quad (67.5)$$

A solution  $\mathbf{a}$  is, therefore, *preferred* to solution  $\mathbf{b}$  if  $d_z(\mathbf{a}) < d_z(\mathbf{b})$ . This condition is an extension of the condition  $f(\mathbf{a}) \prec f(\mathbf{b})$ , therefore, the distance metric may, in fact, substitute the dominance criteria entirely [67.38]. Using this distance metric, the swarm is guided to preferred regions of the Pareto optimal front. Figure 67.7 illustrates the search directions of the algorithm when guided by a reference point, and the corresponding preferred design as a direct result of minimizing the distance metric  $d_z$ .

The distinguishing feature of the reference point distance metric over the mathematical Euclidean distance is that solutions do not converge to the reference point, but on the preferred region of the Pareto front as dictated by the search direction. This is illustrated in Fig. 67.8. All solutions are non-dominated and lie on the circular arc surrounding the reference point  $\bar{\mathbf{z}}$ , and thus the Euclidean distance to the reference point is equal. However, since solution  $i$  has the smallest maximum translational distance to the reference point compared to any other solution, it is considered preferred. The definition of the reference point distance also suggests negative values. If the distance of the preferred solution  $d_z(z') < 0$ , then it can simply be considered that the reference point is dominated or  $z' \prec \bar{\mathbf{z}}$ . Since the designer generally has no prior knowledge of the topology and location of the Pareto front,

**Fig. 67.7** Illustration of the search direction governed by the reference point

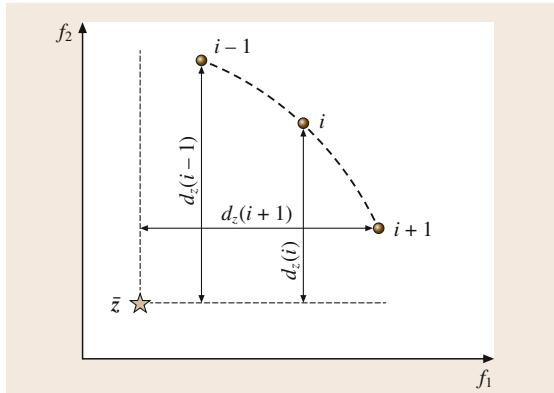

a reference point may be ideally placed in any feasible or infeasible region, as is shown in Fig. 67.7. It is, therefore, the consensus that the reference point draws on the experience of the designer to express the preferred compromise, rather than specific target values or goals. Similarly, the reference point distance metric ranks or assesses the success of a particle as one single scalar, instead of an array of objective values.

### Defining the Preferred Region

As is demonstrated in Fig. 67.7, if there is no control over the solution spread the swarm will explore the preferred search direction and converge to the single solution  $z'$  as dictated by the reference point  $\bar{z}$ . The advantage of maintaining a population of particles provides the designer the possibility to explore a range of interesting alternatives within a preferred region of the Pareto front. The aim is, therefore, to identify a set of solutions surrounding the intersection point  $z'$ . A threshold parameter  $\delta > 0$  is defined, such that a solution  $x$  is within the preferred region if the following conditional statement is true

$$d_z(x) \leq d_z(z') + \delta. \quad (67.6)$$

Figure 67.9 illustrates the preferred region for a bi-objective problem. The extent of the solution spread is proportional to  $\delta$  and evidently as  $\delta \rightarrow 0$ , the designer is interested in determining only the most preferred solution  $z'$ . Conversely, as  $\delta \rightarrow \infty$ , the designer is interested in determining all solutions along the Pareto front, and thus the influence of the reference point location diminishes.

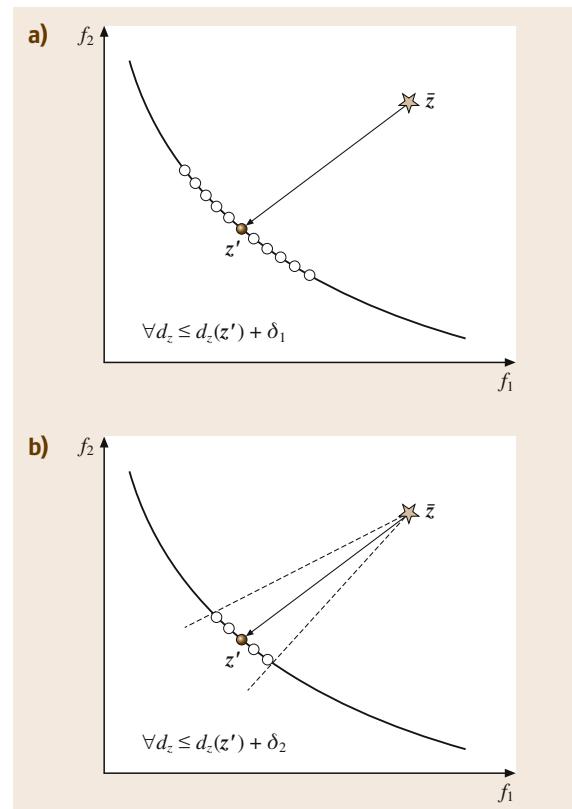

**Fig. 67.8** Illustration of the reference point distance for solutions with equal Euclidean distance

### 67.3.2 User-Preference Multiobjective PSO: UPMOPSO

The proposed algorithm combines the searching proficiency of **PSO** and the guidance of the reference point method. The swarm is guided by the user-defined reference point to confine its search to focus exclusively on the identified preferred region of the Pareto front. While the concept of the reference point is fairly intuitive, ensuring that the swarm is guided by this information to identify preferred solutions is more ambiguous. The algorithm function is consolidated in Algorithm 67.1 and further described in the subsequent steps.

15:   $t = t + 1$ 
16: until  $t = t_{\max}$  OR  $f_{\max}$ 

```

---

### OBTAIN User-Defined Preferences

The designer stipulates the reference point  $\bar{z}$  and the corresponding solution spread  $\delta$  to define the location and extent of the preferred region. For airfoil design applications, designers can exploit the existing domain knowledge to determine the most feasible performance compromise for the desired operating conditions.

### INITIALIZE the Particles

A swarm of  $N$  particles is required to navigate the design space  $S$  bounded by  $\mathbf{x}_{\min}$  and  $\mathbf{x}_{\max}$ . To safeguard against magnitude and scaling issues, all variables are normalized into the unit cube, such that  $S = [0, 1]^n$ . The  $i$ -th particle in the swarm is characterized by the  $n$ -dimensional vectors  $\mathbf{x}_i$  and  $\mathbf{v}_i$ , which are the particle position and velocity, respectively. These vectors are randomly initialized within the unit cube at time  $t = 0$ . The particle personal best position is recorded as the particle position, such that  $\mathbf{p}_i = \mathbf{x}_i$ . The particles are then evaluated with the objective functions and fitness is assigned. The reference point distance metric is computed for each particle to measure the individual preference value.

### UPDATE Archive and SELECT Global Leaders

A secondary population of non-dominated solutions in the form of an elitist archive is maintained at time,  $t$ . The non-dominated solutions identified by the particles are appended to the archive. A non-dominated sorting procedure is applied, where all members pertaining to local inferior fronts are omitted. The archive serves as a mutually accessible memory bank for the particles of the swarm. Each member is a potential candidate for global leadership of the particles during the subsequent velocity update.

Defining the global leaders ultimately governs the direction of the search. The swarm should efficiently navigate the design space such that the search effort is locally focused within the preferred region and provides a uniform spread of solutions. Since all members of the archive are mutually non-dominated, a ranking procedure is necessary to distinguish the most appropriate candidates for leadership from the remaining members. At each time step  $t$ , the most preferred solution  $\mathbf{z}'(t)$  is recorded. The subset of members  $X_g(t)$  selected for global leadership satisfy the condition of (67.6), such that

$$\mathbf{X}_g(t) \in d_z(\mathbf{Q}(t)) \leq d_z(\mathbf{z}'(t)) + \delta. \quad (67.7)$$

Since not every member will initially satisfy this condition, the number of candidate leaders may fluctuate over time. This condition provides the necessary selection pressure for particles to locally focus the search effort within the preferred region, avoiding the unnecessary computational effort of exploring undesired regions of the design space. Each swarm particle is randomly assigned a leader to promote diversity in the search. In the case where all non-dominated solutions satisfy the condition of (67.7), additional guidance through a crowding distance metric (as described in [67.27]) is provided to promote a uniform spread.

As the particles are guided to converge to the preferred region, the number of identified non-dominated solutions will steadily increase. To avoid this number escalating unnecessarily and to maintain high competitiveness within the archive, there is a restriction (denoted by  $K_{\max}$ ) on the number of solutions permitted for entry. If the number of members  $K > K_{\max}$ , the newest solution is permitted entry, and the existing least preferred member is removed. If all archive members exist within the preferred region, the most crowded solutions are removed. This ensures that solutions in densely populated regions are removed in favor of solutions which exploit sparsely populated regions, to further promote a uniform spread.

### UPDATE Particle Position

The update equations of PSO adjust the position of the  $i$ -th particle from time  $t$  to  $t + 1$ . In this algorithm, the constriction type I framework of Clerc and Kennedy [67.50] is adopted. In their studies, the authors studied particle behavior from an eigenvalue analysis of swarm dynamics. The velocity update of the  $i$ -th particle is a function of acceleration components to both the personal best position,  $\mathbf{p}_i$ , and the global best po-

sition,  $\mathbf{p}_g$ . The updated velocity vector is given by the expression,

$$\mathbf{v}_i(t+1) = \chi \{ \mathbf{v}_i(t) + \mathbf{R}_1[0, \varphi_1] \otimes (\mathbf{p}_i(t) - \mathbf{x}_i(t)) \\ + \mathbf{R}_2[0, \varphi_2] \otimes (\mathbf{p}_g(t) - \mathbf{x}_i(t)) \}. \quad (67.8)$$

The velocity update of (67.8) is quite complex and is composed of many quantities that affect certain search characteristics. The previous velocity  $\mathbf{v}_i(t)$  serves as a memory of the previous flight direction and prevents the particle from drastically changing direction and is referred to as the inertia component. The cognitive component of the update equation  $(\mathbf{p}_i(t) - \mathbf{x}_i(t))$  quantifies the performance of the  $i$ -th particle relative to past performances. The effect of this term is that particles are drawn back to their own best positions, which resembles the tendency of individuals to return to situations where they experienced most success. The social component  $(\mathbf{p}_g(t) - \mathbf{x}_i(t))$  quantifies the performance of the  $i$ -th particle relative to the global (or neighborhood) best position. This resembles the tendency of individuals to emulate the success of others.

The two functions  $\mathbf{R}_1[0, \varphi_1]$  and  $\mathbf{R}_2[0, \varphi_2]$  return a vector of uniform random numbers in the range  $[0, \varphi_1]$  and  $[0, \varphi_2]$ , respectively. The constants  $\varphi_1$  and  $\varphi_2$  are equal to  $\varphi/2$  where  $\varphi = 4.1$ . This randomly affects the magnitude of both the social and cognitive components. The constriction factor  $\chi$  applies a dampening effect as to how far the particle explores within the search space and is given by

$$\chi = 2 / |2 - \varphi - \sqrt{\varphi^2 - 4\varphi}|. \quad (67.9)$$

Once the particle velocity is calculated, the particle is displaced by adding the velocity vector (over the unit time step) to the current position,

$$\mathbf{x}_i(t+1) = \mathbf{x}_i(t) + \mathbf{v}_i(t+1). \quad (67.10)$$

Particle flight should ideally be confined to the feasible design space. However, it may occur during flight that a particle involuntarily violates the boundaries of the design space. While it is suggested that particles which leave the confines of the design space should simply be ignored [67.51], the violated dimension is restricted such that the particle remains within the feasible design space without affecting the flight trajectory.

#### UPDATE Personal Best

The ambiguity in updating the personal best using the dominance criteria lies in the treatment of the case

when the personal best solution  $\mathbf{p}_i(t)$  is mutually non-dominated with the solution  $\mathbf{x}_i(t+1)$ . The introduction of the reference point distance metric elegantly deals with this ambiguity. If the particle position  $\mathbf{x}_i(t+1)$  is preferred to the existing personal best  $\mathbf{p}_i(t)$ , then the personal best is replaced. Otherwise the personal best is remained unchanged.

### 67.3.3 Kriging Modeling

Airfoil design optimization problems benefit from the construction of inexpensive surrogate models that emulate the response of exact functions. This section presents a novel development in the field of preference-based optimization. Adaptive Kriging models are incorporated within the swarm framework to efficiently navigate design spaces restricted by a computational budget. The successful integration of these design tools is facilitated through the reference point distance metric, which provides an intuitive criterion to update the Kriging models during the search.

In most engineering problems, to construct a globally accurate surrogate of the original objective landscape is improbable due to the weakly correlated design space. It is more common to locally update the prediction accuracy of the surrogate as the search progresses towards promising areas of the design space [67.40]. For this purpose, the Kriging method has received much interest, because it inherently considers confidence intervals of the predicted outputs. For a complete derivation of the Kriging method, readers are encouraged to follow the work of Jones [67.41] and Forrester et al. [67.40]. We provide a very brief introduction to the ordinary Kriging method, which expresses the unknown function  $y(\mathbf{x})$  as,

$$y(\mathbf{x}) = \beta + z(\mathbf{x}), \quad (67.11)$$

where  $\mathbf{x} = [x_1, \dots, x_n]$  is the data location,  $\beta$  is a constant global mean value, and  $z(\mathbf{x})$  represents a local deviation at the data location  $\mathbf{x}$  based on a stochastic process with zero-mean and variance  $\sigma^2$  following the Gaussian distribution. The approximation  $\hat{y}(\mathbf{x})$  is obtained from

$$\hat{y}(\mathbf{x}) = \hat{\beta} + \mathbf{r}^T \mathbf{R}^{-1} (\mathbf{Y} - \mathbf{1}\hat{\beta}), \quad (67.12)$$

where  $\hat{\beta}$  is the approximation of  $\beta$ ,  $\mathbf{R}$  is the correlation matrix,  $\mathbf{r}$  is the correlation vector,  $\mathbf{Y}$  is the training dataset of  $N$  observed samples at location  $X$ , and  $\mathbf{1}$  is a column vector of  $N$  elements of 1. The correlation

matrix is a modification of the Gaussian basis function,

$$R(\mathbf{x}^i, \mathbf{x}^j) = \exp\left(-\sum_{k=1}^n \theta_k |x_k^i - x_k^j|^2\right), \quad (67.13)$$

where  $\theta_k > 0$  is the  $k$ -th element of the correlation parameter  $\boldsymbol{\theta}$ . Following the work of *Jones* [67.41], the correlation parameter  $\boldsymbol{\theta}$  (and hence the approximations  $\hat{\beta}$  and  $\hat{\sigma}^2$ ) are estimated by maximizing the concentrated ln-likelihood of the dataset  $\mathbf{Y}$ , which is an  $n$ -variable single-objective optimization problem, solved using a pattern search method. The accuracy of the prediction  $\hat{y}$  at the unobserved location  $\mathbf{x}$  depends on the correlation distance with sample points  $\mathbf{X}$ . The closer the location of  $\mathbf{x}$  to the sample points, the more confidence in the prediction  $\hat{y}(\mathbf{x})$ . The measure of uncertainty in the prediction is estimated as

$$\hat{s}^2(\mathbf{x}) = \hat{\sigma}^2 \left[ 1 - \mathbf{r}^T \mathbf{R}^{-1} \mathbf{r} + \frac{(1 - \mathbf{1}^T \mathbf{R}^{-1} \mathbf{r})^2}{\mathbf{1}^T \mathbf{R}^{-1} \mathbf{1}} \right] \quad (67.14)$$

if  $\mathbf{x} \subset \mathcal{X}$ , it is observed from (67.14) that  $\hat{s}(\mathbf{x})$  reduces to zero.

### 67.3.4 Reference Point Screening Criterion

Training a Kriging model from a training dataset is time consuming and is of the order  $O(N^3)$ . Stratified sampling using a maximin Latin hypercube (LHS) [67.52] is used to construct a global Kriging approximation  $[\mathbf{X}, \mathbf{Y}]$ . The non-dominated subset of  $\mathbf{Y}$  is then stored within the elitist archive. This ensures that candidates for global leadership have been precisely evaluated (or with negligible prediction error) and, therefore, offer no false guidance to other particles. Adopting the concept of individual-based control [67.42], Kriging predictions are then used to pre-screen each candidate particle after

the population update (or after mutation) and subsequently flag them for precise evaluation or rejection. The Kriging model estimates a lower-confidence bound for the objective array as

$$\{\hat{f}_1(\mathbf{x}), \dots, \hat{f}_m(\mathbf{x})\}_{lb} = [\{\hat{y}_1(\mathbf{x}) - \omega \hat{s}_1(\mathbf{x})\}, \dots, \{\hat{y}_m(\mathbf{x}) - \omega \hat{s}_m(\mathbf{x})\}], \quad (67.15)$$

where  $\omega = 2$  provides a 97% probability for  $\hat{f}_{lb}(\mathbf{x})$  to be the lower bound value of  $\hat{f}(\mathbf{x})$ . An approximation to the reference point distance,  $\hat{d}_z(\mathbf{x})$ , can thus be obtained using (67.5). This value, whilst providing a means of ranking each solution as a single scalar, also gives an estimate to the improvement that is expected from the solution. At time  $t$ , the archive member with the highest ranking according to (67.5) is recorded as  $d_{min}$ . The candidate  $\mathbf{x}$  may then be accepted for precise evaluation, and subsequent admission into the archive if  $\hat{d}_z(\mathbf{x}) < d_{min}$ . Particles will thus be attracted towards the areas of the design space that provide the greatest resemblance to  $\bar{z}$ , and the direction of the search will remain consistent.

As the search begins in the explorative phase and the prediction accuracy of the surrogate model(s) is low, depending on the deceptivity of the objective landscape(s) there will initially be a large percentage of the swarm that is flagged for precise evaluation. Subsequently, as the particles begin to identify the preferred region and the prediction accuracy of the surrogate model(s) gradually increases, the screening criterion becomes increasingly difficult to satisfy, thereby reducing the number of flagged particles at each time step. To restrict saturation of the dataset used to train the Kriging models, a limit is imposed of  $N = 200$  sample points where lowest ranked solutions according to (67.5) are removed.

## 67.4 Case Study: Airfoil Shape Optimization

The parameterization method and transonic flow solver described in the preceding section are now integrated within the Kriging-assisted UPMOPSO algorithm for an efficient airfoil design framework. The framework is applied to the re-design of the NASA-SC(2)0410 airfoil for robust aerodynamic performance. A three-objective constrained optimization problem is formulated, with  $f_1 = C_d$  and  $f_2 = -C_m$  for  $M = 0.79$ ,  $C_l = 0.4$ , and  $f_3 = \partial C_d / \partial M$  for the design range  $M = [0.79, 0.82]$ ,  $C_l = 0.4$ . The lift constraint is satisfied internally within

the solver, by allowing Fluent to determine the angle of incidence required. A constraint is imposed on the allowable thickness, which is defined through the parameter ranges (see Table 67.2) as approximately 9.75% chord. The reference point is logically selected as the NASA-SC(2)0410, in an attempt to improve on the performance characteristics of the airfoil, whilst still maintaining a similar level of compromise between the design objectives. The solution variance is controlled by  $\delta = 5 \times 10^{-3}$ .

The design application is segregated into three phases: pre-optimization and variable screening; optimization and; post-optimization and trade-off screening.

### 67.4.1 Pre-Optimization and Variable Screening

Global Kriging models are constructed for the aerodynamic coefficients from a stratified sample of  $N = 100$  design points based on a Latin hypercube design. This sampling plan size is considered sufficient in order to obtain sufficient confidence in the results of the subsequent design variable screening analysis. Whilst a larger sampling plan is essential to obtain fairly accurate correlation, the interest here is to quantify the elementary effect of each variable to the objective landscapes. The global Kriging models are initially trained via cross-validation. The cross-validation curves for the Kriging models are illustrated in Fig. 67.10. The subscripts to the aerodynamic coefficients refer to the respective angle of incidence.

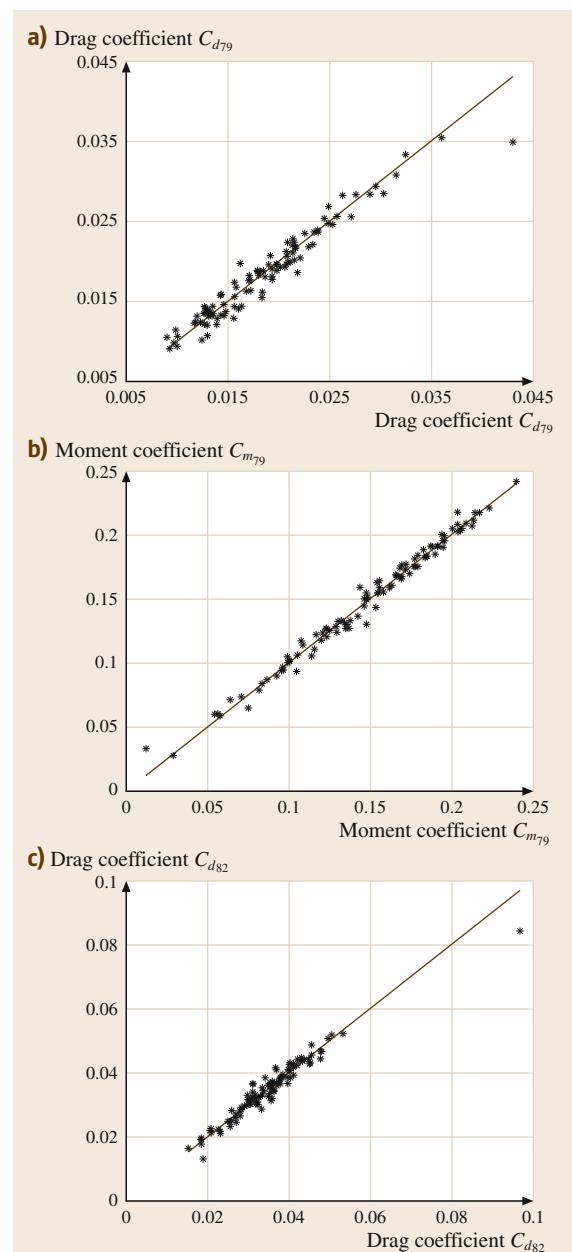

It is observed in Fig. 67.10 that the Kriging models constructed for the aerodynamic coefficients are able to reproduce the training samples with sufficient confidence, recording error margin values between 2 to 4%. It is hence concluded that the Kriging method is very adept at modeling complex landscapes represented by a limited number of precise observations.

To investigate the elementary effect of each design variable on the metamodeled objective landscapes, we present a quantitative design space visualization technique. A popular method for designing preliminary experiments for design space visualization is the screening method developed by Morris [67.53]. This algorithm calculates the elementary effect of a variable  $x_i$  and establishes its correlation with the objective space  $f$  as:

- a) Negligible
- b) Linear and additive
- c) Nonlinear
- d) Nonlinear and/or involved in interactions with  $x_j$ .

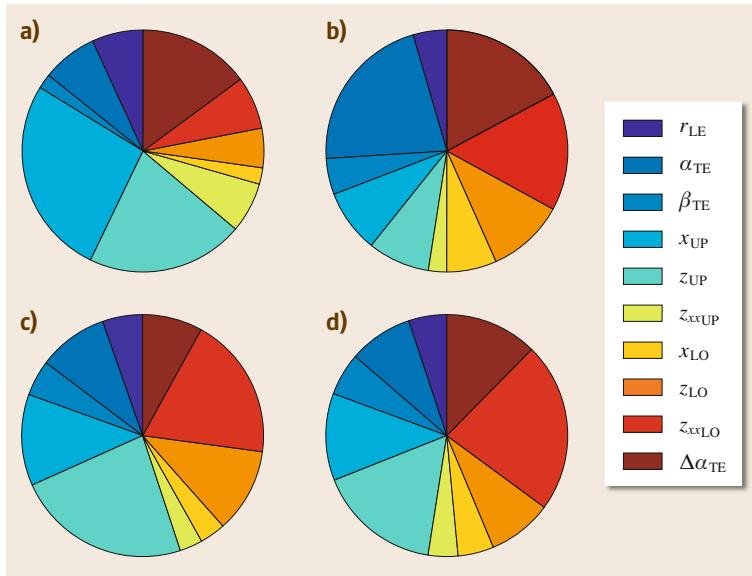

**Table 67.2** NASA-SC(2)0410 airfoil results for the formulated objectives

| Airfoil        | Mach number, $M$ | $f_1$    | $f_2$  | $f_3$    |
|----------------|------------------|----------|--------|----------|
| NASA-SC(2)0410 | 0.79             | 0.008708 | 0.1024 | 0.189625 |

**Fig. 67.10a–c** Cross-validation curves for the constructed Kriging models. (a) Training sample for  $C_d$  at  $M = 0.79$ . (b) Training sample for  $C_m$  at  $M = 0.79$ . (c) Training sample for  $C_d$  at  $M = 0.82$

In plain terminology, the Morris algorithm measures the sensitivity of the  $i$ -th variable to the objective landscape  $f$ . For a detailed discussion on the Morris al-

**Fig. 67.11a–d** Variable influence on aerodynamic coefficients (subscripts refer to the operating Mach number). (a) Drag  $C_{d79}$ . (b) Moment  $C_{m79}$ . (c) Drag  $C_{d82}$ . (d)  $d_z$

gorithm the reader is referred to *Forrester et al.* [67.40] and *Campolongo et al.* [67.54]. Presented here are the results of the variable screening analysis using the Morris algorithm for the proposed design application.

Figure 67.11 graphically shows the results obtained from the design variable screening study. It is immediately observed that the upper thickness coordinates have a relatively large influence on the drag coefficient for both design conditions. At higher Mach numbers the effect of the lower surface curvature  $z_{xxLO}$  is also significant. It is demonstrated, however, that the variables  $z_{xxLO}$  and  $\alpha_{TE}$  have the largest effect on the moment coefficient – variables which directly influence the aft camber (and hence the aft camber) on the airfoil. These variables will no doubt shift the loading on the airfoil forward and aft, resulting in highly fluctuating moment values.

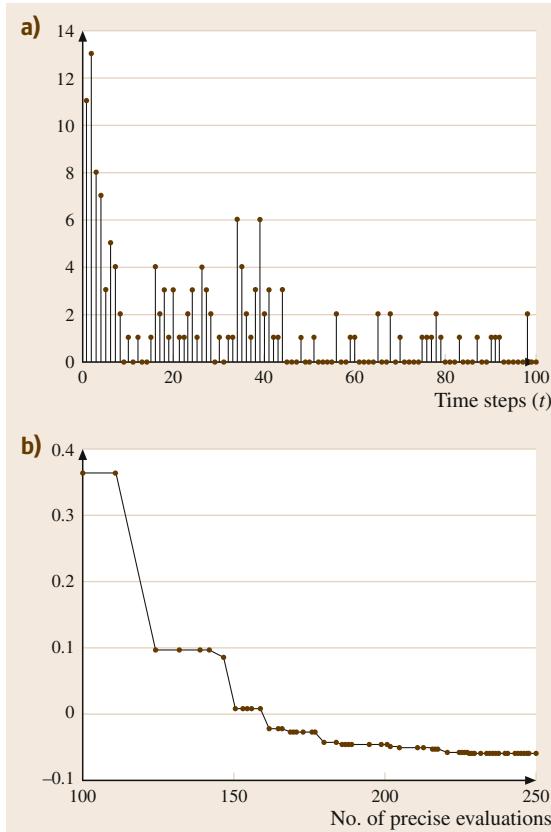

Similar deductions can be made by examining the variable influence on  $d_z$  shown in Fig. 67.11d. The variable influence on  $d_z$  is case specific and entirely dependent on the reference point chosen for the proposed optimization study. Since the value of  $d_z$  is a means of ranking the success of a multiobjective solution as one single scalar, variables may be ranked by influence, which is otherwise not possible when considering a multiobjective array. Preliminary conclusions to the priority weighting of the objectives to the reference point compromise can also be made. It is observed that the variable influence on  $d_z$  most closely resembles the plots of the drag coefficients  $C_{d79}$  and  $C_{d82}$ , suggesting

that the moment coefficient is of least priority for the preferred compromise. It is interesting to see that the trailing edge modification variable  $\Delta\alpha_{TE}$  is of particular importance for all design coefficients, which validates its inclusion in the subsequent optimization study.

## 67.4.2 Optimization Results

A swarm population of  $N_s = 100$  particles is flown to solve the optimization problem. The objective space is normalized for the computation of the reference point distance by  $f_{\max} - f_{\min}$ . Instead of specifying a maximum number of time steps, a computational budget of 250 evaluations is imposed. A stratified sample of  $N = 100$  design points using an LHS methodology was used to construct the initial global Kriging approximations for each objective. A further 150 precise updates were performed over  $t \approx 100$  time steps until the computational budget was breached. As is shown in Fig. 67.12a, the largest number of update points was recorded during the initial explorative phase. As the preferred region becomes populated and  $\hat{s} \rightarrow 0$ , the algorithm triggers exploitation, and the number of update points steadily reduces.

The UPMOPSO algorithm has proven to be very capable for this specific problem. Figure 67.12b features the progress of the highest ranked solution (i.e.,  $d_{\min}$ ) as the number of precise evaluations increase. The reference point criterion is shown to be proficient in filtering out poorer solutions during exploration, since it

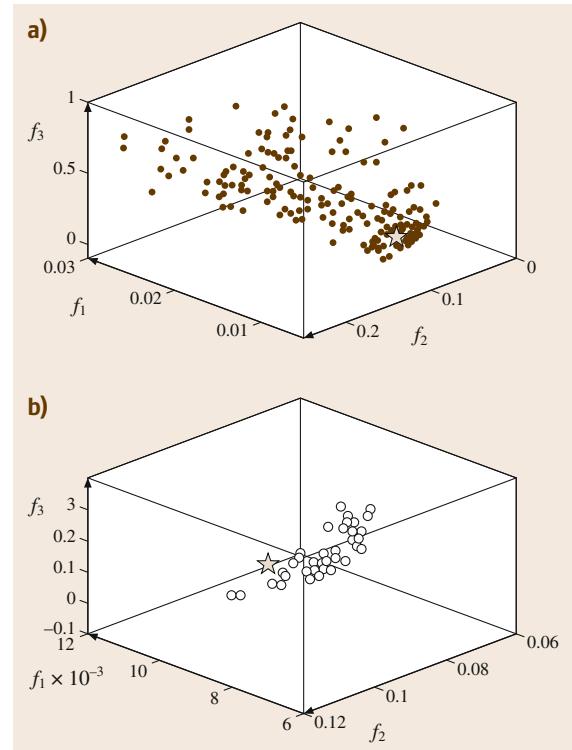

**Fig. 67.12a,b** UPMOPSO performance for transonic airfoil shape optimization. **(a)** History of precise updates. **(b)** Progress of most preferred solution

is only required to reach 50 update evaluations within 15% of  $d_{\min}$ , and to reach a further 50 evaluations within 3%. Furthermore, no needless evaluations as a result of the lower-bound prediction are performed during the exploitation phase. This conclusion is further complemented by Fig. 67.13a, as a distinct attraction to the preferred region is clearly visible. A total of 30 non-dominated solutions were identified in the preferred region, which are shown in Fig. 67.13b.

### 67.4.3 Post-Optimization and Trade-Off Visualization

The reference point distance also provides a feasible means of selecting the most appropriate solutions. For example, solutions may be ranked according to how well they represent the reference point compromise. To illustrate this concept, self-organizing maps

**Fig. 67.13a,b** Precise evaluations performed and the resulting non-dominated solutions. **(a)** Scatter plot of all precise evaluations. **(b)** Preferred region 250 evaluations

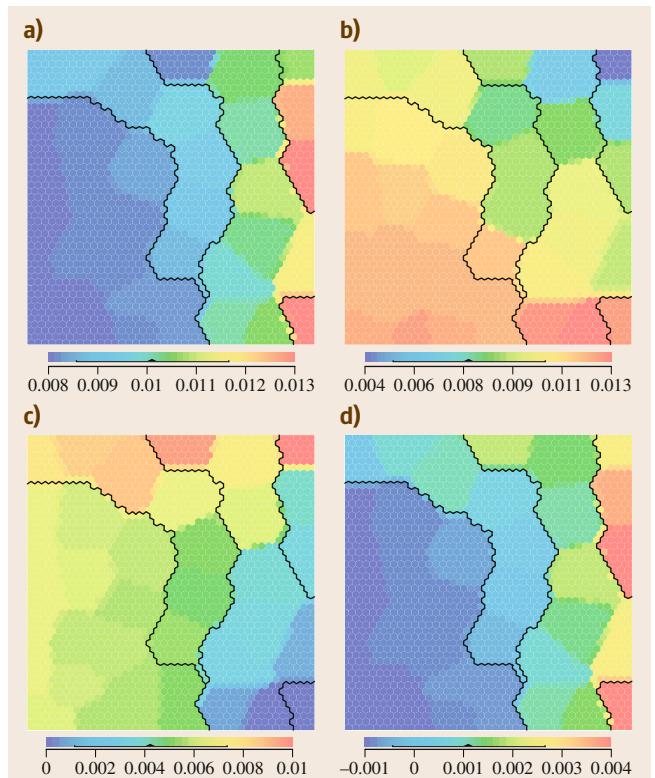

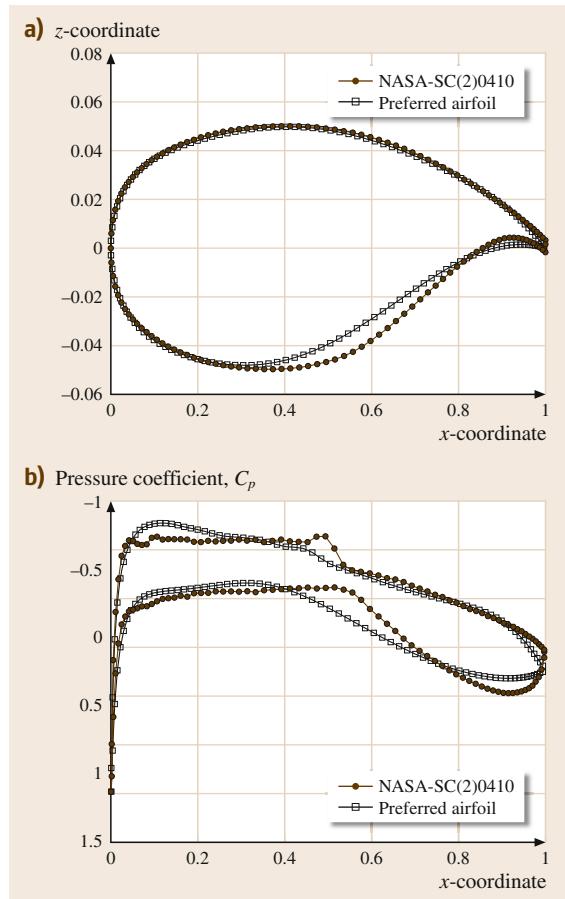

(SOMs) [67.44] are utilized to visualize the interaction of the objectives with the reference point compromise. Clustering SOM techniques are based on a technique of unsupervised artificial neural networks that can classify, organize, and visualize large sets of data from a high to low-dimensional space [67.45]. A neuron used in this SOM analysis is associated with the weighted vector of  $m$  inputs. Each neuron is connected to its adjacent neurons by a neighborhood relation and forms a two-dimensional hexagonal topology [67.45]. The SOM learning algorithm will attempt to increase the correlation between neighboring neurons to provide a global representation of all solutions and their corresponding resemblance to the reference point compromise.

Each input objective acts as a neuron to the SOM. The corresponding output measures the reference point distance (i.e., the resemblance to the reference point compromise). A two-dimensional representation of the data is presented in Fig. 67.14, organized by six SOM-ward clusters. Solutions that yield negative  $d_z$  values

**Table 67.3** Preferred airfoil objective values with measure of improvement

| Airfoil          | $f_1$    | $f_2$  | $f_3$    |
|------------------|----------|--------|----------|
| NASA-SC(2)0410   | 0.008708 | 0.1024 | 0.189625 |
| Preferred design | 0.008106 | 0.0933 | 0.168809 |
| % Improvement    | 6.9      | 8.8    | 10.9     |

indicate success in the improvement over each aspiration value. Solutions with positive  $d_z$  values do not surpass each aspiration value but provide significant improvement in at least one other objective. Each of the node values represent one possible Pareto-optimal solution that the designer may select. The SOM chart colored by  $d_z$  is a measure of how far a solution deviates from the preferred compromise. However, the concept of the preferred region ensures that only solutions that slightly deviate from the compromise dictated by  $\bar{z}$  are identified. Following the SOM charts, it is possible to

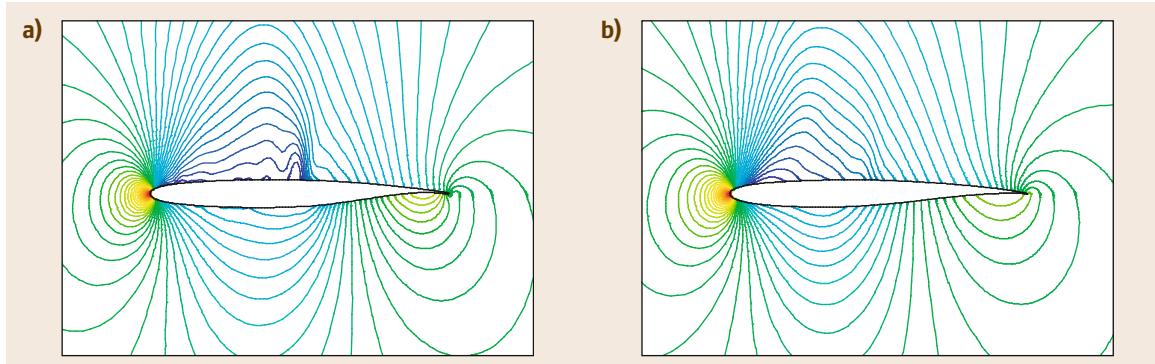

**Fig. 67.14** SOM charts to visualize optimal trade-offs between the design objectives. (a)  $f_1$ , (b)  $f_2$ , (c)  $f_3$ , (d)  $d_z$

visualize the preferred compromise between the design objectives that is obtained. The chart of  $d_z$  closely follows the  $f_1$  chart, which suggests that this objective has the highest priority. If the designer were slightly more inclined towards another specific design objective, then solutions that perhaps place more emphasis on the other objectives should be considered. In this study, the most preferred solution is ideally selected as the highest ranked solution according to (67.5).

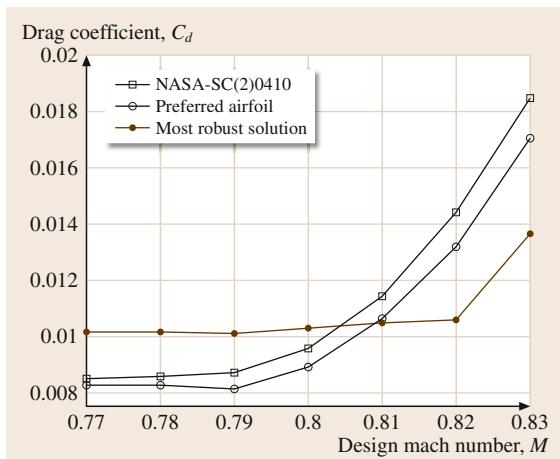

#### 67.4.4 Final Designs

Table 67.3 shows the objective comparisons with the NASA-SC(2)0410. Of interest to note is that the most active objective is  $f_1$ , since the solution which provides the minimum  $d_z$  values also provides the minimum  $f_1$  value. This implies that the reference point was sit-

**Fig. 67.15a,b** The most preferred solution observed by the UPMOPSO algorithm. (a) Preferred airfoil geometry. (b)  $C_p$  distributions for  $M = 0.79$ ,  $C_l = 0.4$  ▶

**Fig. 67.16a, b** Pressure contours for design condition of  $M = 0.79$ ,  $C_l = 0.4$ . (a) NASA-SC(2)0410, (b) Preferred airfoil

**Fig. 67.17** Drag rise curves for  $C_l = 0.4$

uated near the  $f_1$  Pareto boundary. Of the identified set of Pareto-optimal solutions, the largest improvements obtained in objectives  $f_2$  and  $f_3$  are 36.4 and 91.6%, respectively, over the reference point. The preferred airfoil geometry is shown in Fig. 67.15a in comparison with the NASA-SC(2)0410. The preferred airfoil has a thickness of 9.76% chord and maintains a moderate curvature over the upper surface. A relatively small aft curvature is used to gener-

ate the required lift, whilst reducing the pitching moment.

Performance comparisons between the NASA-SC(2)0410 and the preferred airfoil at the design condition of  $M = 0.79$  can be made from the static pressure contour output in Fig. 67.16, and the surface pressure distribution of Fig. 67.15b. The reduction in  $C_d$  is attributed to the significantly weaker shock that appears slightly upstream of the supercritical shock position. The reduction in the pitching moment is clearly visible from the reduced aft loading. Along with the improvement at the required design condition, the preferred airfoil exhibits a lower drag rise by comparison, as is shown in Fig. 67.17. There is a notable decline in the drag rise at the design condition of  $M = 0.79$ , and the drag is recorded as lower than the NASA-SC(2)0410, even beyond the design range. Also visible is the solution that provides the most robust design (i. e.,  $\min f_3$ ). The most robust design is clearly not obtained at the expense of poor performance at the design condition, due to the compromising influence of  $\bar{z}$ . If the designer were interested in obtaining further alternative solutions which provide greater improvement in either objective, it would be sufficient to re-commence (at the current time step) the optimization process with a larger value of  $\delta$ , or by relaxing one or more of the aspiration values,  $\bar{z}_i$ .

## 67.5 Conclusion

In this chapter, an optimization framework has been introduced and applied to the aerodynamic design of transonic airfoils. A surrogate-driven multiobjective particle swarm optimization algorithm is applied to navigate the design space to identify and exploit preferred regions of the Pareto frontier. The integration of all components of the optimization framework is entirely achieved through the use of a reference point distance metric which provides a scalar measure of the preferred interests of the designer. This effectively allows for the scale of the design space to be reduced, confining it to the interests reflected by the designer.

The developmental effort that is reported on here is to reduce the often prohibitive computational cost of multiobjective optimization to the level of practical affordability in computational aerodynamic design. A concise parameterization model was considered to perform the necessary shape modifications in conjunction with a Reynolds-averaged Navier–Stokes flow solver. Kriging models were constructed based on a stratified sample of the design space. A pre-optimization visualization tool was then applied to

screen variable elementary influence and quantify its relative influence to the preferred interests of the designer. Initial design drivers were easily identified and an insight to the optimization landscape was obtained. Optimization was achieved by driving a surrogate-assisted particle swarm towards a sector of special interest on the Pareto front, which is shown to be an effective and efficient mechanism. It is observed that there is a distinct attraction towards the preferred region dictated by the reference point, which implies that the reference point criterion is adept at filtering out solutions that will disrupt or deviate from the optimal search path.

Non-dominated solutions that provide significant improvement over the reference geometry were identified within the computational budget imposed and are clearly reflective of the preferred interest. A post-optimization data mining tool was finally applied to facilitate a qualitative trade-off visualization study. This analysis provides an insight into the relative priority of each objective and their influence on the preferred compromise.

# 68. Ant Colony Optimization for the Minimum-Weight Rooted Arborescence Problem

Christian Blum, Sergi Mateo Bellido

The minimum-weight rooted arborescence problem is an *NP-hard* combinatorial optimization problem which has important applications, for example, in computer vision. An example of such an application is the automated reconstruction of consistent tree structures from noisy images. In this chapter, we present an ant colony optimization approach to tackle this problem. Ant colony optimization is a metaheuristic which is inspired by the foraging behavior of ant colonies. By means of an extensive computational evaluation, we show that the proposed approach has advantages over an existing heuristic from the literature, especially for what concerns rather dense graphs.

## 68.1 Introductory Remarks

Solving combinatorial optimization problems with approaches from the swarm intelligence field has already a considerably long tradition. Examples of such approaches include particle swarm optimization (**PSO**) [68.1] and artificial bee colony (**ABC**) optimization [68.2]. The oldest – and most widely used – algorithm from this field, however, is ant colony optimization (**ACO**) [68.3]. In general, the **ACO** metaheuristic attempts to solve a combinatorial optimization problem by iterating the following steps: (1) Solutions to the problem at hand are constructed using a pheromone model, that is, a parameterized probability distribution over the space of all valid solutions, and (2) (some of) these solutions are used to change the pheromone values in a way being aimed at biasing subsequent sampling toward areas of the search space containing high quality solutions. In particular, the reinforcement of solution components depending on the quality of the solutions in which they appear is an important aspect of **ACO** algorithms. It is implicitly assumed that good solutions consist of good solution components. To learn

which components contribute to good solutions most often helps assembling them into better solutions.

In this chapter, **ACO** is applied to solve the minimum-weight rooted arborescence (**MWRA**) problem, which has applications in computer vision such as, for example, the automated reconstruction of consistent tree structures from noisy images [68.4]. The structure of this chapter is as follows. Section 68.2 provides a detailed description of the problem to be tackled. Then, in Sect. 68.3 a new heuristic for the **MWRA** problem is presented which is based on the deterministic construction of an arborescence of maximal size, and the subsequent application of dynamic programming (**DP**) for finding the best solution within this constructed arborescence. The second contribution is to be found in the application of **ACO** [68.3] to the **MWRA** problem. This algorithm is described in Sect. 68.4. Finally, in Sect. 68.5 an exhaustive experimental evaluation of both algorithms in comparison with an existing heuristic from the literature [68.5] is presented. The chapter is concluded in Sect. 68.6.

## 68.2 The Minimum-Weight Rooted Arborescence Problem

As mentioned before, in this work we consider the **MWRA** problem, which is a generalization of the problem proposed by Venkata Rao and Sridharan in [68.5, 6]. The **MWRA** problem can technically be described as follows. Given is a directed acyclic graph  $G = (V, A)$  with integer weights on the arcs, that is, for each  $a \in A$  exists a corresponding weight  $w(a) \in \mathbb{Z}$ . Moreover, a vertex  $v_r \in V$  is designated as the *root vertex*. Let  $\mathcal{A}$  be the set of all arborescences in  $G$  that are rooted in  $v_r$ . In this context, note that an arborescence is a directed, rooted tree in which all arcs point away from the root vertex (see also [68.7]). Moreover, note that  $\mathcal{A}$  contains all arborescences, not only those with maximal size. The objective function value (that is, the

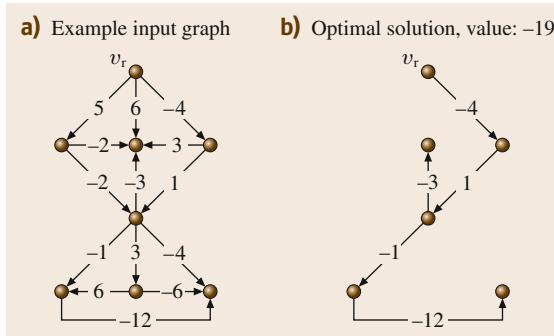

weight)  $f(T)$  of an arborescence  $T \in \mathcal{A}$  is defined as follows:

$$f(T) := \sum_{a \in T} w(a). \quad (68.1)$$

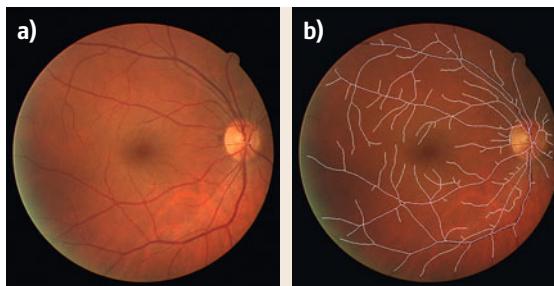

The goal of the **MWRA** problem is to find an arborescence  $T^* \in \mathcal{A}$  such that the weight of  $T^*$  is smaller or equal to all other arborescences in  $\mathcal{A}$ . In other words, the goal is to minimize objective function  $f(\cdot)$ . An example of the **MWRA** problem is shown in Fig. 68.1.

The differences to the problem proposed in [68.5] are as follows. The authors of [68.5] require the root vertex  $v_r$  to have only one single outgoing arc. Moreover, numbering the vertices from 1 to  $|V|$ , the given acyclic graph  $G$  is restricted to contain only arcs  $a_{i,j}$  such that  $i < j$ . These restrictions do not apply to the **MWRA** problem. Nevertheless, as a generalization of the problem proposed in [68.5], the **MWRA** problem is NP-hard. Concerning the existing work, the literature only offers the heuristic proposed in [68.5], which can also be applied to the more general **MWRA** problem.

The definition of the **MWRA** problem as previously outlined is inspired by a novel method which was recently proposed in [68.4] for the automated reconstruction of consistent tree structures from noisy images, which is an important problem, for example, in Neuroscience. Tree-like structures, such as dendritic, vascular, or bronchial networks, are pervasive in biological systems. Examples are 2D retinal fundus images and 3D optical micrographs of neurons. The approach proposed in [68.4] builds a set of candidate arborescences over many different subsets of points likely to belong to the optimal delineation and then chooses the best one according to a global objective function that combines image evidence with geometric priors (Fig. 68.2, for example). The solution of the **MWRA** problem (with additional hard and soft constraints) plays an important role in this process. Therefore, developing better algorithms for the **MWRA** problem may help in composing better techniques for the problem of the automated reconstruction of consistent tree structures from noisy images.

**Fig. 68.1a,b** (a) An input DAG with eight vertices and 14 arcs. The uppermost vertex is the root vertex  $v_r$ . (b) The optimal solution, that is, the arborescence rooted in  $v_r$  which has the minimum weight among all arborescences rooted in  $v_r$  that can be found in the input graph

**Fig. 68.2a,b** (a) A 2D image of the retina of a human eye. The problem consists in the automatic reconstruction (or delineation) of the vascular structure. (b) The reconstruction of the vascular structure as produced by the algorithm proposed in [68.4]

## 68.3 DP-HEUR: A Heuristic Approach to the MWRA Problem

In this section, we propose a new heuristic approach for solving the MWRA problem. First, starting from the root vertex  $v_r$ , a spanning arborescence  $T'$  in  $G$  is constructed as outlined in lines 2–9 of Algorithm 68.1. Second, a DP algorithm is applied to  $T'$  in order to obtain the minimum-weight arborescence  $T$  that is contained in  $T'$  and rooted in  $v_r$ . The DP algorithm from [68.8] is used for this purpose. Given an undirected tree  $T = (V_T, E_T)$  with vertex and/or edge weights, and any integer number  $k \in [0, |V_T| - 1]$ , this DP algorithm provides – among all trees with exactly  $k$  edges in  $T$  – the minimum-weight tree  $T^*$ . The first step of the DP algorithm consists in artificially converting the input tree  $T$  into a rooted arborescence. Therefore, the DP algorithm can directly be applied to arborescences. Moreover, as a side product, the DP algorithm also provides the minimum-weight arborescences for all  $l$  with  $0 \leq l \leq k$ , as well as the minimum-weight arborescences rooted in  $v_r$  for all  $l$  with  $0 \leq l \leq k$ . Therefore, given an arborescence of maximal size  $T'$ , which has  $|V| - 1$  arcs (where  $V$  is the vertex set of the input graph  $G$ ), the DP algorithm is applied with  $|V| - 1$ . Then, among all the minimum-weight arborescences rooted in  $v_r$  for  $l \leq |V| - 1$ , the one with minimum weight is chosen as the output of the DP

algorithm. In this way, the DP algorithm is able to generate the minimum-weight arborescence  $T$  (rooted in  $v_r$ ) which can be found in arborescence  $T'$ . The heuristic described above is henceforth labeled DP-HEUR. As a final remark, let us mention that for the description of this heuristic, it was assumed that the input graph is connected. Appropriate changes have to be applied to the description of the heuristic if this is not the case.

---

**Algorithm 68.1 Heuristic DP-HEUR for the MWRA problem**

```

1: input: a DAG  $G = (V, A)$ , and a root node  $v_r$ 
2:  $T'_0 := (V'_0 = \{v_r\}, A'_0 = \emptyset)$ 
3:  $A_{\text{pos}} := \{a = (v_q, v_l) \in A \mid v_q \in V'_0, v_l \notin V'_0\}$ 
4: for  $i = 1, \dots, |V| - 1$  do
5:    $a^* = (v_q, v_l) := \operatorname{argmin}\{w(a) \mid a \in A_{\text{pos}}\}$ 
6:    $A'_i := A'_{i-1} \cup \{a^*\}$ 
7:    $V'_i := V'_{i-1} \cup \{v_l\}$ 
8:    $T'_i := (V'_i, A'_i)$ 
9:    $A_{\text{pos}} := \{a = (v_q, v_l) \in A \mid v_q \in V'_i, v_l \notin V'_i\}$ 
10: end for
11:  $T := \text{Dynamic\_Programming}(T'_{|V|-1}, k = |V| - 1)$ 
12: output: arborescence  $T$ 

```

## 68.4 Ant Colony Optimization for the MWRA Problem

The ACO approach for the MWRA problem which is described in the following is a MAX-MIN Ant System (MMAS) [68.9] implemented in the hyper-cube framework (HCF) [68.10]. The algorithm, whose pseudocode can be found in Algorithm 68.2, works roughly as follows. At each iteration, a number of  $n_a$  solutions to the problem is probabilistically constructed based on both pheromone and heuristic information. The second algorithmic component which is executed at each iteration is the pheromone update. Hereby, some of the constructed solutions – that is, the iteration-best solution  $T^{\text{ib}}$ , the restart-best solution  $T^{\text{rb}}$ , and the best-so-far solution  $T^{\text{bs}}$  – are used for a modification of the pheromone values. This is done with the goal of focusing the search over time on high-quality areas of the search space. Just like any other MMAS algorithm, our approach employs restarts consisting of a re-initialization of the pheromone values. Restarts are controlled by the so-called convergence factor ( $\text{cf}$ ) and

a Boolean control variable called  $bs\_update$ . The main functions of our approach are outlined in detail in the following.

---

**Algorithm 68.2 Ant Colony Optimization for the MWRA Problem**

```

1: input: a DAG  $G = (V, A)$ , and a root node  $v_r$ 
2:  $T^{\text{bs}} := (\{v_r\}, \emptyset)$ ,  $T^{\text{rb}} := (\{v_r\}, \emptyset)$ ,  $\text{cf} := 0$ ,
    $bs\_update := \text{false}$ 
3:  $\tau_a := 0.5$  for all  $a \in A$ 
4: while termination conditions not met do
5:    $S := \emptyset$ 
6:   for  $i = 1, \dots, n_a$  do
7:      $T := \text{Construct\_Solution}(G, v_r)$ 
8:      $S := S \cup \{T_i\}$ 
9:   end for
10:   $T^{\text{ib}} := \operatorname{argmin}\{f(T) \mid T \in S\}$ 
11:  if  $T^{\text{ib}} < T^{\text{rb}}$  then  $T^{\text{rb}} := T^{\text{ib}}$ 
12:  if  $T^{\text{ib}} < T^{\text{bs}}$  then  $T^{\text{bs}} := T^{\text{ib}}$ 

```

```

14:   cf := ComputeConvergenceFactor(T)
15:   if cf > 0.99 then
16:     if bs_update = true then
17:        $\tau_a := 0.5$  for all  $a \in A$ 
18:        $T^b := (\{v_r\}, \emptyset)$ 
19:       bs_update := false
20:     else
21:       bs_update := true
22:     end if
23:   end if
24: end while
25: output:  $T^{bs}$ , the best solution found by the algorithm

```

**Construct\_Solution**( $G, v_r$ ): This function, first, constructs a spanning arborescence  $T'$  in the way which is shown in lines 2–9 of Algorithm 68.1. However, the choice of the next arc to be added to the current arborescence at each step (see line 5 of Algorithm 68.1) is done in a different way. Instead of deterministically choosing from  $A_{pos}$ , the arc which has the smallest weight value, the choice is done probabilistically, based on pheromone and heuristic information. The pheromone model  $\mathcal{T}$  that is used for this purpose contains a pheromone value  $\tau_a$  for each arc  $a \in A$ . The heuristic information  $\eta(a)$  of an arc  $a$  is computed as follows. First, let

$$w_{max} := \max\{w(a) \mid a \in A\}. \quad (68.2)$$

Based on this maximal weight of all arcs in  $G$ , the heuristic information is defined as follows:

$$\eta(a) := w_{max} + 1 - w(a). \quad (68.3)$$

In this way, the heuristic information of all arcs is a positive number. Moreover, the arc with minimal weight will have the highest value concerning the heuristic information. Given an arborescence  $T'_i$  (obtained after the  $i$ th construction step), and the nonempty set of arcs  $A_{pos}$  that may be used for extending  $T'_i$ , the probability for choosing arc  $a \in A_{pos}$  is defined as follows

$$\mathbf{p}(a \mid T'_i) := \frac{\tau_a \cdot \eta(a)}{\sum_{\hat{a} \in A_{pos}} \tau_{\hat{a}} \cdot \eta(\hat{a})}. \quad (68.4)$$

However, instead of choosing an arc from  $A_{pos}$  always in a probabilistic way, the following scheme is applied at each construction step. First, a value  $r \in [0, 1]$  is chosen uniformly at random. Second,  $r$  is compared to

a so-called *determinism rate*  $\delta \in [0, 1]$ , which is a fixed parameter of the algorithm. If  $r \leq \delta$ , arc  $a^* \in A_{pos}$  is chosen to be the one with the maximum probability, that is

$$a^* := \operatorname{argmax}\{\mathbf{p}(a \mid T'_i) \mid a \in A_{pos}\}. \quad (68.5)$$

Otherwise, that is, when  $r > \delta$ , arc  $a^* \in A_{pos}$  is chosen probabilistically according to the probability values.

The output  $T$  of the function **Construct\_Solution**( $G, v_r$ ) is chosen to be the minimum-weight arborescence which is encountered during the process of constructing  $T'$ , that is,

$$T := \operatorname{argmin}\{f(T'_i) \mid i = 0, \dots, |V| - 1\}.$$

**ApplyPheromoneUpdate**(*cf, bs\_update, T, T<sup>ib</sup>, T<sup>rb</sup>, T<sup>bs</sup>*): The pheromone update is performed in the same way as in all *MMAS* algorithms implemented in the **HCF**. The three solutions  $T^{ib}$ ,  $T^{rb}$ , and  $T^{bs}$  (as described at the beginning of this section) are used for the pheromone update. The influence of these three solutions on the pheromone update is determined by the current value of the convergence factor *cf*, which is defined later. Each pheromone value  $\tau_a \in \mathcal{T}$  is updated as follows:

$$\tau_a := \tau_a + \rho \cdot (\xi_a - \tau_a), \quad (68.6)$$

where

$$\xi_a := \kappa_{ib} \cdot \Delta(T^{ib}, a) + \kappa_{rb} \cdot \Delta(T^{rb}, a) + \kappa_{bs} \cdot \Delta(T^{bs}, a), \quad (68.7)$$

where  $\kappa_{ib}$  is the weight of solution  $T^{ib}$ ,  $\kappa_{rb}$  the one of solution  $T^{rb}$ , and  $\kappa_{bs}$  the one of solution  $T^{bs}$ . Moreover,  $\Delta(T, a)$  evaluates to 1 if and only if arc  $a$  is a component of arborescence  $T$ . Otherwise, the function evaluates to 0. Note also that the three weights must be chosen such that  $\kappa_{ib} + \kappa_{rb} + \kappa_{bs} = 1$ . After the application

**Table 68.1** Setting of  $\kappa_{ib}$ ,  $\kappa_{rb}$ , and  $\kappa_{bs}$  depending on the convergence factor **cf** and the Boolean control variable *bs\_update*

|               | <i>bs_update</i> = FALSE |                        |                 | <i>bs_update</i><br>TRUE |
|---------------|--------------------------|------------------------|-----------------|--------------------------|
|               | <i>cf</i> < 0.7          | <i>cf</i> ∈ [0.7, 0.9] | <i>cf</i> ≥ 0.9 |                          |
| $\kappa_{ib}$ | 2/3                      | 1/3                    | 0               | 0                        |
| $\kappa_{rb}$ | 1/3                      | 2/3                    | 1               | 0                        |
| $\kappa_{bs}$ | 0                        | 0                      | 0               | 1                        |

of (68.6), pheromone values that exceed  $\tau_{\max} = 0.99$  are set back to  $\tau_{\max}$ , and pheromone values that have fallen below  $\tau_{\min} = 0.01$  are set back to  $\tau_{\min}$ . This prevents the algorithm from reaching a state of complete convergence. Finally, note that the exact values of the weights depend on the convergence factor  $cf$  and on the value of the Boolean control variable  $bs\_update$ . The standard schedule as shown in Table 68.1 has been adopted for our algorithm.

**ComputeConvergenceFactor( $\mathcal{T}$ ):** The convergence factor ( $cf$ ) is computed on the basis of the

pheromone values

$$cf := 2 \left( \left( \frac{\sum_{\tau_a \in \mathcal{T}} \max\{\tau_{\max} - \tau_a, \tau_a - \tau_{\min}\}}{|\mathcal{T}| \cdot (\tau_{\max} - \tau_{\min})} \right) - 0.5 \right).$$

This results in  $cf = 0$  when all pheromone values are set to 0.5. On the other side, when all pheromone values have either value  $\tau_{\min}$  or  $\tau_{\max}$ , then  $cf = 1$ . In all other cases,  $cf$  has a value in (0, 1). This completes the description of all components of the proposed algorithm, which is henceforth labeled ACO.

## 68.5 Experimental Evaluation

The algorithms proposed in this chapter – that is, DP-HEUR and ACO – were implemented in ANSI C++ using GCC 4.4 for compiling the software. Moreover, the heuristic proposed in [68.5] was reimplemented. As mentioned before, this heuristic – henceforth labeled VENSRI – is the only existing algorithm which can directly be applied to the MWRA problem. All three algorithms were experimentally evaluated on a cluster of PCs equipped with Intel Xeon X3350 processors with 2667 MHz and 8 Gb of memory. In the following, we first describe the set of benchmark instances that have been used to test the three algorithms. Afterward, the algorithm tuning and the experimental results are described in detail.

### 68.5.1 Benchmark Instances

A diverse set of benchmark instances was generated in the following way. Three parameters are necessary for the generation of a benchmark instance  $G = (V, A)$ . Hereby,  $n$  and  $m$  indicate, respectively, the number of vertices and the number of arcs of  $G$ , while  $q \in [0, 1]$  indicates the probability for the weight of any arc to be positive (rather than negative). The process of the generation of an instance starts by constructing a random arborescence  $T$  with  $n$  vertices. The root vertex of  $T$  is called  $v_r$ . Each of the remaining  $m - n + 1$  arcs was generated by randomly choosing two vertices  $v_i$  and  $v_j$ , and adding the corresponding arc  $a = (v_i, v_j)$  to  $T$ . In this context,  $a = (v_i, v_j)$  may be added to  $T$ , if and only if by its addition no directed cycle is produced, and neither  $(v_i, v_j)$  nor  $(v_j, v_i)$  form already part of the graph. The weight of each arc was chosen by, first, deciding with probability  $q$  if the weight is to be positive (or nonpositive). In the case of a positive weight, the weight value

was chosen uniformly at random from [1, 100], while in the case of a nonpositive weight, the weight value was chosen uniformly at random from [-100, 0].

In order to generate a diverse set of benchmark instances, the following values for  $n$ ,  $m$ , and  $q$  were considered:

- $n \in \{20, 50, 100, 500, 1000, 5000\}$ ;
- $m \in \{2n, 4n, 6n\}$ ;
- $q \in \{0.25, 0.5, 0.75\}$ .

For each combination of  $n$ ,  $m$ , and  $q$ , a total of 10 problem instances were generated. This resulted in a total of 540 problem instances, that is, 180 instances for each value of  $q$ .

### 68.5.2 Algorithm Tuning

The proposed ACO algorithm has several parameters that require appropriate values. The following parameters, which are crucial for the working of the algorithm, were chosen for tuning:

- $n_a \in \{3, 5, 10, 20\}$ : the number of ants (solution constructions) per iteration;
- $\rho \in \{0.05, 0.1, 0.2\}$ : the learning rate;
- $\delta \in \{0.0, 0.4, 0.7, 0.9\}$ : the determinism rate.

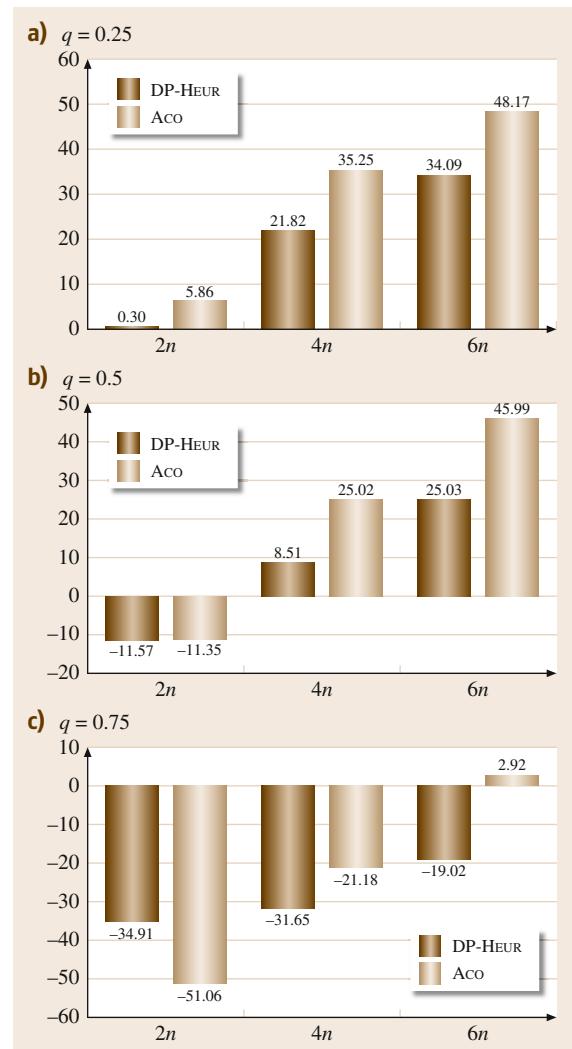

We chose the first problem instance (out of 10 problem instances) for each combination of  $n$ ,  $m$ , and  $q$  for tuning. A full factorial design was utilized. This means that ACO was applied (exactly once) to each of the problem instances chosen for tuning. The stopping criterion was fixed to 20 000 solution evaluations for each application of ACO. For analyzing the results, we used

a rank-based analysis. However, as the set of problem instances is quite diverse, this rank-based analysis was performed separately for six subsets of instances. For defining these subsets, we refer to the instances with  $n \in \{20, 50, 100\}$  as *small instances*, and the remaining ones as *large instances*. With this definition, each of the three subsets of instances concerning the three different values for  $q$ , was further separated into two subsets concerning the instance size. For each of these six subsets, we used the parameter setting with which ACO achieved the best average rank for the corresponding tuning instances. These parameter settings are given in Table 68.2.

### 68.5.3 Results

The three algorithms considered for the comparison were applied exactly once to each of the 540 problem instances of the benchmark set. Although ACO is a stochastic search algorithm, this is a valid choice, because results are averaged over groups of instances that were generated with the same parameters. As in the case of the tuning experiments, the stopping criterion for ACO was fixed to 20 000 solution evaluations. Tables 68.3–68.5 present the results averaged – for each algorithm – over the 10 instances for each combination of  $n$  and  $m$  (as indicated in the first two table columns). Four table columns are used for presenting the results of each algorithm. The column with heading *value* provides the average of the objective function values of the best solutions found by the respective algorithm for the 10 instances of each combination of  $n$  and  $m$ . The second column (with heading *std*) contains the corresponding standard deviation. The third column (with heading *size*) indicates the average size (in terms of the number of arcs) of the best solutions found by the respective algorithm (remember that solutions – that is, arborescences – may have any number of arcs between 0 and  $|V| - 1$ , where  $|V|$  is the number of the input DAG  $G = (V, A)$ ). Finally, the fourth column (with heading *time (s)*) contains the average computation time (in sec-

onds). For all three algorithms, the computation time indicates the time of the algorithm termination. In the case of ACO, an additional table column (with heading *evals*) indicates at which solution evaluation, on average, the best solution of a run was found. Finally, for each combination of  $n$  and  $m$ , the result of the best-performing algorithm is indicated in bold font.

**Fig. 68.3a–c** Average improvement (in %) of ACO and DP-HEUR over VENSRI. Positive values correspond to an improvement, while negative values indicate that the respective algorithm is inferior to VENSRI. The improvement is shown for the three different arc-densities that are considered in the benchmark set, that is,  $m = 2n$ ,  $m = 4n$ , and  $m = 6n$

**Table 68.2** Parameter setting (concerning ACO) used for the final experiments

Concerning the 180 instances with  $q = 0.25$ , the results allow us to make the following observations. First, ACO is for all combinations of  $n$  and  $m$  the

**Fig. 68.4** These graphics show, for each combination of  $n$  and  $m$ , information about the average size – in terms of the number of arcs – of the solutions produced by DP-HEUR, ACO, and VENSRI

best-performing algorithm. Averaged over all problem instances ACO obtains an improvement of 29.8% over VENSRI. Figure 68.3a shows the average improvement of ACO over VENSRI for three groups of input instances concerning the different arc densities. It is interesting to observe that the advantage of ACO over VENSRI seems to grow when the arc density increases. On the downside, these improvements are obtained at the cost of a significantly increased computation time. Concerning heuristic DP-HEUR, we can observe that it improves over VENSRI for all combinations of  $n$  and  $m$ , apart from  $(n = 100, m = 2n)$  and  $(n = 500, m = 2n)$ . This seems to indicate that, also for DP-HEUR, the sparse instances pose more of a challenge than the dense instances. Averaged over all problem instances, DP-HEUR obtains an improvement of 18.6% over VENSRI. The average improvement of DP-HEUR over VENSRI is shown for the three groups of input instances concerning the different arc-densities in Fig. 68.3a. Concerning a comparison of the computation times, we can state that DP-HEUR has a clear advantage over VENSRI especially for large-size problem instances.

Concerning the remaining 360 instances ( $q = 0.5$  and  $q = 0.75$ ), we can make the following additional observations. First, both ACO and DP-HEUR seem to experience a downgrade in performance (in comparison to the performance of VENSRI) when  $q$  increases. This holds especially for rather large and rather sparse graphs. While both algorithms still obtain an average improvement over VENSRI in the case of  $q = 0.5$  – that is, 19.9% improvement in the case of ACO and 7.3% in the case of DP-HEUR – both algorithms are on average inferior to VENSRI in the case of  $q = 0.75$ .

Finally, Fig. 68.4 presents the information which is contained in column *size* of Tables 68.3–68.5 in graphical form. It is interesting to observe that the solutions produced by DP-HEUR consistently seem to be the smallest ones, while the solutions produced by VENSRI seem generally to be the largest ones. The size of the solutions produced by ACO is generally in between these two extremes. Moreover, with growing  $q$  the difference in solution size as produced by the three algorithms seems to be more pronounced. We currently have no explanation for this aspect, which certainly deserves further examination.

## 68.6 Conclusions and Future Work

In this work, we have proposed a heuristic and an ACO approach for the minimum-weight rooted arborescence problem. The heuristic makes use of dynamic programming as a subordinate procedure. Therefore, it may be regarded as a hybrid algorithm. In contrast, the proposed ACO algorithm is a pure metaheuristic approach. The experimental results show that both approaches are superior to an existing heuristic from the literature in those cases in which the number of arcs with positive weights is not too high and in the case of rather dense graphs. However, as far as sparse graphs with a rather

large fraction of positive weights are concerned, the existing heuristic from the literature seems to have advantages over the algorithms proposed in this chapter.

Concerning future work, we plan to develop a hybrid ACO approach which makes use of dynamic programming as a subordinate procedure, in a way similar to the proposed heuristic. Moreover, we plan to implement an integer programming model for the tackled problem – in the line of the model proposed in [68.11] for a related problem – and to solve the model with an efficient integer programming solver.

# 69. An Intelligent Swarm of Markovian Agents

Dario Bruneo, Marco Scarpa, Andrea Bobbio, Davide Cerotti, Marco Gribaudo

We define a Markovian agent model (**MAM**) as an analytical model formed by a spatial collection of interacting Markovian agents (**MAs**), whose properties and behavior can be evaluated by numerical techniques. **MAMs** have been introduced with the aim of providing a flexible and scalable framework for distributed systems of interacting objects, where both the local properties and the interactions may depend on the geographical position. **MAMs** can be proposed to model biologically inspired systems since they are suited to cope with the four common principles that govern swarm intelligence: positive feedback, negative feedback, randomness, and multiple interactions. In the present work, we report some results of a **MAM** for a wireless sensor network (**WSN**) routing protocol based on swarm intelligence, and some preliminary results in utilizing **MAs** for very basic ant colony optimization (**ACO**) benchmarks.

## 69.1 Swarm Intelligence: A Modeling Perspective

Swarm intelligent (**SI**) algorithms are variously inspired from the way in which colonies of biological organisms self-organize to produce a wide diversity of functions [69.1, 2]. Individuals of the colony have a limited knowledge of the overall behavior of the system and follow a small set of rules that may be influenced by the interaction with other individuals or by modifications produced in the environment. The collective behavior of large groups of relatively simple individuals, interacting only locally with few neighboring elements, produces global patterns. Even if many approaches have been proposed that differentiate in many respects, four basic common principles have been isolated that govern **SI**:

- *Positive feedback*
- *Negative feedback*

- *Randomness*
- *Multiple interactions.*

The same four principles also govern a class of algorithms inspired by the expansion dynamics of slime molds in the search for food [69.3, 4], that have been utilized as the base for the generation of routing protocols in wireless sensor networks (**WSNs**).

Through the adoption of the above four principles, it is possible to design distributed, self-organizing, and fault tolerant algorithms able to self-adapt to the environmental changes, that present the following main properties [69.1]:

- i) Single individuals are assumed to be simple with low computational intelligence and communication capabilities.

- ii) Individuals communicate indirectly, through modification of the environment (this property is known as *stigmergy* [69.2]).
- iii) The range of the interaction may be very short; nevertheless, a robust global behavior emerges from the interaction of the nodes.
- iv) The global behavior adapts to topological and environmental changes.

The usual way to study such systems is through simulation, due to the large number of involved individuals that lead to the well-known state explosion problem. Analytical techniques are preferable if, starting from the peculiarities of **SI** systems, they allow to realize effective and scalable models. Along this line, new stochastic entities, called Markovian agents (**MAs**) [69.5, 6] have been introduced with the aim of providing a flexible, powerful, and scalable technique for modeling complex systems of distributed interacting objects, for which feasible analytical and numerical solution algorithms can be implemented. Each object has its own local behavior that can be modified by the mutual interdependences with the other objects. **MAs** are scattered over a geographical area and retain their spatial position so that the local behavior and the mutual interdependencies may be related to their geographical positions and other features like the transmittance characteristics of the interposed medium. **MAs** are modeled by a discrete-state continuous-time finite Markov chain (**CTMC**) whose infinitesimal generator is influenced by the interaction with other **MAs**. The interaction among agents is represented by a *message passing model* combined with a *perception function*. When residing in a state or during a transition, an **MA** is allowed to send messages that are perceived by the other **MAs**, according to a spatial-dependent *perception function*, modifying their behavior. Messages may model real

physical messages (as in **WSNs**) or simply the mutual influences of an **MA** over the other ones.

The flexibility of the **MA** representation, the spatial dependency, and the mutual interaction through message passing and perception function, make **MA** models suited to cope with various biologically inspired mechanisms governed by the four aforementioned principles. In fact, the **MAM**, whose constituent elements are the **MAs**, was specifically studied to cope with the following needs [69.6]:

- i) Provide analytical models that can be solved by numerical techniques, thus avoiding the need of long and expensive simulation runs.
- ii) Provide a flexible and scalable modeling framework for distributed systems of interacting objects.
- iii) Provide a framework in which local properties can be coupled with global properties.
- iv) Local and global properties and interactions may depend on the position of the objects in the space (space-sensitive models).
- v) The solution algorithm self-adapts to variations in the system topology and in the interaction mechanisms.

Interactive Markovian agents have been first introduced in [69.5, 7] for single class **MAs** and then extended to multiclass multimesage Markovian agent model in successive works [69.8–10]. In [69.9, 11, 12], **MAs** have been applied to routing algorithms in **WSNs**, adopting **SI** principles [69.13].

This work describes the structure of **MAMs** and the numerical solution algorithms in Sect. 69.2. Then, applications derived from biological models are presented: a swarm intelligent algorithm for routing protocols in **WSNs** (Sect. 69.3) and a simple ant colony optimization (**ACO**) example (Sect. 69.4).

## 69.2 Markovian Agent Models

The structure of a single **MA** is represented in Fig. 69.1. States  $i, j, \dots, k$  are the states of the **CTMC** representing the **MA**. The transitions among the states are of two possible types and are drawn in a different way:

- Solid lines (like the transition from  $i$  to  $j$  or the self-loops in  $i$  or in  $j$ ) indicate the fixed component of the infinitesimal generator and represent the local or autonomous behavior of the object that is

independent of the interaction with the other **MAs** (like, for instance, the time-to-failure distribution, or the reaction to an external stimulus). Note that we include in the representation also self-loop transitions that require a particular notation since they are not visible in the infinitesimal generator of the **CTMC** [69.14].

- Dashed lines (like the transition from  $i$  to  $k$  or the transitions entering into  $i$  or  $j$  from other states

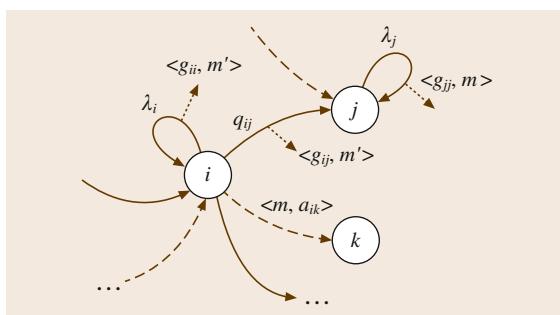

not shown in the figure) represent the transitions induced by the interaction with the other **MAs**. The way in which the rates of the induced transitions are computed is explained in the following section.

During a local transition (or a self-loop) an **MA** can emit a message of any type with an assigned probability, as represented by the dotted arrows in Fig. 69.1 emerging from the solid transitions. The pair  $\langle g_{ij}, m \rangle$  denotes both the message generation probability and the message type. Messages generated by an **MA** may be perceived by other **MAs** with a given probability, according to a suitable perception function, and the interaction mechanism between emitted messages and perceived messages generates the induced transitions (dashed lines). The pair  $\langle m, a_{ik} \rangle$  denotes both the type of the perceived message and the corresponding acceptance probability.

An **MAM** is a collection of interacting **MAs** defined over a geographical space  $\mathcal{V}$ . Given a position  $\mathbf{v}$  inside  $\mathcal{V}$ ,  $\rho(\mathbf{v})$  denotes the density of **MAs** in  $\mathbf{v}$ . According to the definition of the density  $\rho(\mathbf{v})$ , we can classify a **MAM** with the following taxonomy:

- An **MAM** is *static* if  $\rho(\mathbf{v})$  does not depend on time, and *dynamic* if it does depend on time.
- An **MAM** is *discrete* if the geographical area on which the **MAs** are deployed is discretized and  $\rho(\mathbf{v})$  is a discrete function of the space or it is *continuous* if  $\rho(\mathbf{v})$  is a continuous function of the space.

Further, **MAs** may belong to a single class or to different classes with different local behaviors and interaction capabilities, and messages may belong to different types where each type induces a different effect on the interaction mechanism. The perception function describes how a message of a given type emitted by an **MA** of a given class in a given position in the space

**Fig. 69.1** Schematic structure of a Markovian agent

is perceived by an **MA** of a given class in a different position.

### 69.2.1 Mathematical Formulation

A *multiple agent class, multiple message type MAM* is defined by the tuple [69.12]

$$\text{MAM} = \{C, \mathcal{M}, \mathcal{V}, \mathcal{U}, \mathcal{R}\}, \quad (69.1)$$

where  $C = \{1, \dots, C\}$  is the set of agent classes. We denote with  $\text{MA}^c$  an agent of class  $c \in C$ .  $\mathcal{M} = \{1, \dots, M\}$  is the set of message types. Each agent (independently of its class) can send or receive messages of type  $m \in \mathcal{M}$ .  $\mathcal{V}$  is the finite space over which Markovian agents are spread.  $\mathcal{U} = \{u^1(\cdot), \dots, u^M(\cdot)\}$  is a set of  $M$  perception functions (one for each message type).  $\mathcal{R} = \{\rho^1(\cdot), \dots, \rho^C(\cdot)\}$  is a set of  $C$  agent density functions (one for each agent class). Each agent  $\text{MA}^c$  of class  $c$  is characterized by a state space with  $n_c$  states, and it is defined by the tuple

$$\text{MA}^c = \{\mathbf{Q}^c(\mathbf{v}), \mathbf{A}^c(\mathbf{v}), \mathbf{G}^c(\mathbf{v}, m), \mathbf{A}^c(\mathbf{v}, m), \pi_0^c(\mathbf{v})\}, \quad (69.2)$$

where  $\mathbf{Q}^c(\mathbf{v})$  is the local component of the infinitesimal generator;  $\mathbf{A}^c(\mathbf{v})$  is the vector of the self-jump transition rates;  $\mathbf{G}^c(\mathbf{v}, m)$  is the matrix containing the probabilities of generating a message of type  $m$ ;  $\mathbf{A}^c(\mathbf{v}, m)$  is the matrix containing the probabilities of accepting a message of type  $m$ ;  $\pi_0^c(\mathbf{v})$  is the initial probability vector.

Note that even if the structure of the **CTMC** associated to each **MA** of a given class is the same for all the objects, the values of the parameters may depend on position  $\mathbf{v}$  and, therefore, may vary from **MAs** belonging to the same class.

An **MAM** can be analyzed solving a set of coupled differential equations. Let us call  $\rho_i^c(t, \mathbf{v})$  the density of agents of class  $c$ , in state  $i$ , located in position  $\mathbf{v}$  at time  $t$ . In the following, we will focus on static **MAMs** thus assuming that the total density of agents in position  $\mathbf{v}$  remains constant over the time; we have that

$$\sum_{i=1}^{n_c} \rho_i^c(t, \mathbf{v}) = \rho^c(\mathbf{v}), \quad \forall \mathbf{v}, \forall t \geq 0. \quad (69.3)$$

We collect the state densities into a vector  $\rho^c(t, \mathbf{v}) = [\rho_1^c(t, \mathbf{v}), \dots, \rho_{n_c}^c(t, \mathbf{v})]$  and we are interested in computing the transient evolution of  $\rho^c(t, \mathbf{v})$ .

From the above definitions, we can compute the total rate  $\beta_j^c(\mathbf{v}, m)$  at which messages of type  $m$  are gen-

erated by an agent of class  $c$  in state  $j$  in position  $\mathbf{v}$

$$\begin{aligned}\beta_j^c(\mathbf{v}, m) &= \lambda_j^c(\mathbf{v}) g_{jj}^c(\mathbf{v}, m) \\ &+ \sum_{k \neq j} q_{jk}^c(\mathbf{v}) g_{jk}^c(\mathbf{v}, m),\end{aligned}\quad (69.4)$$

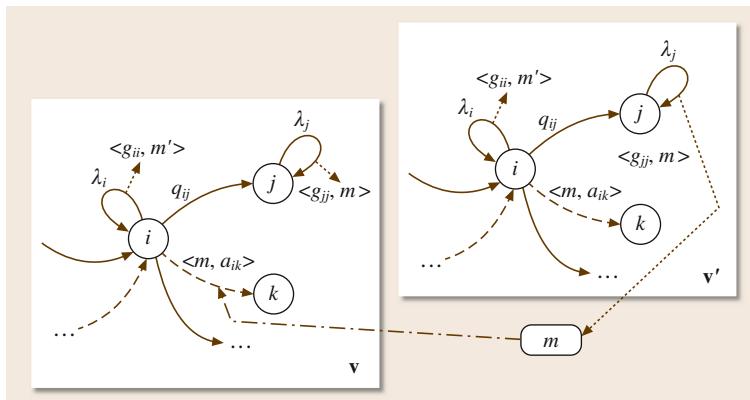

where the first term on the right-hand side is the contribution of the messages of type  $m$  emitted during a self-loop from  $j$  and the second term is the contribution of messages of type  $m$  emitted during a transition from  $j$  to any  $k$  ( $\neq j$ ).

The interdependences among **MA**s are ruled by a set of perception functions whose general form is

$$u^m(c, \mathbf{v}, i, c', \mathbf{v}', j). \quad (69.5)$$

The perception function  $u^m(\cdot)$  in (69.5) represents how an **MA** of class  $c$  in position  $\mathbf{v}$  in state  $i$  perceives the messages of type  $m$  emitted by an **MA** of class  $c'$  in position  $\mathbf{v}'$  in state  $j$ . The functional form of  $u^m(\cdot)$  identifies the perception mechanisms and must be specified for any given application since it determines how an **MA** is influenced by the messages emitted by the other **MA**s. The transition rates of the induced transitions are primarily determined by the structure of the perception function.

A pictorial and intuitive representation of how the perception function  $u^m(c, \mathbf{v}, i, c', \mathbf{v}', j)$  acts, is given in Fig. 69.2. The **MA** in the top right portion of the figure in position  $\mathbf{v}'$  broadcasts a message of type  $m$  from state  $j$  that propagates in the geographical area until reaches the **MA** in the bottom left portion of the figure in position  $\mathbf{v}$  and in state  $i$ . Upon acceptance of the message according to the acceptance probability  $a_{ik}(\mathbf{v}, m)$ , an induced transition from state  $i$  to state  $k$  (represented by a dashed line) is triggered in the model.

With the above definitions we are now in the position to compute the components of the infinitesimal generator of an **MA** that depends on the interaction with the other **MA**s and that constitutes the original and innovative part of the approach.

We define  $\gamma_{ii}^c(t, \mathbf{v}, m)$  the total rate at which messages of type  $m$  coming from the whole volume  $\mathcal{V}$  are perceived by an **MA** of class  $c$  in state  $i$  in location  $\mathbf{v}$ .

$$\gamma_{ii}^c(t, \mathbf{v}, m) = \int_{\mathcal{V}} \sum_{c'=1}^C \sum_{j=1}^{n_{c'}} u^m(c, \mathbf{v}, i, c', \mathbf{v}', j) \times \beta_j^{c'}(m) \rho_j^{c'}(t, \mathbf{v}') d\mathbf{v}', \quad (69.6)$$

where  $\gamma_{ii}^c(t, \mathbf{v}, m)$  is computed by taking into account the total rate of messages of type  $m$  emitted by all the **MA**s in state  $j$  and in a given position  $\mathbf{v}'$  (the term  $\beta_j^c(\mathbf{v}, m)$ ) times the density of **MA**s in  $\mathbf{v}'$  (the term  $\rho_j^{c'}(t, \mathbf{v}')$ ) times the perception function (the term  $u^m(c, \mathbf{v}, i, c', \mathbf{v}', j)$ ) summed over all the possible states  $j$  and class  $c'$  of each **MA** and integrated over the whole space  $\mathcal{V}$ . From an **MA** of class  $c$  in position  $\mathbf{v}$  and in state  $i$  an induced transition to state  $k$  (drawn in dashed line) is triggered with rate  $\gamma_{ii}^c(t, \mathbf{v}, m) a_{ik}(\mathbf{v}, m)$  where  $a_{ik}(\mathbf{v}, m)$  is the appropriate entry of the acceptance matrix  $\mathbf{A}(\mathbf{v}, m)$ .

We collect the rates (69.6) in a diagonal matrix  $\Gamma^c(t, \mathbf{v}, m) = \text{diag}(\gamma_{ii}^c(t, \mathbf{v}, m))$ . This matrix can be used to compute  $\mathbf{K}^c(t, \mathbf{v})$ , the infinitesimal generator of a class  $c$  agent at position  $\mathbf{v}$  at time  $t$

$$\mathbf{K}^c(t, \mathbf{v}) = \mathbf{Q}^c + \sum_m \Gamma^c(t, \mathbf{v}, m) [\mathbf{A}^c(m) - \mathbf{I}]. \quad (69.7)$$

The first term on the right-hand side is the local transition rate matrix and the second term contains the rates induced by the interactions.

**Fig. 69.2** Message passing mechanism ruled by a perception function

The evolution of the entire model can be studied by solving  $\forall \mathbf{v}, c$  the following differential equations:

$$\rho^c(0, \mathbf{v}) = \rho^c(\mathbf{v})\pi_0^c, \quad (69.8)$$

$$\frac{d\rho^c(t, \mathbf{v})}{dt} = \rho^c(t, \mathbf{v})\mathbf{K}^c(t, \mathbf{v}). \quad (69.9)$$

From the density of agents in each state, we can compute the probability of finding a class  $c$  agent at time  $t$  in position  $\mathbf{v}$  in state  $i$  as

$$\pi_i^c(t, \mathbf{v}) = \frac{\rho_i^c(t, \mathbf{v})}{\rho^c(\mathbf{v})}. \quad (69.10)$$

We collect all the terms in a vector  $\boldsymbol{\pi}^c(t, \mathbf{v}) = [\pi_i^c(t, \mathbf{v})]$ . Note that the definition of (69.10) together with (69.3) ensures that  $\sum_i \pi_i^c(t, \mathbf{v}) = 1, \forall t, \forall \mathbf{v}$ .

Note that each equation in (69.9) has the dimension  $n_c$  of the CTMC of a single MA of class  $c$ . In this way, a problem defined over the product state space of all the MAs is decomposed into several subproblems, one for each MA, having decoupled the interaction by means of (69.6). Equation (69.9) provides the basic time-dependent measures to evaluate more complex performance indices associated to the system. Equation (69.9) is discretized both in time and space and are solved by resorting to standard numerical techniques for differential equations.

## 69.3 A Consolidated Example: WSN Routing

In this section, we present our first attempt to model swarm intelligence inspired mechanisms through the MAM formalism. This application describes an MAM model for the analysis of a swarm intelligence routing protocol in WSNs and was first proposed in [69.9] and then enriched in [69.12]. In this work, we show new experiments to illustrate the self-adaptability of the MAM model to the changing of environmental conditions.

WSNs are large networks of tiny sensor nodes that are usually randomly distributed over a geographical region. The network topology may vary in time in an unpredictable manner due to many different causes. For example, in order to reduce power consumption, battery-operated sensors undergo cycles of sleeping – active periods; additionally, sensors may be located in hostile environments increasing their likelihood of failure; furthermore, data might also be collected from different sources at different times and directed to different sinks. For this reason, multihop routing algorithms used to route messages from a sensor node to a sink should be rapidly adaptable to the changing topology. Swarm intelligence has been successfully used to face these problems thanks to its ability in converging to a single global behavior starting from the interaction of many simple local agents.

### 69.3.1 A Swarm Intelligence Based Routing

In [69.15], a new routing algorithm, inspired by the biological process of *pheromone* emission (a chemical substance produced and laid down by ants and other biological entities), has been proposed. The rout-

ing table in each node stores the *pheromone level* owned by each neighbor, coded as a natural integer quantity [69.15]; when a data packet has to be sent it is forwarded to the neighbor with the highest pheromone level. This approach correctly works only if a sequence of increasing values of pheromone levels toward the sinks exists; in other words, the sinks must have the maximum pheromone level in the WSN and a decreasing pheromone gradient must be established around the sinks covering all the net.

To build the pheromone gradient, the initial setting of the WSN is as follows: the sinks are set to a fixed maximum pheromone level, whereas the sensor nodes' pheromone levels are set to 0. When the WSN is operating, each node periodically sends a signaling packet with its pheromone level and updates its value based on the level of its neighbors.

More specifically, the algorithm for establishing the pheromone gradient is based on two types of nodes in the WSN, called *sinks* and *sensors*, respectively, and the pheromone is assumed discretized into  $P$  different levels, ranging from 0 to  $P - 1$ . In this way, routing paths toward the sink are established through the exchange of pheromone packets containing the pheromone level  $p$  ( $0 \leq p \leq P - 1$ ) of each node.

Sink nodes, once activated, set their internal pheromone level to the highest value  $p = P - 1$ . Then, they, at fixed time interval, broadcast a pheromone message to their neighbors with the value  $p$ . We assume  $T1$  is the time interval incurring between two consecutive sending of pheromone message.

Instead, the pheromone level of a sensor node is initially set to 0 and then it is periodically updated ac-

cording to two distinct actions – *excitation action* (the positive feedback) and *evaporation action* (the negative feedback):

- *Excitation action*: Sensor nodes periodically broadcast to the neighbors a pheromone message containing their internal pheromone level  $p$ . Like the sink node, sensor nodes perform the sending at regular time interval  $T1$ . When a sensor node receives a pheromone level  $p_n$  sent by a neighbor it compares  $p_n$  with its own level  $p$  and updates the latter if  $p_n > p$ . The new value is computed as a function of the current and the received pheromone level  $update(p, p_n)$ . In this context, we use the average of the sender and the receiver level as the new updating value, thus the function is assumed to be  $update(p, p_n) = round((p + p_n)/2)$ .
- *Evaporation action*: it is triggered at regular time interval  $T2$  and it simply decreases the current value of  $p$  by one unit assuring it maintains a value greater or equal to 0.

We note that, despite all nodes perform their excitation action with the same mean time interval  $T1$ , no synchronization activity is required among the nodes; all of them act asynchronously in accordance with the principles of biological systems where each entity acts autonomously with respect to the others.

The excitation–evaporation process, like in biological systems, assures the stability of the system and the adaptability to possible changes in the environment or in some nodes. Any change in the network condition is captured by an update of the pheromone level of the involved nodes that modifies the pheromone gradient automatically driving the routing decisions toward the new optimal solution. In this way, the network can self-organize its topology and adapt to environmental changes. Moreover, when link failures occur, the network reorganization task is accomplished by those nodes near the broken links. This results in a robust and self-organized architecture.

The major drawback of this algorithm is the difficulty in appropriately setting the parameter  $T1$  and  $T2$ : as shown in [69.12, 15], the stability of the system and the *quality* of the produced pheromone gradient is strictly dependent on the parameters ratio. When  $T1$  decreases and  $T2$  is fixed, pheromone messages are exchanged more rapidly among the nodes and their pheromone level tends to the maximum level because the sink node always sends the same maximum value. Without an appropriate balancing action, the pheromone level saturates all the nodes of the **WSN**.

At the opposite, let us suppose  $T1$  is fixed and  $T2$  decreases; in this case the pheromone level in each sensor node decreases more quickly than its updating according to the value of the neighbors. As a result all the levels will be close to zero. From this behavior, we note that: (1) both timers are necessary to ensure that the algorithm could properly work, and (2) a smart setting of both timers is necessary in order to have the best gradient shape all over the network. The **MAM** model we are going to describe in the next section helps us to determine the best parameter values.

### 69.3.2 The MAM Model

The **MAM** model used to study the gradient formation is based on two agent classes: the class *sink node* denoted by a superscript  $s$  and the class *sensor node* denoted by a superscript  $n$ . The message exchange is modeled by using  $M$  different message types. As we will explain later, since each message is used to send a pheromone level, we set  $M = P$ , where  $P$  is the number of different pheromone intensities considered in the model.

#### Geographical Space

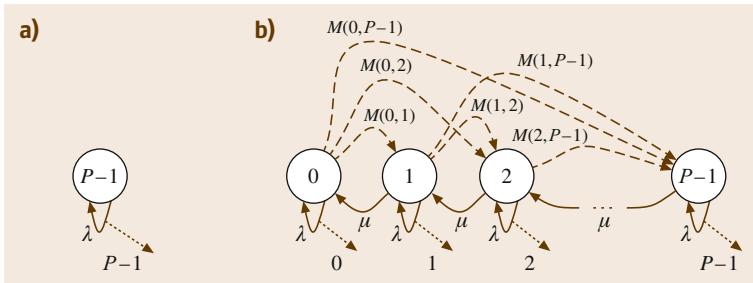

The geographical space  $\mathcal{V}$  where the  $N$  agents are located is modeled as a  $n_h \times n_w$  rectangular grid, and each cell has a square shape with side  $d_s$ . Sensors can only be located in the center of each cell and we allow at most one node per cell: i. e., some cell might be empty, and  $N \leq n_h \times n_w$ . Moreover, sink nodes are very few with respect to the number of sensor nodes.

#### Agent's Structure and Behavior

Irrespective of the **MA** class considered, we model the pheromone level of a node with a state and this choice determines two different **MA** structures.

The *sink* class (Fig. 69.3a) is very simple and is characterized by a single state labeled  $P - 1$  with a self-loop of rate  $\lambda = \frac{1}{T1}$ . The sink has always the same maximum pheromone level, and emits a single message of type  $P - 1$  with rate  $\lambda$ .

Instead, the *sensor* class (Fig. 69.3b) has  $P$  states identifying the range of all the possible pheromone levels. Each state is labeled with the pheromone intensity  $i$  ( $i = 0, \dots, P - 1$ ) in the corresponding node and has a self-loop of rate  $\lambda = \frac{1}{T1}$  that represents the firing of timer at regular intervals equal to  $T1$ . This event causes the sending of a message (Sect. 69.3.2). The evaporation phenomenon is modeled by the solid arcs (local transitions) connecting state  $i$  with state  $i - 1$

**Fig. 69.3a,b** Markovian agent models. (a) Agent class = sink, (b) Agent class = sensor

$(0 < i \leq P - 1)$ . The evaporation rate is set to  $\mu = \frac{1}{T_2}$ ; in such a way we represent the firing of timer  $T_2$ .

### Message Types

The types of messages in the model correspond to the different levels of pheromone a node can store, thus we define  $\mathcal{M} = \{0, 1, \dots, P - 1\}$ . Any self-loop transition in state  $i$  emits a message of the corresponding type  $i$  at a constant rate  $\lambda$ , both in sink and in sensor nodes. The sink message is always of type  $P - 1$ , representing the maximum pheromone intensity, whereas the messages emitted by a sensor node corresponds to the state where it actually is.

When a message of type  $m$  is emitted, neighboring nodes are able to receive it changing their state accordingly. This behavior is implemented through the dashed arcs (whose labels are defined through (69.11)) that model the transitions induced by the reception of a message. In particular, when a node in state  $i$  receives a message of type  $m$ , it immediately jumps to state  $j$  if  $m \in M(i, j)$ , with

$$\begin{aligned} M(i, j) = \{m \in [0, \dots, P - 1] : \text{round}((m + i)/2) = j\} \\ \forall i, j \in [0, \dots, P - 1] : j > i. \end{aligned} \quad (69.11)$$

In other words, an MA in state  $i$  jumps to the state  $j$  that represents the pheromone level equal to the mean between the current level  $i$  and the level  $m$  encoded in the perceived message.

### Perception Function

Messages of any type sent by a node are characterized by the same transmission range  $t_r$  that defines the radius of the area in which an MA can perceive a message produced by another MA. This property is reflected in the perception function  $u^m(\cdot)$  that,  $\forall m \in [1, \dots, M]$ , is defined as

$$u^m(\mathbf{v}, c, i, \mathbf{v}', c', i') = \begin{cases} 0 & \text{dist}(\mathbf{v}, \mathbf{v}') > t_r \\ 1 & \text{dist}(\mathbf{v}, \mathbf{v}') \leq t_r \end{cases}, \quad (69.12)$$

where  $\text{dist}(\mathbf{v}, \mathbf{v}')$  represents the Euclidean distance between the two nodes at position  $\mathbf{v}$  and  $\mathbf{v}'$ .

As can be observed, the perception function in (69.12) is defined irrespective of the message type, because in this kind of application the reception of a message of any type  $i$  depends only on the distance between the emitting and the perceiving node. The transmission range  $t_r$  depends on the properties of the sensor and it influences the number  $\eta$  of neighbors perceiving the message. In the numerical experimentation, we consider  $d_s \leq t_{r4} < \sqrt{2} d_s$  corresponding to  $\eta = 4$ .

### Generation and Acceptance Probabilities

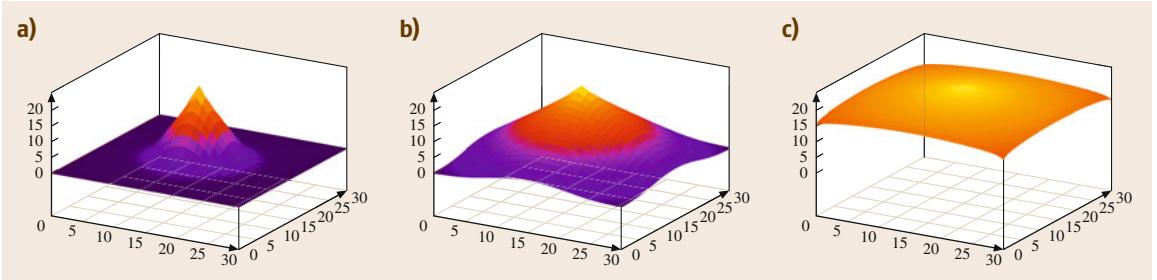

In this application, messages are only generated during self-loop transitions with probability 1, so that  $\forall i, j$ ,  $g_{ii}^c(m) = 1$  and  $g_{ij}^c(m) = 0$ , ( $i \neq j$ ). Similarly, we assume either  $a_{ij}^c(m) = 0$  or  $a_{ij}^c(m) = 1$ , that is incoming messages are always accepted or always ignored.

### 69.3.3 Numerical Results

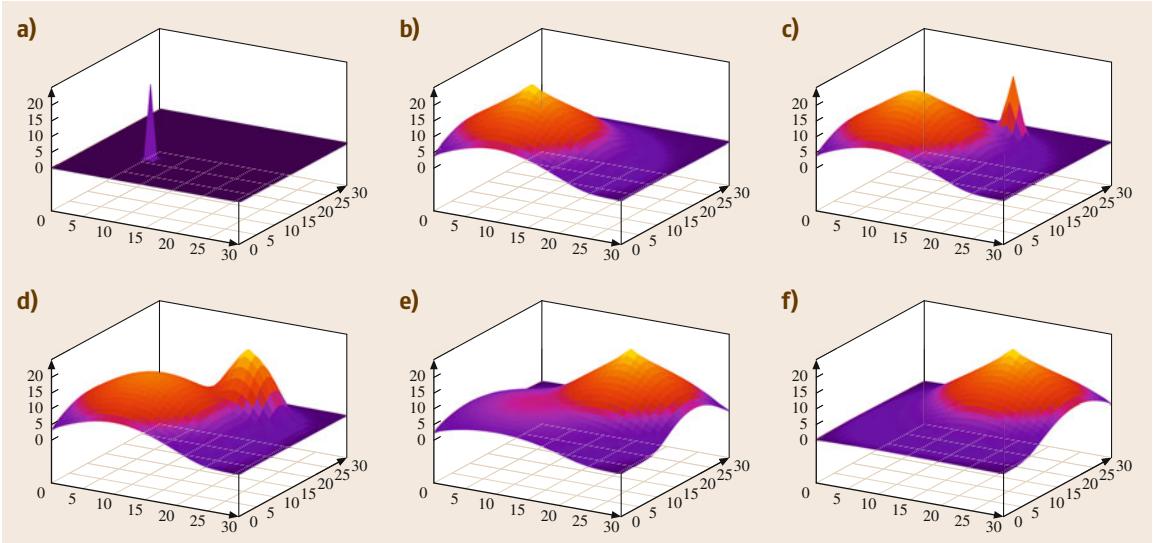

In order to analyze the behavior of the WSN model, the main measure of interest is the evolution of  $\pi_i^n(t, \mathbf{v})$  i.e., the distribution of the pheromone intensity of a sensor node over the entire area  $\mathcal{V}$  as a function of the time. The value of  $\pi_i^n(t, \mathbf{v})$  can be computed from (69.10) and allows us to obtain several performance indices like the average pheromone intensity  $\phi(t, \mathbf{v})$  at time  $t$  for each cell  $\mathbf{v} \in \mathcal{V}$

$$\phi(t, \mathbf{v}) = \sum_{i=0}^{P-1} i \cdot \pi_i^n(t, \mathbf{v}). \quad (69.13)$$

The distribution of the pheromone intensity over the entire area  $\mathcal{V}$  depends both on the pheromone emission rate  $\lambda$  and on the pheromone evaporation rate  $\mu$ ; furthermore, the excitation–evaporation process depends on the transmission range  $t_r$  that determines the number of neighboring cells  $\eta$  perceived by an MA in a given position. To take into account this physical mechanism,

**Fig. 69.4a–c** Distribution of the pheromone intensity varying  $r$ . (a)  $r = 1.2$ , (b)  $r = 1.8$ , (c)  $r = 2.4$

**Fig. 69.5a–f** Distribution of the pheromone intensity with respect to  $t$  when two sinks are alternately activated. The change is applied at time  $t = 17.5$  s. (a)  $t = 0$  s, (b)  $t = 17$  s, (c)  $t = 17.5$  s, (d)  $t = 19$  s, (e)  $t = 24$  s, (f)  $t = 29$  s

we define the following quantity,

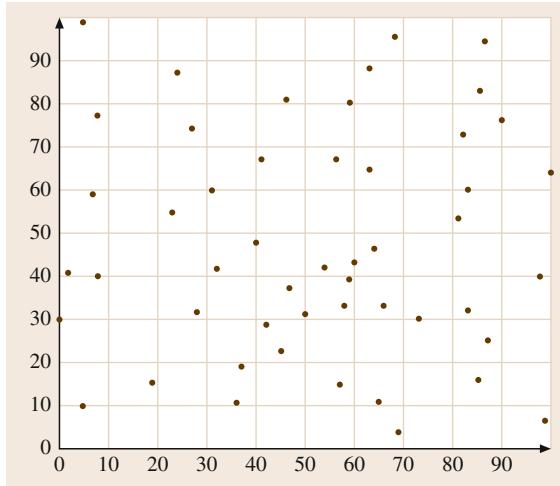

$$r = \frac{\lambda \cdot \eta}{\mu}, \quad (69.14)$$

which regulates the balance between the pheromone emission and evaporation in the **SI** routing algorithm. For a complete discussion about the performance indices that can be derived and analyzed using the described **MAM**, refer to [69.12].

The numerical results have been obtained with the following experimental setting. The geographical space is a square grid of sizes  $n_h = n_w = 31$ , where  $N = 961$  sensors are uniformly distributed with a spatial density equal to 1 (one sensor per cell). Further, we set  $\lambda = 4.0$ ,  $P = 20$ , and  $\eta = 4$ . The first experiment aims at investigating the formation of the pheromone gradient around

the sink as a function of the model parameters. To this end, a single sink node is placed at the center of the area and the pheromone intensity distribution is evaluated as a function of the parameter  $r$ , by varying  $\mu$  being  $\lambda$  and  $\eta$  fixed.

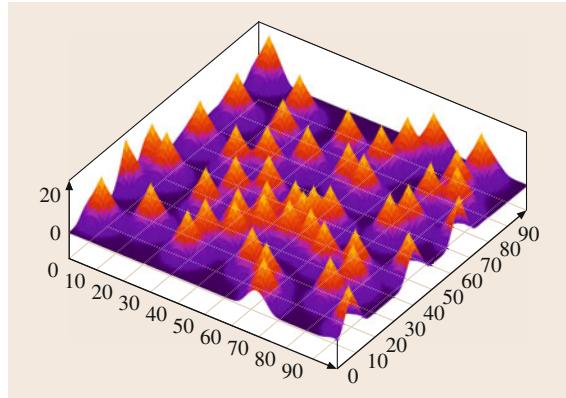

Figure 69.4 shows the distribution of the pheromone intensity  $\phi(t, v)$  measured in the stable state for three different values of  $r$ . If the value of  $r$  is small ( $r = 1.2$ ) or high ( $r = 2.4$ ), the quality of the gradient is poor. This is due to the prevalence of one of the two feedbacks: negative (with  $r = 1.2$  evaporation prevails) or positive (with  $r = 2.4$  excitation prevails and all sensors saturate). On the contrary, intermediate values ( $r = 1.8$ ) generate well-formed pheromone gradients able to cover the whole area, thanks to the correct balance between the two feedbacks. Then, an opportune evaluation of the value of  $r$  has to be carried

**Fig. 69.6** The  $100 \times 100$  grid with 10 000 cells and 50 randomly scattered sinks

out in order to generate a pheromone gradient that fits with the topological specification of the **WSN** under study.

In order to understand the dynamic behavior of the **SI** algorithm, we carried out a transient analysis able to highlight different phases of the gradient construction process when the position of the sink changes in time. In particular, in the following experiment (Fig. 69.5) we analyzed how the algorithm self-adapts to topological modifications by recalculating the pheromone gradient when two different sinks are present in the network and they are alternately activated. Figure 69.5a,b show how the pheromone signal is spread on the space  $\mathcal{V}$  until the stable state is reached. At this point ( $t = 17.5$  s), we deactivated the old sink and we activated a new one in a different position (Fig. 69.5c). Figure 69.5d,e describe the evolution of the gradient modification. It is possible to observe that, thanks to the properties of the **SI** algorithm, the **WSN** is able to rapidly discover the new sink and to change the pheromone gradient by forgetting the old information until a new stable state is reached (Fig. 69.5f).

**Fig. 69.7** Distribution of the pheromone intensity when the network is composed by a grid of 10 000 sensor nodes with 50 sinks

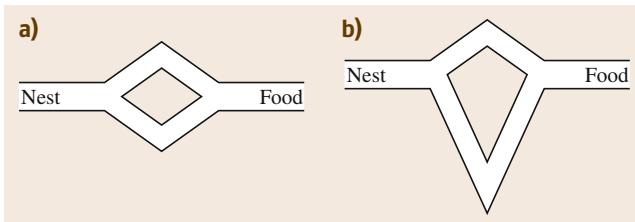

Finally, in order to test the scalability of the **MAM** in more complex scenarios, we have assumed a rectangular grid with  $n_h = n_w = 100$  hence with  $N = 100 \times 100 = 10\,000$  sensors, and we have randomly scattered 50 sinks in the grid. The grid is represented in Fig. 69.6, where the sinks are drawn as black spots. Since each sensor is represented by an **MA** with  $P = 20$  states (Fig. 69.3b), the product state space of the overall system has  $N = 20^{10\,000}$  states!

The steady pheromone intensity distribution for the geographical space represented in Fig. 69.6 is reported in Fig. 69.7. Through this experiment, we can assess that the pheromone gradient is also reached when no symmetries are present in the network and that the proposed model is able to capture the behavior of the protocol in generating a correct pheromone gradient also in the presence of different maximums. Using the same protocol configurations found for a simple scenario, the **SI** algorithm is able to create a well-formed pheromone gradient also in a completely different situation, making such routing technique suitable in nonpredictable scenarios. This scenario also demonstrates the scalability of the proposed analytical technique that can be easily adopted in the analysis of very large networks.

## 69.4 Ant Colony Optimization

The aim of this section is to show how **MAMs** can be adopted to represent one of the more classical swarm intelligence algorithm known as **ACO** [69.2], that was inspired by the foraging behavior of ant colonies which, during food search, exhibit the ability to solve simple shortest path problems. To this end, in this work, we simply show how to build a **MAM** that solves the famous *Double Bridge Experiment* which was first proposed by Deneubourg et al. in the early 90s [69.16, 17], and that has been proposed as an entry benchmark for **ACO** models.

In the experiment, a nest of Argentine ants is connected to a food source using a double bridge as shown in Fig. 69.8. Two scenarios are considered: in the first one the bridges have equal length (Fig. 69.8a), in the second one the lengths of the bridges are different (Fig. 69.8b). The collective behavior can be explained by the way in which ants communicate indirectly among them (*stigmergy*). During the journey from the nest to the food source and vice versa, ants release on the ground an amount of *pheromone*. Moreover ants can perceive pheromone and they choose with greater probability a path marked by a stronger concentration of pheromone. As a result, ants releasing pheromone on a branch, increase the probability that other ants choose it. This phenomenon is the realization of the positive feedback process described in Sect. 69.1 and it is the reason for the convergence of ants to the same branch in the equal length bridge case. When lengths are different, the ants choosing the shorter path reach the food source quicker than those choosing the longer path. Therefore, the pheromone trail grows faster on the shorter bridge and more ants choose it to reach food. As a result, eventually all ants converge to follow the shortest path.

**Fig. 69.8a,b** Experiment scenarios. Modified from Goss et al. [69.17]. (a) Equal branches, (b) Different branches

### 69.4.1 The MAM Model

We represent the double bridge experiment through a multiple agent class and multiple message type **MAM**. We model ants by messages, and locations that ants traverse by **MA**s. Three different **MA** classes are introduced: the class *Nest* denoted by superscript n, the class *Terrain* denoted by superscript t, and the class *Food* denoted by superscript f. Two types of messages are used: ants walking from the nest to the food source correspond to messages of type fw (*forward*), whereas ants coming back to the nest correspond to messages of type bw (*backward*).

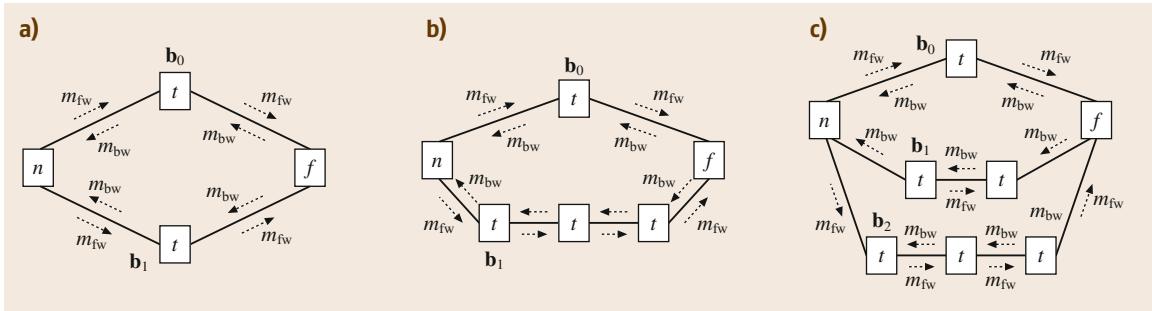

#### Geographical Space

Agents (either nest, terrain, or food source) are deployed on a discrete geographical space  $\mathcal{V}$  represented as an undirected graph  $G = (V, E)$ , where the elements in the set  $V$  are the vertices and the elements in the set  $E$  are the edges of the graph. In Fig. 69.9a,b, we show the locations of agents for the equal and the different length bridge scenarios, respectively. The squares are the vertices of the graph and the labels inside them indicate the class of the agent residing on the vertex. In this model, we assume that only a single agent resides on each vertex. Message passing from a node to another is depicted as little arrows labeled by the message type. As shown in Fig. 69.9, different lengths of the branches are represented by a different number of hops needed by a message to reach the food source starting from the nest. Figure 69.9c represents a three branches bridge with branches of different length.

#### Agent's Structure and Behavior

The structure of the three **MA** classes is described in the following:

- **MA Nest:** The nest is represented by a single **MA** of class  $n$ , shown in Fig. 69.10a. The nest **MA**<sup>n</sup> is composed by a single state that emits messages of type fw at a constant rate  $\lambda$ , modeling ants leaving the nest in search for food.
- **MA Terrain:** An **MA** of class  $t$  (Fig. 69.10c) represents a portion of terrain on which an ant walks and encodes in its state space the concentration of the pheromone trail on that portion of the ground. We assume that the intensity of the pheromone trail is discretized in  $P$  levels numbered  $0, 1, \dots, P - 1$ .

**Fig. 69.9a–c** Graph used to model the experiment scenarios. (a) Equal branches, (b) two different branches, (c) three different branches

With reference to Fig. 69.10c, the meaning of the states is the following:

- $t_0$  denotes no pheromone on the ground and no ant walking on it;
- $t_i$  denotes a concentration of pheromone of level  $i$  and no ant on the ground;
- $t_{if}$  denotes an ant of forward type residing on the terrain while the pheromone concentration is at level  $i$ ;
- $t_{ib}$  denotes an ant of backward type residing on the terrain while the pheromone concentration is at level  $i$ .

The behavior of the  $\text{MA}^t$  agent at the reception of the messages is the following:

- *fw – forward ant:* A message of type fw perceived by an  $\text{MA}^t$  in states  $t_i$ , induces a transition to state  $t_{(i+1)f}$  meaning that the arrival of a forward ant increases the pheromone concentration of one level (*positive feedback*).
- *bw – backward ant:* A message of type bw perceived by an  $\text{MA}^t$  in states  $t_i$ , induces a transition to state  $t_{(i+1)b}$  meaning that the arrival of a backward ant increases the pheromone concentration of one level (*positive feedback*).

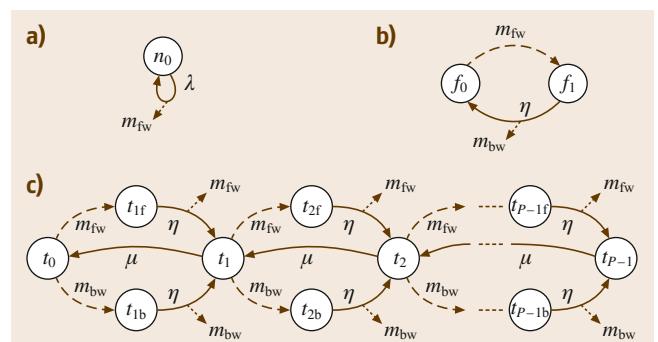

Ants remain on a single terrain portion for a mean time of  $1/\eta$  s, then they leave toward another destination. The local transitions from states  $t_{if}$  to states  $t_i$  and the generation of message fw model this behavior for forward ants. An analogous behavior is represented for backward ants by local transitions from states  $t_{ib}$  to states  $t_i$ . The local transitions at constant rate  $\mu$  from states  $t_i$  to states  $t_{i-1}$  indicate the decreasing of one unit of the concentration of pheromone due to evaporation (*negative feedback*):

- **MA Food source:** An MA of class  $f$  represents the food source (Fig. 69.10b). The reception of a message of type fw in state  $f_0$  indicates that a forward ant has reached the food source. After a mean time of  $1/\eta$  s, such an ant leaves the food and starts the way back to the nest becoming a backward ant (emission of message of type bw).

In order to keep model complexity low thus increasing the model readability, we have chosen to limit to 1 the number of ants that can reside at the same time on a portion of terrain (or in the food source). For this reason, message reception is not enabled in states  $t_{if}$  or  $t_{ib}$  for MAs of class  $t$  and in the state  $f_1$  for MAs of class  $f$ . In future works, we will study effective techniques (e.g., intervening on MA density) in order to release such an assumption.

#### Perception Function

The perception function rules the interactions among agents and, in this particular example, defines the prob-

**Fig. 69.10a–c** Markovian agent models for the ACO experiment. (a)  $\text{MA}^n$ : Agent of class nest. (b)  $\text{MA}^f$ : Agent of class food. (c)  $\text{MA}^t$ : Agent of class terrain

ability that a message (ant) follows a specific path both on the forward and backward direction. The definition of the perception function takes inspiration on the stochastic model proposed in [69.16, 17] to describe the dynamic of the ant colony. In such a model the probability of choosing the shorter branch is given by

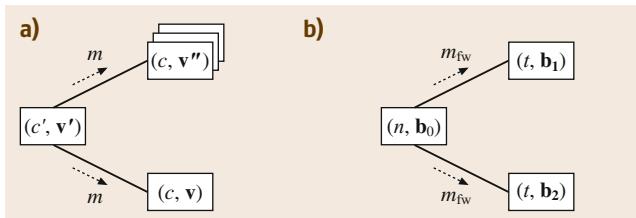

$$p_{is}(\tau) = \frac{(k + \varphi_{is}(\tau))^\alpha}{(k + \varphi_{is}(\tau))^\alpha + (k + \varphi_{il}(\tau))^\alpha}, \quad (69.15)$$

where  $p_{is}(\tau)$  (respectively  $p_{il}(\tau)$ ) is the probability of choosing the shorter (longer) branch,  $\varphi_{is}(\tau)$  ( $\varphi_{il}(\tau)$ ) is the total amount of pheromone on the shorter (longer) branch at a time  $\tau$ . The parameter  $k$  is the degree of attraction attributed to an unmarked branch. It is needed to provide a non-null probability of choosing a path not yet marked by pheromone. The exponent  $\alpha$  provides a nonlinear behavior.

In our MA model, the perception function  $u^m(\cdot)$  is defined,  $\forall m \in \{fw, bw\}$ , as

$$u^m(\mathbf{v}, c, i, \mathbf{v}', c', j, \tau) = \frac{(k + E[\pi^c(\tau, \mathbf{v})])^\alpha}{\sum_{(c'', v'') \in \text{Next}^m(\mathbf{v}', c')} (k + E[\pi^{c''}(\tau, \mathbf{v}'')])^\alpha}, \quad (69.16)$$

where  $k$  and  $\alpha$  have the same meaning as in (69.15),  $E[\pi^c(\tau, \mathbf{v})]$  gives the mean value of the concentration of pheromone at a time  $\tau$  in position  $\mathbf{v}$  on the ground, and corresponds to  $\varphi(\tau)$ . The computation of  $E[\pi^c(\tau, \mathbf{v})]$  will be addressed in (69.18). The function  $\text{Next}^m(\mathbf{v}', c')$  gives the set of pairs  $\{(c'', \mathbf{v}'')\}$  such that the agent of class  $c''$  in position  $\mathbf{v}''$  perceives a message of type  $m$  emitted by the agent of class  $c'$  in position  $\mathbf{v}'$ . Figure 69.11a helps to interpret (69.16). The multiple box stands for all the agents receiving a message  $m$  sent by the agent of class  $c'$  in position  $\mathbf{v}'$ . The value of  $u^m(\mathbf{v}, c, i, \mathbf{v}', c', j, \tau)$  is proportional to the mean pheromone concentration of the agent in class  $c$

**Fig. 69.11a,b** Perception function description. (a) General case, (b) example of scenario in Fig. 69.9b

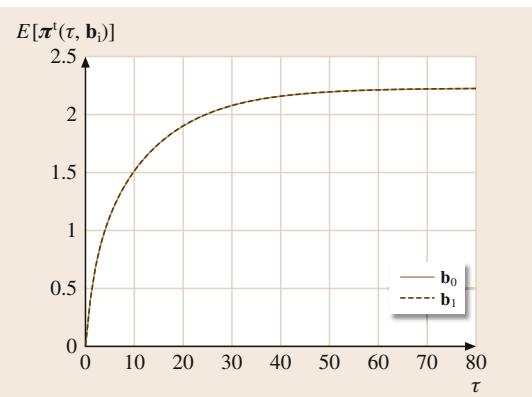

at position  $\mathbf{v}$  with respect to the sum of the mean concentrations of all the agents that receive message  $m$  by the agent in class  $c'$  and position  $\mathbf{v}'$ . For instance, we consider the scenario depicted in Fig. 69.11b, where a class  $n$  agent in position  $\mathbf{b}_0$  sends messages of type fw to two other class  $t$  agents at position  $\mathbf{b}_1$  and  $\mathbf{b}_2$ , and we compute  $u^{\text{fw}}(\mathbf{b}_2, t, i, \mathbf{b}_0, n, j, \tau)$ . In such case, the evaluation of function  $\text{Next}^{\text{fw}}(\mathbf{b}_0, n)$  gives the set of pair  $\{(t, \mathbf{b}_1), (t, \mathbf{b}_2)\}$  and the value of the function is

$$u^{\text{fw}}(\mathbf{b}_2, t, i, \mathbf{b}_0, n, j, \tau) = \frac{(k + E[\pi^t(\tau, \mathbf{b}_2)])^\alpha}{(k + E[\pi^t(\tau, \mathbf{b}_1)])^\alpha + (k + E[\pi^t(\tau, \mathbf{b}_2)])^\alpha}. \quad (69.17)$$

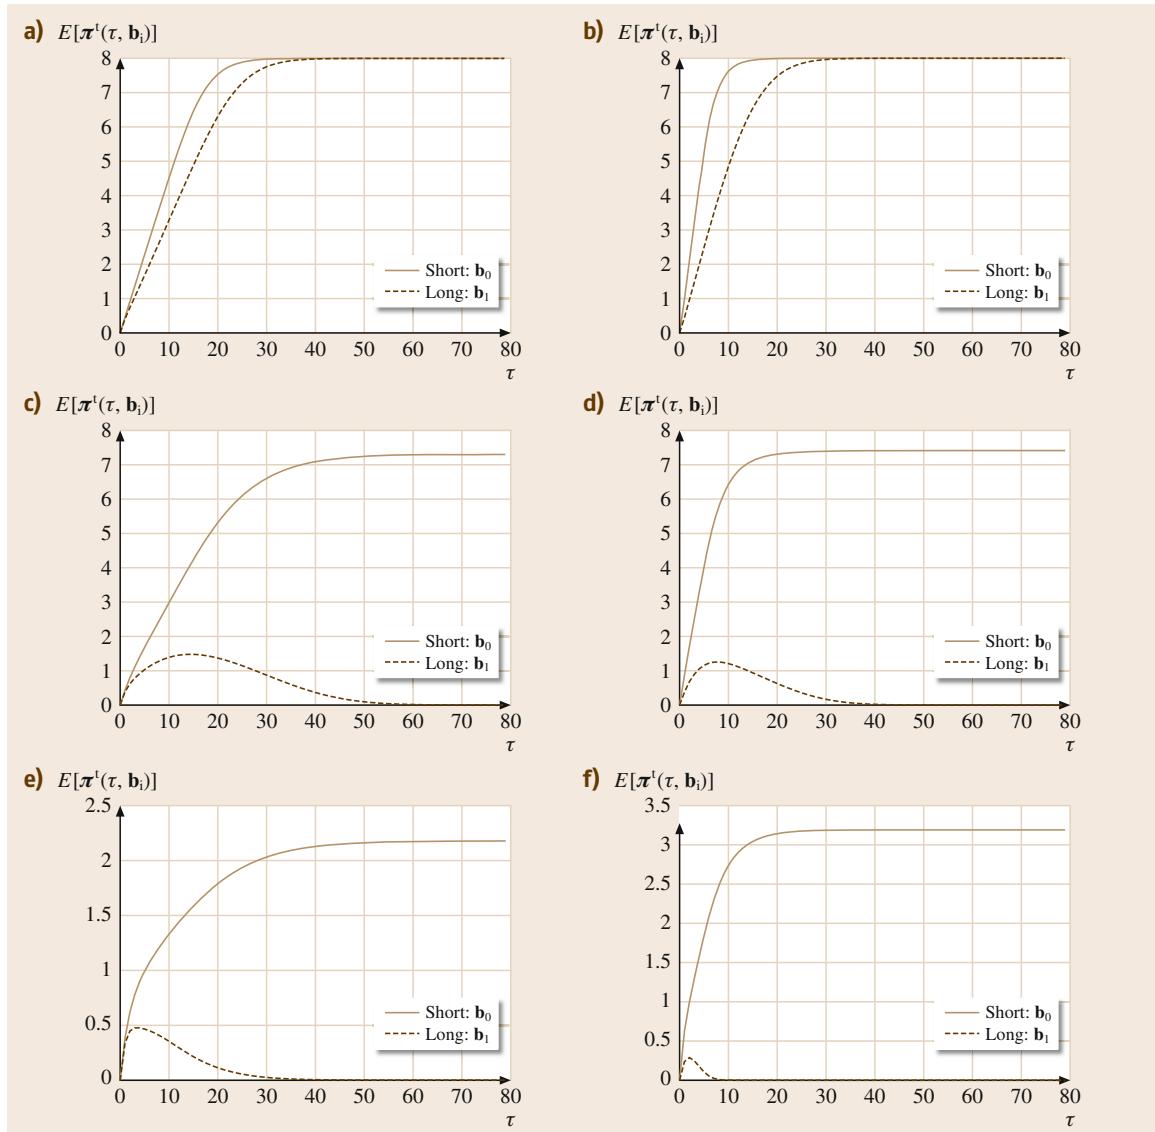

As a final remark, we highlight that  $u^m(\cdot)$  does not depend on the state variables  $i$  and  $j$  of the sender and receiver agents even if these variables appear in the definition of  $u^m(\cdot)$  ((69.16)). Instead,  $u^m(\cdot)$  depends on the whole probability distribution  $\pi^c(\tau, \mathbf{v})$  needed to compute the mean value  $E[\pi^c(\tau, \mathbf{v})]$ .

### Generation and Acceptance Probabilities

As in Sect. 69.3, also in this ACO-MAM model we only allow  $g_{i,j}^c(m) = 0$  or  $g_{i,j}^c(m) = 1$  and  $a_{i,j}^c(m) = 0$  or  $a_{i,j}^c(m) = 1 \forall c, m$ . In particular, for the terrain agent MA<sup>t</sup>, messages of type fw are sent with probability  $g_{it,f}^t(\text{fw}) = 1$ , and are accepted with probability  $a_{i,(i+1)f}^t(\text{fw}) = 1$  only in a  $t_i$  state inducing a transition to a  $t_{(i+1)f}$  state. An analogous behavior is followed during emission and reception of messages of type bw.

**Fig. 69.12** Mean pheromone concentration with  $\lambda = 1.0$ ,  $\mu = 1$  and  $\eta = 1$  for the equal branches experiment

**Fig. 69.13a–f** Mean pheromone concentration for the case with two different branches. **(a)** Mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 0$  and  $\eta = 1$ , **(b)** mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 0$  and  $\eta = 10$ , **(c)** mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 0.5$  and  $\eta = 1$ , **(d)** mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 0.5$  and  $\eta = 10$ , **(e)** mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 2$  and  $\eta = 1$ , **(f)** mean pheromone concentration  $\lambda = 1.0$ ,  $\mu = 2$  and  $\eta = 10$

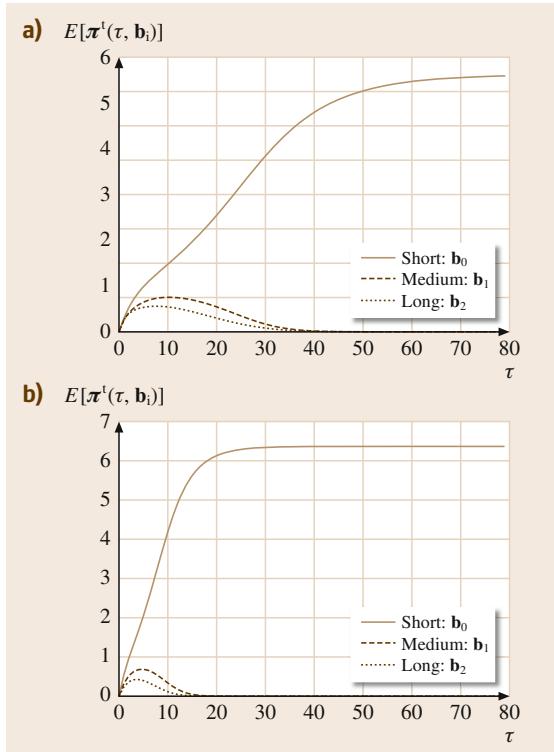

### 69.4.2 Numerical Results for ACO Double Bridge Experiment

We have performed several experiments on the ACO model. In particular, we study *the mean value of the concentration of pheromone* at a time  $\tau$  in position  $\mathbf{v}$

for a class  $c$  agent,  $E[\pi^c(\tau, \mathbf{v})]$ , defined as

$$E[\pi^c(\tau, \mathbf{v})] = \sum_{s \in S^c} \pi_s(\mathbf{v}, c) I(s), \quad (69.18)$$

where  $S^c$  denotes the state space of a class  $c$  agent,  $I(s)$  represents the pheromone level in state  $s$ , and it corre-

**Fig. 69.14a,b** Mean pheromone concentration for the case with three different branches. (a)  $\eta = 10$ , (b)  $\eta = 10$

sponds to

$$I(s) = i, \quad \forall s \in \{t_i\} \cup \{t_{ii}\} \cup \{t_{ib}\}. \quad (69.19)$$

This value is used in (69.16) to compute  $u^m(\cdot)$  which, as previously said, rules the ant's probability to follow a specific path; therefore, such performance index provides useful insights of the modeled ant's behavior.

## 69.5 Conclusions

In this work, we have presented how the Markovian agents performance evaluation formalism can be used to study swarm intelligent algorithms. Although the formalism was developed to study largely distributed systems like sensor networks, or physical propagation phenomena like fire or earthquakes, it has been proven to be very efficient in capturing the main features of swarm intelligence.

Beside the two cases presented in this chapter, routing in WSNs and ant colony optimiza-

We consider three scenarios depicted in Fig. 69.9, the labels  $b_i$  denote the positions where we compute the mean value of the concentration of pheromone. In all the experiments, the intensity of the pheromone trail is discretized in  $P = 8$  levels.

In Fig. 69.12, the mean pheromone concentration  $E[\pi^c(\tau, b_i)]$  over the time for the equal branches experiment is plotted. As it can be seen, both mean pheromone concentrations have exactly the same evolution proving that ants do not prefer one of the routes.

The case with two different branches is considered in Fig. 69.13. The speed of the ants (i. e., parameter  $\eta$ ) is considered in the column (the left column corresponds to  $\eta = 1.0$  and the right column to  $\eta = 10$ ), while the evaporation of the pheromone is taken into account in the rows (respectively with  $\mu = 0$ ,  $\mu = 0.5$ , and  $\mu = 2$ ). When no evaporation is considered (Fig. 69.13a,b), both paths are equally chosen due to the finite amount of the maximum pheromone level considered in this work. However the shorter path reaches its maximum level earlier than the longer route. In all the other cases, it can be seen that the longer path is abandoned after a while in favor of the shorter one. The evaporation of the pheromone and the speed of the ants both play a role in the time required to drop the longer path. Increasing either of the two, reduces the time required to discover the shorter route.

Finally, Fig. 69.14 considers a case with three branches of different length and different evaporation levels ( $\eta = 1$  and  $\eta = 10$ ). Also in this case the model is able to predict that ants will choose the shortest route. It also shows that longer paths are dropped in an order proportional to their length: the longest route is dropped first, and the intermediate route is discarded second. Also in this case, the evaporation rates determine the speed at which paths are chosen and discarded.

tion, the formalism is capable of considering other cases like Slime Mold models. Future research lines will try to emphasize the relations between Markovian agents and swarm intelligence, trying to integrate both approaches: using Markovian agents to formally study new swarm intelligent algorithms, and use swarm intelligent techniques to study complex Markovian agents models in order to find optimal operation points and best connection strategies.

# 70. Honey Bee Social Foraging Algorithm for Resource Allocation

Jairo Alonso Giraldo, Nicanor Quijano, Kevin M. Passino

Bioinspired mechanisms are an emerging area in the field of optimization, and various algorithms have been developed in the last decade. We introduce a novel bioinspired model based on the social behavior of honey bees during the foraging process, and we show how this algorithm solves a class of dynamic resource allocation problems. To illustrate the practical utility of the algorithm, we show how it can be used to solve a dynamic voltage allocation problem to achieve a maximum uniform temperature in a multizone temperature grid. Its behavior is compared with other evolutionary algorithms.

Over several decades researchers' interest in understanding the patterns and collective behaviors of some organisms has increased because of the possibility of generating mathematical models that can be used for solving problems [70.1]. These bioinspired models have been used to develop robust technological solutions in different research fields [70.2]. One of the first models based on natural behaviors is the genetic algorithm (**GA**), proposed by *Holland* in [70.3]. This method reproduces the concepts of evolution considering natural selection, reproduction, and mutation in organisms. Many variations have been developed since then [70.4], and a wide variety of applications have been implemented [70.5, 6]. A sub-field of bioinspired algorithms is the so-called *swarm intelligence* [70.1, 7], which is inspired by the collective behavior of social animals that are able to solve distributed and complex problems following individual simple rules and producing emerging behaviors. Swarm intelligence mainly refers to those techniques

inspired by the social behavior of insects, such as ants [70.8] and bees [70.9–11], or the social interaction of different animal societies (e.g., flocks of birds) [70.12]. Ant colony optimization (**ACO**), as introduced by *Dorigo* et al. [70.13], mimics the foraging behavior of a colony of ants, based on pheromone proliferation, and it has been used in the solution of optimization problems [70.1, 14], and in some engineering applications [70.15–17]. Another common approach is particle swarm optimization (**PSO**), which mimics the behavior of social organisms that move according to the knowledge of their neighbors' goodness, and it is able to solve continuous optimization problems [70.18]. This technique has been widely implemented in a variety of applications, such as economical dispatch [70.19, 20], feature selection [70.21], and some resource allocation problems [70.22, 23], to name just a few.

There are also several bioinspired techniques based on the collective behavior of foraging bees, and

each one has different characteristics and applications. In [70.24], a decentralized honey bee algorithm is presented, which is based on the distribution of forager bees amongst flower patches, which occurs in such a way that the nectar intake is maximized. This technique has been applied to Internet servers hosting distribution. *Tereshko* in [70.25] also developed a model of the foraging behavior of a honey bee colony based only on the recruitment and abandonment process, taking into account just the local information of a food source. However, in [70.26], the algorithm was improved by considering either local and global information of food sources. Another approach of honey bee foraging algorithms was developed by *Karaboga* [70.27], and it is called the artificial bee colony (**ABC**), which can be used to solve unconstrained optimization problems. In [70.28], a comparison of the **ABC** algorithm performance was made with other common heuristic algorithms, such as genetic algorithms and particle swarm optimization. The authors conclude that **ABC** can be used for multivariable and multimodal function optimization. Several applications have been developed [70.29–31], and some improvements have been made in order to solve constrained optimization problems [70.32]. *Teodorović* and *Dell'Orco* in [70.33] introduced another algorithm based on honey bee foraging called bee colony optimization (**BCO**). This technique is very similar to **ABC** and follows almost the same steps of exploring, foraging, and recruitment based on the waggle dance. However, in **ABC**, the initial population is distributed in such a way that scouts and foragers are in equal proportion, while in **BCO** the initial population distribution is not fixed. Some applications have been developed using **BCO** to solve difficult optimization problems, such as combined heat and power dispatch [70.34], and job scheduling [70.35]. There are many other applications, and we refer the reader to [70.36] for an extensive literature review of the field.

In general, none of the previous optimization methods based on honey bee social foraging attempt to mimic the whole behavior of the foraging process. They mainly concentrate on the communication between the agents (bees), which is achieved through the waggle dance. One of the goals of this chapter is to show another swarm intelligence method (i.e., a honey bee social foraging) that mimics very closely the real behavior of a hive (or even multiple hives) of bees, in order to solve dynamic resource allocation problems. This method is based on the models obtained by *Seeley* and *Passino* in [70.37, 38], where each bee can be an

explorer, an employed forager, an observer, or a rester. The foraging process consists of exploring a landscape with different profitability sites. Hence, if a site is good enough, the explorer will try to recruit other bees in the hive using the waggle dance, which varies its intensity according to the quality of the site and the nectar unloading time. The observers will tend to follow the bees with the higher dance intensity and they may become employed foragers. If a site is no longer good enough, the bees may tend to become observers and will try to follow another waggle dance. One of the advantages of this method is that each bee only considers local information about its position and the profitability of the forage site. Besides, the communication is only considered in the waggle dance process, which depends on the nectar unloading wait time. Hence, we do not need to have full information of each agent. However, with only the unloading wait time information, an emerging behavior is produced, and complex resource allocation problems can be solved. This method is based on experimental results and imitates almost the whole behavior of honey bees during the foraging process, which is not the case with the other approaches presented before, which only considered a few actions of the foraging activity. On the other hand, the utility of the theoretical concepts that are introduced in this chapter are illustrated in an engineering application, which consists of a multizone temperature control grid. These kinds of problems are very important in commercial and industrial applications, including the distributed control of thermal processes, semiconductor processing, and smart building temperature control [70.39–42]. Here, we use a multizone grid similar to the one in [70.43], with four zones, each one with a temperature sensor, and a lamp that varies its temperature. The complexity of these kinds of problems arises mainly due to the interzone effects (e.g., lamps affecting the temperature in neighboring zones), ambient temperature and external wind currents, zone component differences, and sensor noise. This is why common control strategies cannot be applied. For this reason, different experiments are implemented in order to observe the performance of the algorithm under different conditions. Besides, we compare its behavior with two common evolutionary algorithms, i.e., genetic algorithm and **PSO**, which have been selected because of their low computational cost and their high capability to solve optimization problems. These algorithms have been modified in order to solve dynamic resource allocation problems, and their behavior can be compared with the honey bee social foraging algorithm.

This chapter is organized as follows. First, in Sect. 70.1, we introduce the honey bee social foraging algorithm. Then, in Sect. 70.2 the multizone temperature problem is presented and the other two evolution-

ary strategies, genetic algorithm and PSO for resource allocation are introduced. The results and comparisons are presented in Sects. 70.3 and 70.4, and in Sect. 70.5 some conclusions are drawn.

## 70.1 Honey Bee Foraging Algorithm

The honey bee social foraging algorithm models the behavior of social honey bees during nectar foraging, based on experimental studies summarized in [70.37] and some ideas from other mathematical models. This algorithm models some activities such as exploration and foraging, nectar unload, dance strength decisions, explorer allocation, recruitment on the dance floor, and interactions with other hives. The theory and the experiments are based on the work developed by Quijano and Passino in [70.43].

### 70.1.1 Landscape of Foraging Profitability

The landscape is assumed as a spatial distribution of forage sites with encoded information of the foraging profitability that quantifies the distance from the hive, nectar sugar content, nectar abundance, and any other relevant site variables. There is a number of  $B$  bees that are represented by a two-dimensional position  $\theta^i \in \mathbb{R}^2$ , for  $i = 1, 2, \dots, B$ . During foraging, bees sample a *foraging profitability landscape* denoted by  $J_f(\theta) \in [0, 1]$ , which is proportional to the profitability of nectar at location  $\theta$ . Hence,  $J_f(\theta) = 1$  represents a location with the highest possible profitability and  $J_f(\theta) = 0$  represents a location with no profitability.

As an example, assume the foraging landscape  $J_f(\theta)$  is zero everywhere except at forage sites. We could have four forage sites, indexed by  $j = 1, 2, 3, 4$ , centered at various positions that are initially unknown to the bees. Each site can be represented as a cylinder with radius  $\epsilon_f^j$ , and height  $N_f^j \in [0, 1]$  that is proportional to nectar profitability. We may also assume that the profitability of a bee being at site  $j$  decreases as the number of bees visiting that site increases. This can be denoted by  $s_j$ , which in behavioral ecology theory is called the *suitability function* [70.44].

### 70.1.2 Roles and Expedition of Bees

There are several kinds of bees involved in the foraging process during an expedition, and each kind has a different function. An expedition can be considered as a time

instant where each bee executes a function according to its role. There are  $B_f(k)$  *employed foragers* that actively bring nectar back from some site, and some of them dance to recruit new bees if the site is good.  $B_e(k)$  *explorer foragers* go to random positions in the environment, bring their nectar back if they find any, dance to recruit, and they can become foragers if they find a relative good site. There are  $B_u(k) = B_o(k) + B_r(k)$  *unemployed foragers*, with  $B_r(k)$  bees that rest (or are involved in some other activity), and  $B_o(k)$  that observe the dances of employed and explorer foragers on the dance floor. Some of the observers will follow the dances.

We ignore the specific path used by the foragers on expeditions and we assume that a bee samples the foraging profitability landscape once on its expedition, and this value is held when the bee returns to the hive. Let the foraging profitability assessment by the employed forager or explorer  $i$  be

$$F^i(k) = \begin{cases} 1 & \text{if } J_f(\theta^i(k)) \\ & + \omega_f^i(k) \geq 1, \\ J_f(\theta^i(k)) + \omega_f^i(k) & \text{if } 1 > J_f(\theta^i(k)) \\ & + \omega_f^i(k) > \epsilon_n, \\ 0 & \text{if } J_f(\theta^i(k)) \\ & + \omega_f^i(k) \leq \epsilon_n, \end{cases}$$

where  $\theta^i(k)$  represents the position of the  $i$ -th bee at the  $k$ -th expedition, and  $\omega_f^i(k)$  is the profitability assessment noise, which can be considered uniformly distributed between  $(-0.1, 0.1)$ . The value  $\epsilon_n$  sets a lower threshold on site profitability, and here we use  $\epsilon_n = 0.1$ .

### 70.1.3 Dance Strength Determination

The number of waggle runs of bee  $i$  at the  $k$ -th expedition is called *dance strength* and is denoted by  $L_f^i(k)$ . The unemployed foragers have  $L_f^i(k) = 0$ , and the employed foragers that have  $F^i(k) = 0$  will have  $L_f^i(k) = 0$

since they do not find a location above the profitability threshold  $\epsilon_n$ , and for this reason they will become unemployed foragers.

### Unloading Waiting Time

Now, we will explain dance strength decisions for the employed foragers and explorers that find a site of sufficiently good profitability and have  $F^i(k) > \epsilon_n$ . Firstly, we have to model the unloading wait time in order to relate it with the dance strength. Let  $F_t(k) = \sum_{i=0}^B F^i(k)$  be the total nectar profitability assessment at time  $k$  for the hive and  $F_q^i(k)$  be the quantity of nectar gathered for a profitability assessment  $F^i(k)$ . We assume that  $F_q^i(k) = \alpha F^i(k)$ , where  $\alpha > 0$  is a proportionality constant. We may choose  $\alpha = 1$ , such that the total hive nectar influx  $F_{tq}(k)$  is equal to the total nectar profitability assessment. Suppose that the number of food-storer bees is sufficiently large so the wait time  $W^i(k)$  that bee  $i$  experiences is given by

$$W^i(k) = \psi \max \{F_{tq}(k) + \omega_\omega^i(k), 0\}, \quad (70.1)$$

where  $\psi$  is a scale factor and  $\omega_\omega^i(k)$  is a random variable uniformly distributed in  $(-\omega_\omega, \omega_\omega)$  that represents variations in the wait time a bee experiences. When the total nectar influx is maximum, the value of the wait time is approximately 30 s, based on the experiments in [70.45]. With this assumption we can obtain the values of  $\psi$  and  $\omega_\omega$  from the fact that the maximum wait time from (70.1) is given by  $\psi(B + \omega_\omega) = 30$ . Hence, it can be noted that  $\psi\omega_\omega$  is the variation in the number of seconds in wait time due to the noise, and  $\omega_\omega$  has to be set adequately. If we let  $\psi\omega_\omega = 5$  and we have assumed that  $B = 200$ , we obtain two equations and two unknowns, which gives  $\psi = 52/200$  and  $\omega_\omega = 40$ .

### Dance Decision Function

Now, we assume that each successful forager converts the wait time it experienced into a scaled version of an estimate of the total nectar influx that we define as

$$\hat{F}_{tq}(k) = \delta W^i(k). \quad (70.2)$$

The value  $\hat{F}_{tq}(k)$  provides bee  $i$  a noisy estimate of the whole colony's foraging performance, since it provides an indication of how many successful foragers are waiting to be unloaded [70.37]. The proportionality constant is  $\delta > 0$ , and since  $W^i(k) \in [0, \psi(B + \omega_\omega)] = [0, 30]$  s, it implies that  $\hat{F}_{tq}^i(k) \in [0, 30\delta]$ . In order to ensure that  $\hat{F}_{tq}^i(k) \in [0, 1]$ , we consider that  $0 < \delta < \frac{1}{30}$ .

With this estimation, each bee has to decide how long to dance according to some forage site variables that determine the energetic profitability (e.g., distance from hive, sugar content of nectar, nectar abundance), and some conditions that determine the threshold of the dance response (e.g., weather, time of day, colony's nectar influx). The *decision function* is

$$L_f^i = \max \left\{ \beta \left( F^i(k) - \hat{F}_{tq}(k) \right), 0 \right\}, \quad (70.3)$$

which indicates the number of waggle runs of bee  $i$  at expedition  $k$ . The parameter  $\beta > 0$  has the effect of a gain on the rate of recruitment for sites above the dance threshold, and experimentally [70.37] we can set  $\beta = 100$ .

When a bee has  $L_f^i(k) > 0$ , it may consider dancing for her forage site. The probability that bee  $i$  will choose to dance for the site it is dedicated to is given by

$$p_r(i, k) = \frac{\phi}{\beta} L_f^i(k),$$

where  $\phi \in [0, 1]$ ; matching the behavior of what is found in experiments, we choose  $\phi = 1$ .

### 70.1.4 Explorer Allocation and Forager Recruitment

Bees that are not successful on an expedition, or those that do not consider dancing, become unemployed foragers. Some of these bees will start to rest or they will become observers and they will start seeking dancing bees in order to get recruited. The probability that an unemployed forager or current rester bee will become an observer is  $p_o \in [0, 1]$ . Based on the results in [70.46], we choose  $p_o = 0.35$  in such a way that in times where there are no forage sites being harvested there can be about 35% of the bees performing as forage explorers.

If an observer bee does not find any dance to follow, it will go exploring. So we take the  $B_o(k)$  observer bees and each one can become an explorer with probability  $p_e(k)$  or can follow the dance and become an employed forager with probability  $1 - p_o(k)$ . We choose

$$p_e(k) = \exp \left( -\frac{1}{2} \frac{L_t^2(k)}{\sigma^2} \right), \quad (70.4)$$

where  $L_t(k) = \sum_{i=1}^{B_f(k)} L_f^i(k)$  is the total number of waggle runs on the dance floor at step  $k$ . Notice that

if  $L_t(k) = 0$ , there are no dancing bees on the dance floor, so  $p_e(k) = 1$  and all the observers will explore (i.e., 35% of the unemployed foragers). Here, we choose  $\sigma = 1000$  since it produces patterns of foraging behavior in simulations that correspond to experiments.

Now, we take the observer bees that did not go to explore and some of them will be recruited in order to follow the dance of bee  $i$  with probability

$$p_i(k) = \frac{L_f^i(k)}{\sum_{j=1}^{B_f(k)} L_f^j(k)}. \quad (70.5)$$

In this way, bees that dance more strongly will tend to recruit more foragers for their site.

Algorithm 70.1 summarizes the pseudo-code of the honey bee social foraging algorithm described above.

## 70.2 Application in a Multizone Temperature Control Grid

In order to apply the proposed algorithm in the context of a physical resource allocation problem, we implement the multi-zone temperature control grid introduced in [70.43], with four zones as shown in Fig. 70.1. The relations between our problem and the proposed algorithm can be summarized as follows:

1. We assume that there is a population of  $B$  individuals (i.e., bees, chromosomes, or particles) that contains the information of a position  $\theta_i$ , where  $i = 1, \dots, B$ .
2. The search space is composed of *allocation sites*, which are denoted with a position  $R_j$  and a width  $\epsilon_f^j$ .

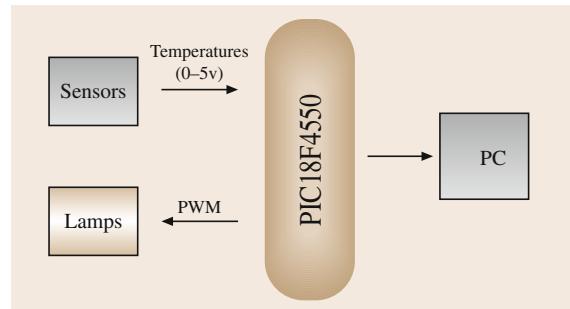

**Fig. 70.1** Layout for the multizone temperature control grid

3. Each allocation site corresponds to the zone  $j$  in the temperature grid, for  $j = 1, \dots, 4$ .
4. Let  $T_j^d$  and  $T_j$  be a temperature reference and the temperature for each zone  $j$ , respectively.
5. We consider the temperature error for zone  $j$  as  $e_j = T_j^d - T_j$ , and if an individual is located in a zone, its fitness is given by  $\gamma e_j$ , for  $\gamma$  being a positive constant that sets the fitness value in the range of  $[0, 1]$ .

### 70.2.1 Hardware Description

A zone contains a temperature sensor LM35 and a lamp that varies its intensity in order to increase or decrease the temperature of the zone. The data acquisition and the lamps' intensity variations are performed using a microcontroller PIC18F4550, which receives the temperature values (voltages between 0 and 5 V) and transmits them through the USB port to a PC using the USB-bulk communication class. We cannot guarantee that the four sensors have the same characteristics (they have  $\pm 0.2^\circ\text{C}$  typical accuracy, and  $\pm 0.5^\circ\text{C}$  guaranteed). With these temperature values, a Matlab program executes an iteration of one of the algorithms and sends pulse width modulation (PWM) width information back to the peripheral interface controller (PIC) (Fig. 70.2). PWM signals are generated using four digital outputs of the PIC and a couple of transistors that drive the amount of current and voltage necessary to control the lamps. The width of the PWM signal depends on the number of individuals (i.e., bees,

**Fig. 70.2** Layout of data acquisition and temperature control

chromosomes, or particles) allocated on a site. Each individual is equivalent to a portion of the PWM, and a 100% duty cycle corresponds to 12 V of direct current (DC).

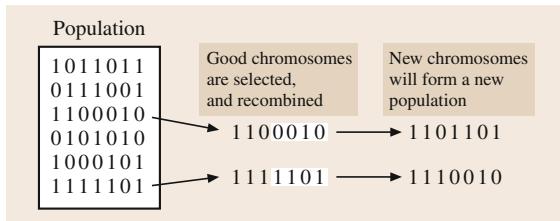

We assume that there is a total amount of voltage that can be distributed between the four zones. The goal is to allocate that voltage in such a way that the reference temperature for each zone can be achieved. However, to achieve this goal is complicated due to external effects, such as ambient temperature and wind currents, interzone effects, differences between the components of a zone, and sensor noise. For this reason, the total voltage amount has to be dynamically allocated, despite the external and internal effects.

### 70.2.2 Other Algorithms for Resource Allocation

In order to compare the behavior of the honey bee social foraging algorithm to solve dynamic resource allocation problems, two evolutionary algorithms were selected, i.e., the genetic algorithm (GA) and particle swarm optimization (PSO). These methods have been implemented in a wide variety of applications because of their low computational cost and their huge capability for solving optimization problems. Some implementations for resource allocation can be found in [70.22, 23, 47]. We will show below that these algorithms can be adapted in such a way that these resource allocation problems can be solved.

#### Genetic Algorithms

A genetic algorithm (GA) is a random search algorithm based on the mechanics of natural selection, genetics, and evolution [70.48]. The basic structure of the population is the chromosome. During each generation, chromosomes are evaluated based on a fitness function

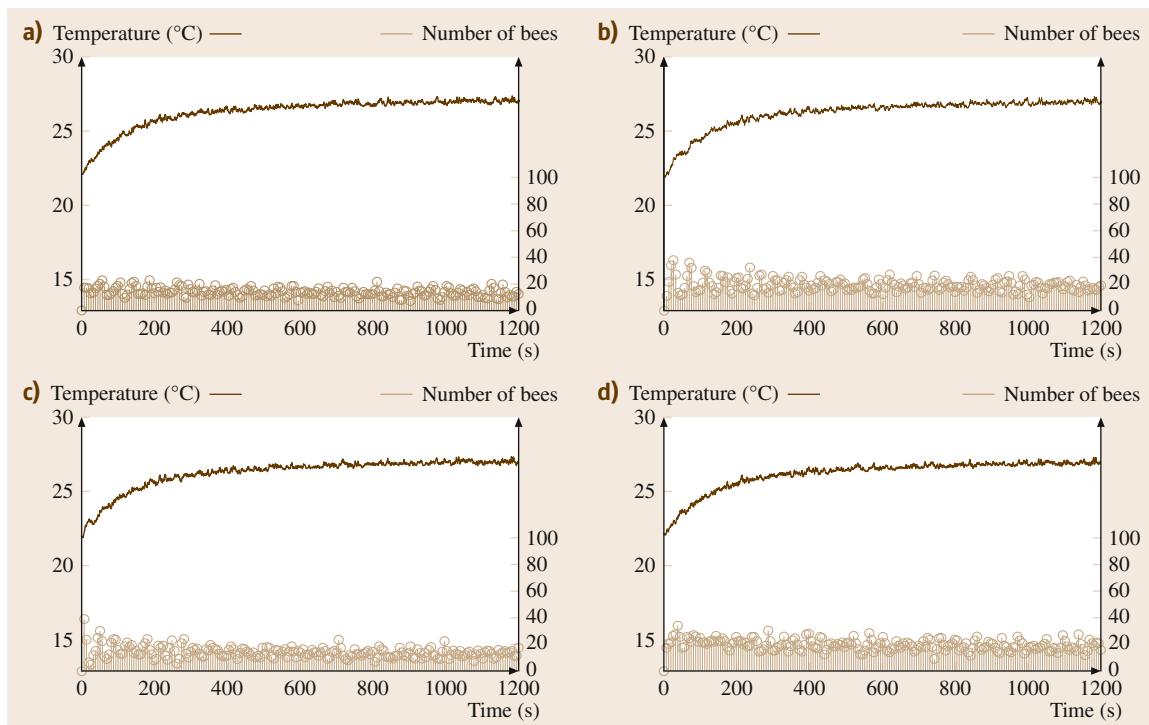

**Fig. 70.3** Selection and crossover in GA

and some of them are stochastically selected depending on their fitness values. The population evolves from generation to generation through the application of genetic operators [70.49].

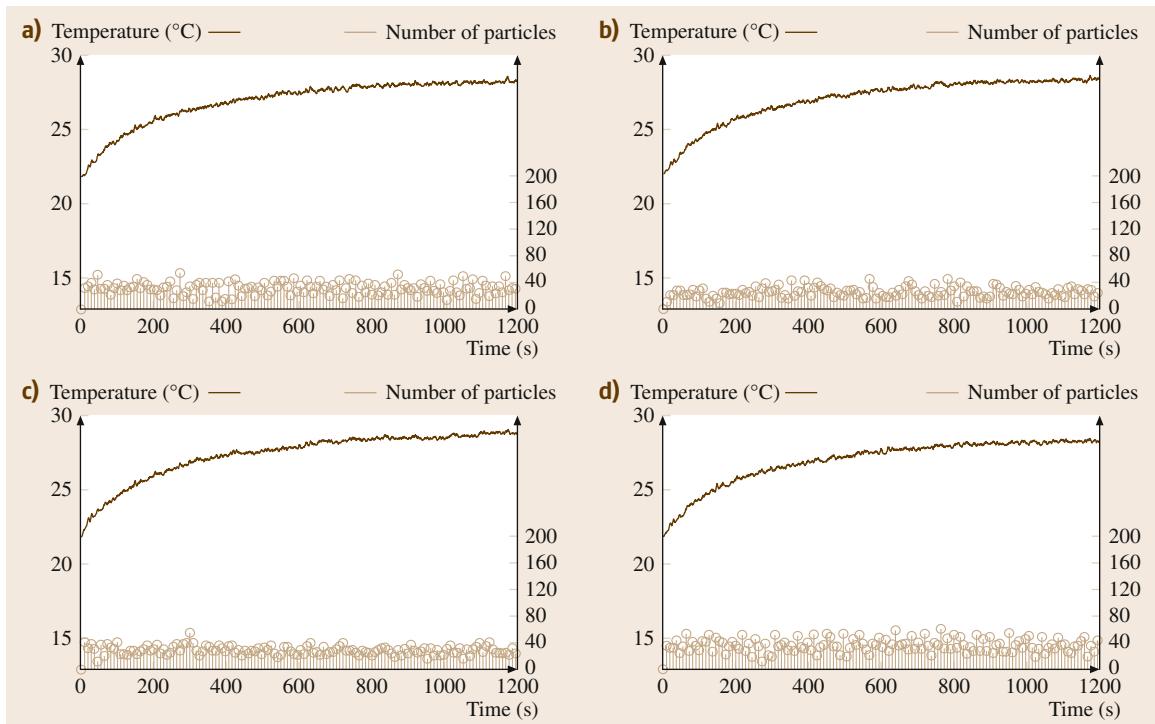

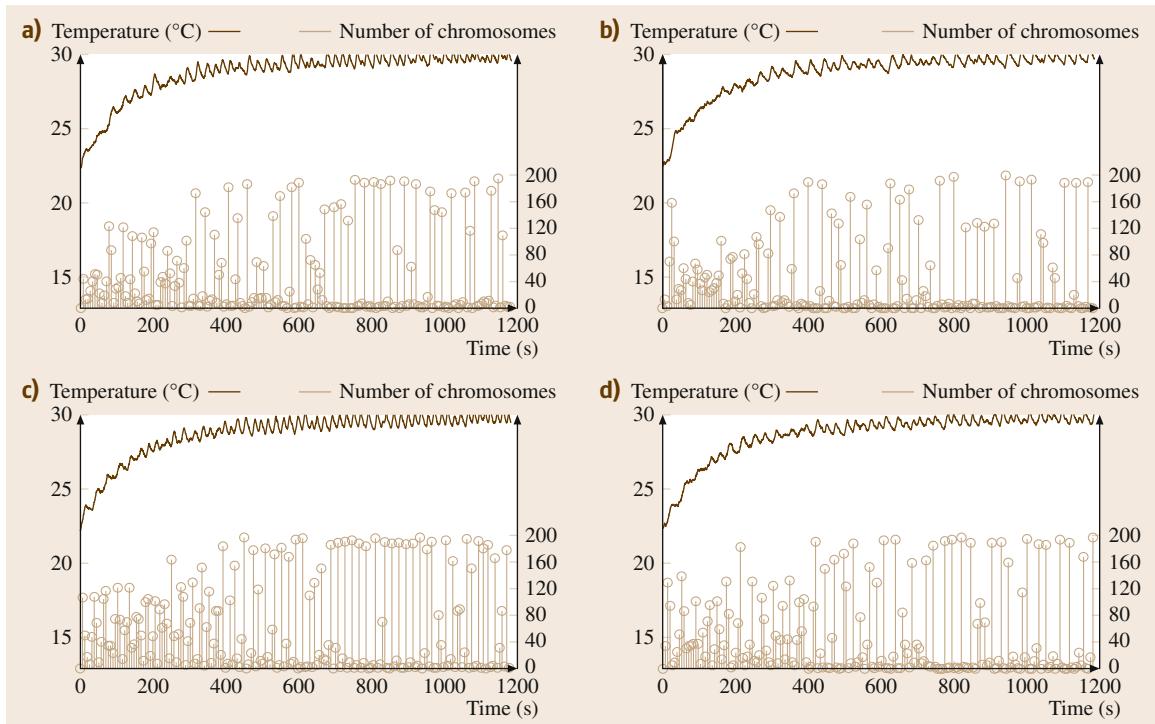

The simplest GA form uses chromosome information, which is encoded into a binary string. The chromosomes are modified using three operators: selection, crossover, and mutation [70.3]. *Selection* is an artificial version of natural selection, and only the fittest chromosomes from the population are selected. With *crossover*, two parents are chosen for reproduction, and a crossover site (a bit position) is randomly selected. The subsequences after the crossover site

are exchanged with a probability  $p_c$ , producing two offspring with information from both parents. Then, *mutation* randomly inverts a bit on a string with a very low probability, and introduces new information into the population at the bit level. Figure 70.3 illustrates the GA selection and crossover process for the simplest GA algorithm.

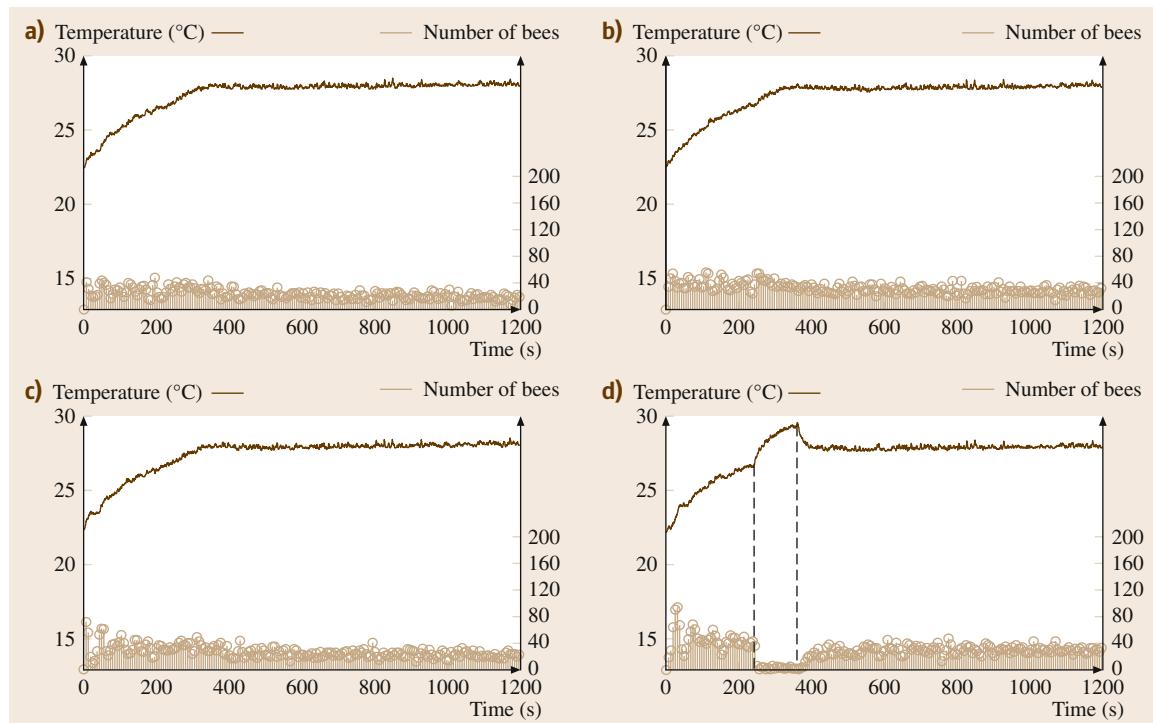

To solve a resource allocation problem, we adjust this algorithm as follows: we set a population of  $B$  individuals, each one with binary encoded information about its position  $\theta_i$ , for  $i = 1, \dots, B$ . There is a landscape that contains 4 different resources sites, each one located in a position  $R_j$  with a width  $\epsilon_f^j$ , for  $j = 1, \dots, 4$ . Each resource site corresponds to a temperature zone in the multizone control grid. When an individual is located in a resource site  $j$ , the fitness of that individual is given by the error between the current temperature  $T_j$  and the reference temperature  $T_j^d$ , otherwise, the fitness is 0. As was pointed out before, each individual corresponds to a portion of the total amount of voltage. For that reason, if the fitness is good, the population evolves, most of the individuals will have the same genetic information (position), and they will be allocated

**Fig. 70.4a-d** Average temperature (solid lines) and number of bees per zone (stem plots) using the honey bee foraging algorithm

**Fig. 70.5a-d** Average temperature (solid lines) and number of chromosomes per zone (stem plots) using the genetic algorithm ◀

**Fig. 70.7a-d** Average temperature (solid lines) and number of bees per zone (stem plots) using the honey bee foraging algorithm. Dashed lines indicate the beginning and end of the disturbance

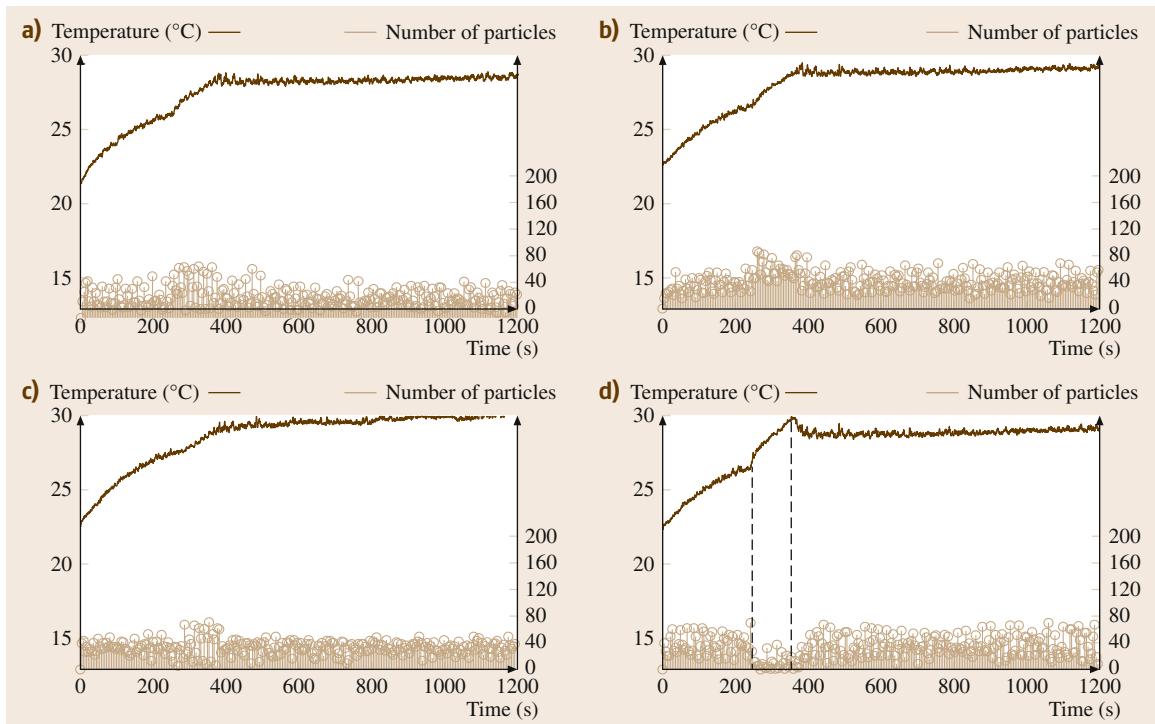

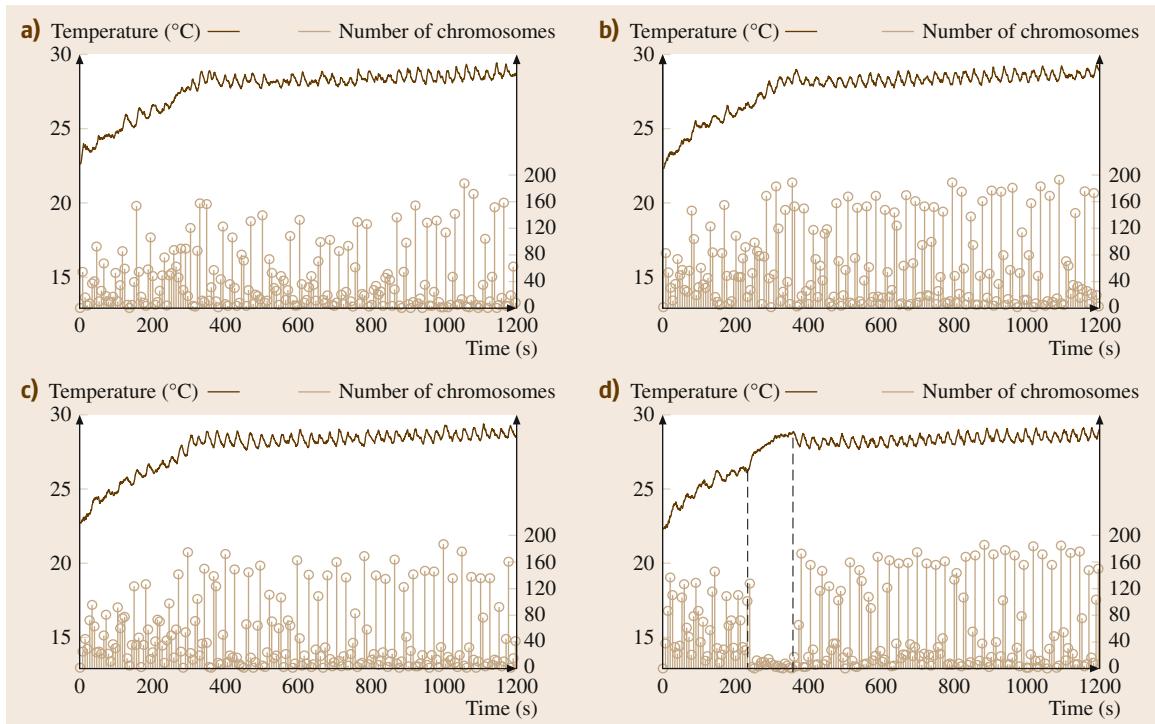

**Fig. 70.6a-d** Average temperature (solid) and number of particles per zone (stem plots) using the PSO algorithm ◀

at that site. Then, the amount of voltage applied to that zone increases as well as the temperature, which provokes that the fitness associated to that site decreases, and it will become less profitable. For the next generation, the individuals tend to be reallocated into another more profitable zone, and after some generations, the population is distributed in such a way that a uniform temperature is achieved for all sites.

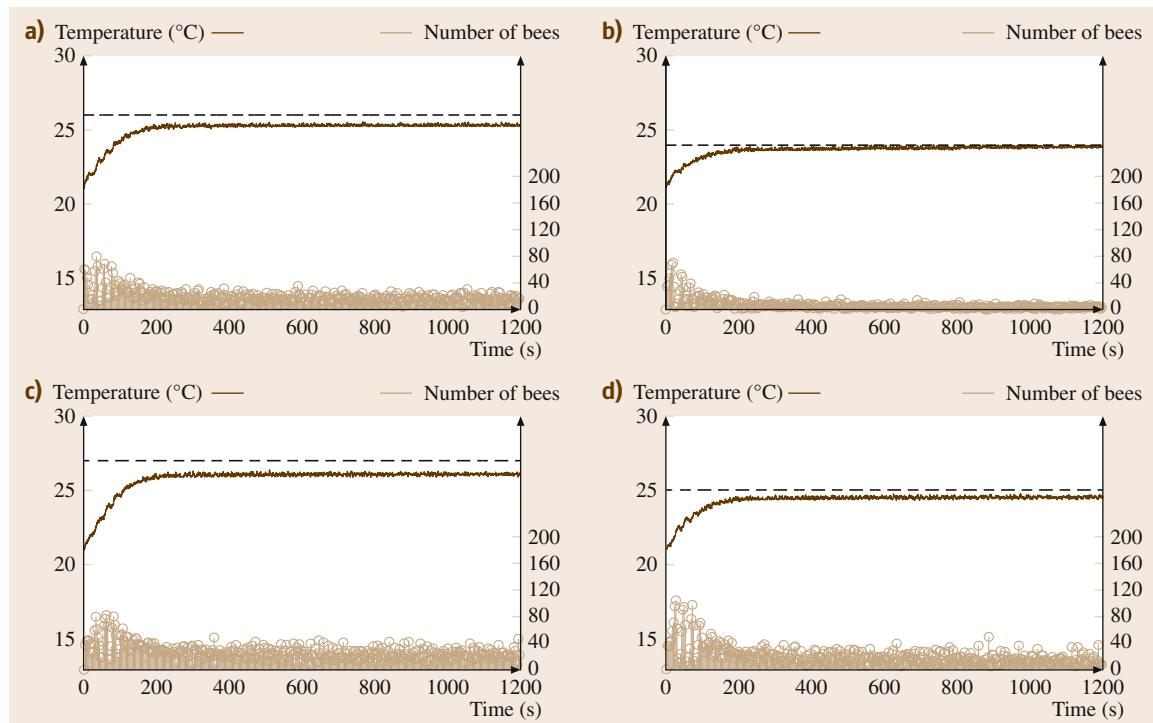

#### Particle Swarm Optimization

Particle swarm optimization (**PSO**) is a population-based stochastic optimization technique, inspired by the social behavior of animals (e.g., bird flocks, fish schools, or even human groups) [70.7]. In **PSO**, the potential solutions, called *particles*, fly through the problem space by following the currently best particles. They have two essential reasoning capabilities: mem-

ory of their own best position and knowledge of the global or their neighborhood's best. Each particle in a population has the information about its current position that defines a potential solution, and its fitness value associated to that position. A change of position of a particle is defined by the velocity, which is a vector of numbers that are added to the position coordinates in order to move the particle from one time step to another. At each iteration, a particle's velocity is updated depending on the difference between the individual's previous best and current positions, and the difference between the neighborhood's best and the individual's current position. With these simple rules, individuals tend to follow the particles associated to the more profitable sites, and optimization problems can be solved. The details of this method are summarized in [70.7].

**Fig. 70.8a-d** Average temperature (solid lines) and number of chromosomes per zone (stem plots) using the genetic algorithm. Dashed lines indicate the beginning and end of the disturbance ▶

**Fig. 70.10a-d** Average temperature (solid lines) and number of bees per zone (stem plots) using the honey bee foraging algorithm. The dashed lines indicate the different set points for each zone

**Fig. 70.9a-d** Average temperature (solid lines) and number of particles per zone (stem plots) using the PSO algorithm. Dashed lines indicate the beginning and end of the disturbance ▶

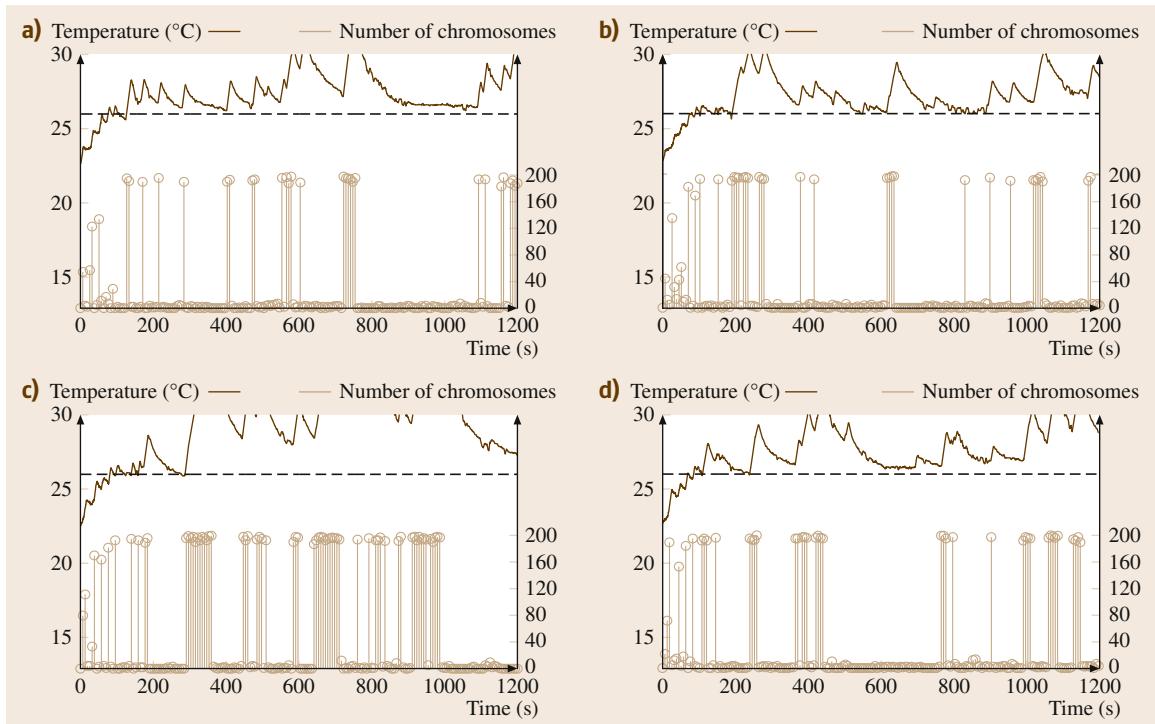

To solve a dynamic resource allocation problem, an adjustment to this algorithm is made as follows. First, we assume a population of  $B$  particles, where each particle represents a one-dimensional position  $\theta_i$  in the search space. The fitness of each individual is defined by the temperature error  $\gamma e_j$  shown above. When a particle has a good fitness, most of

the individuals will tend to fly to the same position, provoking a temperature increment and a decrease of the error. For that reason, the particles are reallocated to a more profitable place, and after some generations, the population is distributed in such a way that a uniform temperature is achieved for all sites.

## 70.3 Results

In order to compare the behavior of the proposed algorithms to solve the dynamic resource allocation problem, three experiments are performed using the multi-zone temperature control grid described in Sect. 70.2.1. In the first experiment, we seek the maximum uniform

temperature with a single population of  $B = 200$  individuals. The second experiment illustrates the response of the individuals when a disturbance is applied in the fourth zone. Finally, multiple temperature set points are assigned to each zone. Our results show the behavior

**Fig. 70.11a–d** Average temperature (solid lines) and number of chromosomes per zone (stem plots) using the genetic algorithm. The dashed lines show the set point for each zone

of the three algorithms applied in a resource allocation implementation under the same circumstances.

### 70.3.1 Experiment I: Maximum Uniform Temperature

In this experiment, we want to achieve a maximum uniform temperature for all zones. For this reason, we set reference temperatures  $T_j^d = 30$ , for all  $j = 1, \dots, 4$  (this value cannot be achieved by the system). We have a population of 200 individuals and a PWM frequency of 70 Hz, where each individual corresponds to a duty cycle of 0.5% (i.e., each individual corresponds to 0.06 V.) For example, 50 individuals in a zone are equal to 25% of the duty cycle and they correspond to 3 volts. Figures 70.4–70.6 show the temperature results and the number of individuals allocated in each zone.

### 70.3.2 Experiment II: Disturbance

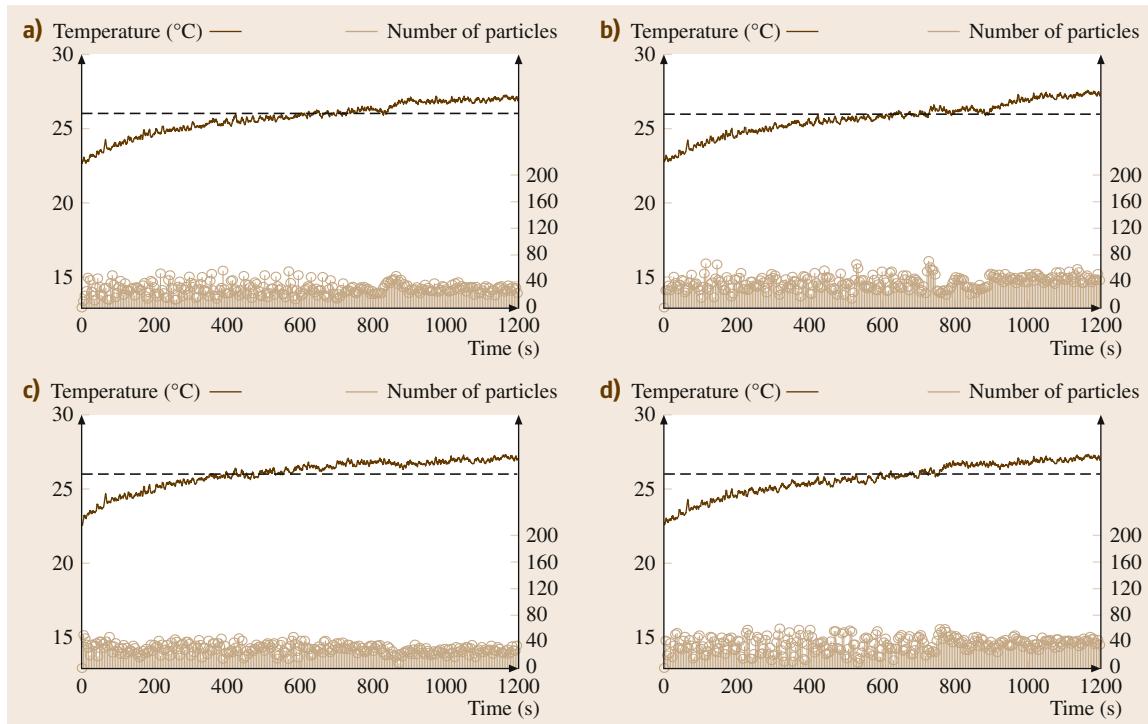

This experiment is similar to the first one, but now we add a controlled disturbance. An extra lamp is placed next to zone 4; it is turned on after 4 min, and is turned

off 2 min later. When we apply this disturbance, the temperature in zone 4 increases drastically and site 4 becomes the least profitable. Then, the number of individuals in that site are reallocated, provoking a small increase in temperatures of the other three zones. Figures 70.7–70.9 illustrate the behavior of the system applying the three algorithms.

### 70.3.3 Experiment III: Multiple Set Points

In this experiment we want to achieve multiple set points (26, 24, 27, and 25  $^{\circ}\text{C}$ , respectively, for each of the four zones), which are lower than the ones achieved before. Figure 70.10 presents the results obtained using the honey bee foraging algorithm. We can observe that the set points are never achieved, but the temperatures get very close to it, and the steady states are reached quickly. This is because the algorithm requires an error for each zone  $e_j > 0$ , which implies that the temperatures are always below the set point.

On the other hand, with the GA and PSO, the behavior is very different. When one of the set points is achieved, the resources tend to reallocate to the other

**Fig. 70.12a–d** Average temperature (solid lines) and number of chromosomes per zone (stem plots) using the **PSO**. The dashed lines show the set point for each zone

zones. Therefore, when all the zones reach their set points, all the fitnesses (which are proportional to the error values) are equal to 0, and the remaining resources should not be allocated. However, for these two methods, most of the resources need to be allocated to any site, and the remaining resources stay in the last site, provoking a drastic increase of the temperature in only that zone. When the temperature in any other zone de-

creases, agents tend to be reallocated to that new site very quickly, until the temperature increases again. Figures 70.11 and 70.12 show this behavior for the **GA** and **PSO**, respectively, with a fixed set point of 26 °C for all four zones. The drastic changes produced by the non-needed resources can be observed, and it can be seen that these methods are not feasible for these kinds of problems.

## 70.4 Discussion

The experiments that were performed using the bioinspired algorithms show behaviors common to each of the three techniques, and some advantages and disadvantages can be discussed. In Sect. 70.3.1, we saw how the maximum uniform temperature can be achieved by the three methods implemented. We obtained the average values and standard deviation of temperatures after ten experiments (Table 70.1). We observe that the genetic algorithm achieves the highest average temperatures, but the standard deviations are also high, which means that the **GA** behavior is unsteadier. This is be-

cause the **GA** is very susceptible to changes and, as soon as a zone becomes more profitable (the temperature decreases), most chromosomes tend to abandon their current positions and go to the more profitable one. That is why the number of chromosomes changes abruptly (Fig. 70.5), and the temperature variation is also high for each one of the ten experiments. On the other hand, the other algorithm's reactions are slower, and the number of individuals remains almost constant (very low variations). Table 70.1 illustrates that the honey bee social foraging algorithm has the lowest

**Table 70.1** Average temperatures and standard deviations for the last 10 min, using each algorithm

| Algorithms | Zone 1           | Zone 2           | Zone 3           | Zone 4           |
|------------|------------------|------------------|------------------|------------------|
| Honey bee  | $27.28 \pm 0.12$ | $27.26 \pm 0.12$ | $27.22 \pm 0.11$ | $27.18 \pm 0.11$ |
| GA         | $29.78 \pm 0.38$ | $29.8 \pm 0.3$   | $29.75 \pm 0.34$ | $29.76 \pm 0.36$ |
| PSO        | $27.84 \pm 0.17$ | $27.86 \pm 0.18$ | $28.55 \pm 0.14$ | $27.81 \pm 0.16$ |

temperature variation, which means that for every experiment, the maximum temperature achieved for each zone is practically the same. This is an advantage, because repeatability is a very important characteristic in practical applications. Besides, the low variations in the amount of individuals (i.e., low voltage changes), implying a low deterioration of the electric elements.

Section 70.3.2 shows the results when a disturbance is applied to the fourth zone. When this disturbance is turned on, the temperature increases in that zone, and that site becomes less profitable, provoking a reallocation of the individuals into the other zones. Figures 70.7–70.9 show how the resources are reallocated and the temperatures in the other sites increase. It can be observed that during the disturbance, the number of individuals in the fourth zone tends to 0 and, as soon as the disturbance is turned off, the temperature in that zone decreases. These results illustrate the robustness of the three techniques for external disturbances, and we can also observe that regardless of the type of disturbance, the maximum uniform temperature is achieved.

Experiment 3 illustrates the behavior of the algorithms when low temperature set points are considered. We observed that most of the resources should be allocated to the sites, and low temperature references could not be achieved. This is because the individuals move from one place to another, looking for the more profitable site, i.e., the one with the lowest temperature. When all the set points are achieved, all profitability values are 0, and the individuals will remain in their current position. Hence, temperatures continue to rise, even if the reference has been achieved. Figures 70.11 and 70.12 illustrate this behavior for the GA algorithm and PSO when a reference temperature of  $26^{\circ}\text{C}$  is set. However, the honey bee foraging algorithm can solve this kind of problem because of its capability to allocate only the *necessary* bees into the foraging places, and the non-needed resources are simply not used. This characteristic of our technique may be very useful in practical applications, such as in smart building temperature control, where multiple temperature references for different rooms need to be achieved.

## 70.5 Conclusions

In this chapter, a novel bioinspired method for dynamic resource allocation based on the social behavior of honey bees during the foraging process was presented, and an application that illustrates the validity of the approach was studied. The application that we used is a multizone temperature control grid, where the objective is to achieve some reference temperatures for each one of the zones, taking into account the complexity induced by the interzone effects and external or internal noise. Some comparative analyses have been developed

with two evolutionary algorithms, i.e., GA and PSO. We can see that the proposed method has some advantages compared to other bioinspired methods due to its capability of allocating only the necessary resources, and the low variability of the number of individuals in each one of the four zones. Clearly, there are other applications for the social foraging method for resource allocation. For instance, in the area of task allocation of agents, formation control, economic dispatch, and smart building temperature control.

# 71. Fundamental Collective Behaviors in Swarm Robotics

Vito Trianni, Alexandre Campo

In this chapter, we present and discuss a number of types of fundamental collective behaviors studied within the swarm robotics domain. Swarm robotics is a particular approach to the design and study of multi-robot systems, which emphasizes decentralized and self-organizing behavior that deals with limited individual abilities, local sensing, and local communication. The desired features for a swarm robotics system are flexibility to variable environmental conditions, robustness to failure, and scalability to large groups. These can be achieved thanks to well-designed collective behavior – often obtained via some sort of bio-inspired approach – that relies on cooperation among redundant components. In this chapter, we discuss the solutions proposed for a limited number of problems common to many swarm robotics systems – namely aggregation, synchronization, coordinated motion, collective exploration, and decision making. We believe that many real-word applications subsume one or more of these problems, and tailored solutions can be developed starting from the studies we review in this chapter. Finally, we propose possible directions for future research and discuss the relevant challenges to be addressed in order to push forward the study and the applications of swarm robotics systems.

## 71.1 Designing Swarm Behaviours

Imagine the following scenario: in a large area there are multiple items that must be reached, and possibly moved elsewhere or processed in some particular way. There is no map of the area to be searched, and the area is rather unknown, unstructured, and possibly dangerous for the intervention of humans or any valuable asset. The items must be reached and processed as quickly as possible, as a timely intervention would correspond to a higher overall performance. This is the typical scenario to be tackled with swarm robotics. It contains all the properties and complexity issues that make a swarm robotics solution particularly appropriate. Parallelism, scalability, robustness, flexibility, and adaptability to unknown conditions are features that are required from a system confronted with such a scenario, and exactly those features are sought in swarm robotics research.

Put in other terms, swarm robotics promises the solution of complex problems through robotic systems made up of multiple cooperating robots. With respect to other approaches in which multiple robots are exploited at the same time, swarm robotics emphasizes aspects like decentralization of control, limited individual abilities, lack of global knowledge, and scalability to large groups.

One important aspect that characterizes a swarm robotics system concerns the robotic units, which are unable to solve the given problem individually. The limitation is given either by physical constraints that would prevent the single robot to individually tackle the problem (e.g., the robot has to move some items that are too heavy), or by time constraints that would make a solitary action very inefficient (e.g., there are too many items to be collected in a limited time). Another source of limitation for the individual robot comes from its inability to acquire a global picture of the problem, having only access to partial (local) information about the environment and about the collective activity. These limitations imply the need for cooperation to ensure task achievement and better efficiency. Groups of autonomous cooperating robots can be exploited to synergistically achieve a complex task, by joining forces and sharing information, and to distributedly undertake the given task and achieve higher efficiency through parallelism.

The second important aspect in swarm robotics is redundancy in the system, which is intimately connected with robustness and scalability. Swarm robotics systems are made by homogeneous robots (or by relatively few heterogeneous groups of homogeneous

robots). This means that the failure of a single or a few robots is not a relevant fact for the system as a whole, because the failing robot can easily be replaced by another teammate. Differently from a centralized system, in a swarm robotics system there is no single point of failure, and every component is interchangeable with other components. Redundancy, distributed control, and local interactions also allow for scalability, enabling the robotic system to seamlessly adapt to varying group sizes. This is a significant advantage with respect to centralized systems, which would present an exponential increase in complexity for larger group sizes.

Because all the above features are desiderata, the problem remains as to how to design and implement such a robotic system. The common starting point in swarm robotics is the biological metaphor, for which the fundamental mechanisms that govern the organization of animal societies can be distilled in simple rules to be implemented in the robotic swarm. This approach allowed us to extract the basic working principles for many types of collective behavior, and several examples will be presented in this chapter. However, it is worth noting that swarm robotics systems are not constrained to mimicking nature. Indeed, in many cases there is no biological example to be taken as reference, or the mechanisms observed in the natural system are too difficult to be implemented in the robotic swarm (e.g., odor perception is an open problem in robotics, preventing easy exploitation of pheromone-based mechanisms by using real chemicals). Still, even in those systems that have no natural counterpart, the relevant property that should be present is self-organization, for which group behavior is the emergent result of the numerous interactions among different individuals. Thanks to self-organization, simple control rules repeatedly executed by the individual robots may result in complex group behavior.

If we consider the scenario presented at the beginning of this chapter, it is possible to recognize a number of problems common to many swarm robotics systems, which need to be addressed in order to develop suitable controllers. One first problem in swarm robotics is having robots get together in some place, especially when the robotic system is composed by potentially many individuals. Getting together (i.e., aggregation) is the precondition for many types of collective behavior, and needs to be addressed according to the particular characteristics of the robotic system and of the environment

in which it must take place. The aggregation problem is discussed in Sect. 71.2. Once groups are formed, robots need some mechanism to stay together and to keep a coherent organization while performing their task. A typical problem is, therefore, how to maintain such coherence, which corresponds to ensuring the synchronization of the group activities (Sect. 71.3), and to keep the group in coordinated motion when the swarm must move across the environment (Sect. 71.4). Another common problem in swarm robotics corresponds to searching together and processing some items in the environment. To this aim, different strategies can be adopted to cover the available space, and to identify relevant navigation routes without resorting to maps

and global knowledge (Sect. 71.5). Finally, to maintain coherence and efficiency, the swarm robotics system is often confronted with the necessity to behave as a single whole. Therefore, it must be endowed with collective perception and collective decision mechanisms. Some examples are discussed in Sect. 71.6. For each of these problems, we describe some seminal work that produced solutions in a swarm robotics context. In each section, we describe the problem along with some possible variants, the biological inspiration and the theoretical background, the relevant studies in swarm robotics, and a number of other works that are relevant for some particular contribution given to the specific problem.

## 71.2 Getting Together: Aggregation

Aggregation is a task of fundamental importance in many biological systems. It is the basic behavior for the creation of functional groups of individuals, and therefore, supports the emergence of various forms of cooperation. Indeed, it can be considered a prerequisite for the accomplishment of many collective tasks. In swarm robotics too, aggregation has been widely studied, both as a standing-alone problem or within a broader context. Speaking in general terms, aggregation is a collective behavior that leads a group of agents to gather in some place. Therefore, from a (more or less) uniform distribution of agents in the available space, the system converges to a varied distribution, with the formation of well recognizable aggregates. In other words, during aggregation there is a transition from a homogeneous to a heterogeneous distribution of agents.

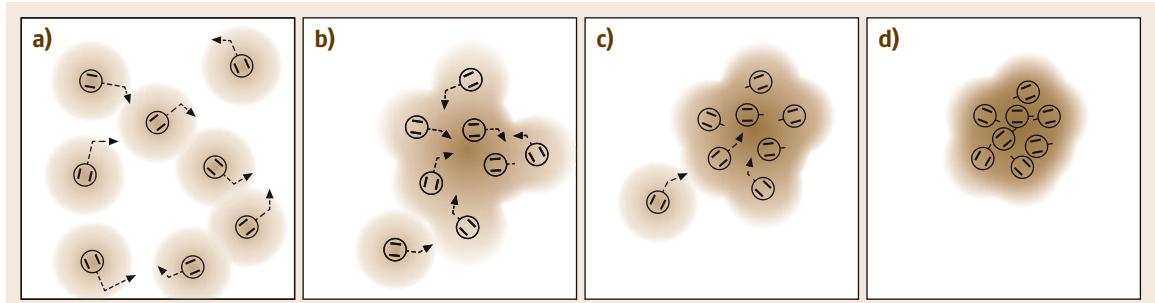

### 71.2.1 Variants of Aggregation Behavior

Aggregation can be achieved in many different ways. The main issue to be considered is whether or not the environment contains pre-existing heterogeneities that can be exploited for aggregation: light or humidity gradients (think of flies or sow bugs), corners, shelters, and so forth represent heterogeneities that can be easily exploited. Their presence can, therefore, be at the basis of a collective aggregation behavior, which, however, may not exploit interactions between different agents. Instead, whenever heterogeneities are not present (or cannot be exploited for the aggregation behavior), the problem is more complex. The agents must behave in order to create the heterogeneities that support the formation of aggregates. In this case, the basic mechanism

of aggregation relies on a self-organizing process based on a positive feedback mechanism. Agents are sources of some small heterogeneity in the environment (e.g., being the source of some signal that can be chemical, tactile or visual). The more aggregated agents, the higher the probability to be attracted by the signal. This mechanism leads to amplification of small heterogeneities, leading to the formation of large aggregates.

### 71.2.2 Self-Organized Aggregation in Biological Systems

Several biological systems present self-organized aggregation behavior. One of the best studied examples is given by the cellular slime mold *Dictyostelium discoideum*, in which aggregation is enabled by self-generated biochemical signals that support the migration of cells and the formation of a multi-cellular body [71.1, 2]. A similar aggregation process can be observed in many other unicellular organisms [71.3]. Social and pre-social insects also present multiple forms of aggregation [71.4, 5]. In all these systems, it is possible to recognize two main variants of the aggregation process. On the one hand, the agents can emit a signal that creates an intensity gradient in the surrounding space. This gradient enables the aggregation process: agents react by moving in the direction of higher intensity, therefore aggregating with their neighbors (Fig. 71.1). On the other hand, aggregation may result from agents modulating their stopping time in response to social cues. Agents have a certain probability to stop and remain still for some time. The vicinity to other agents increases the probability of stopping and of remaining

**Fig. 71.1a–d** Aggregation process based on a diffusing signal that creates an intensity gradient. **(a)** Agents individually emit a signal and move in the direction of higher concentration. **(b)** The individual signals sum up to form a stronger intensity gradient in correspondence with forming aggregates. **(c)** A positive feedback loop amplifies the aggregation process until all agents are in the same cluster **(d)**

within the aggregate, eventually producing an aggregation process mediated by social influences (Fig. 71.2). In both cases, the same general principle is at work. Aggregation is dependent on two main probabilities: the probability to enter an aggregate, which increases with the aggregate size, and the probability to leave an aggregate, which decreases accordingly. This creates a positive feedback loop that makes larger aggregates more and more attractive with respect to small ones. Some randomness in the system helps in breaking the symmetry and reaching a stable configuration.

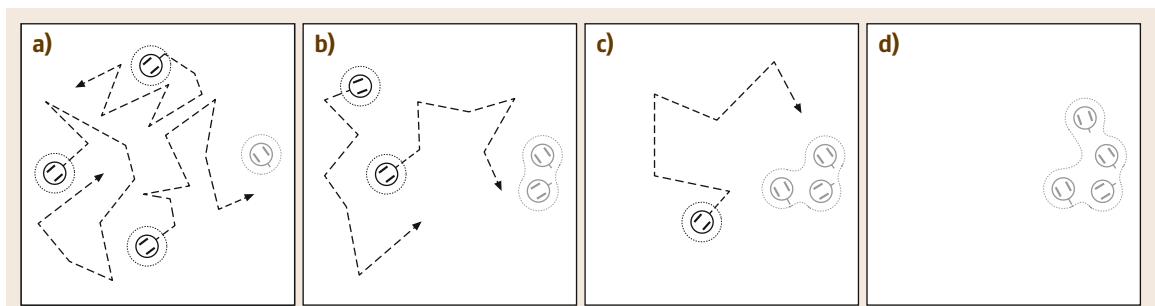

### 71.2.3 Self-Organized Aggregation in Swarm Robotics

On the basis of the studies of aggregation in biological systems, various robotic implementations have been presented, based on either of the two behavioral mod-

els described above. Of particular interest is the work presented in [71.6], in which the robotic system was developed to accurately replicate the dynamics observed in the cockroach aggregation experiments presented in [71.5]. In this work, a group of Alice robots [71.7] was used and their controller was implemented by closely following the behavioral model derived from experiments with cockroaches. The behavioral model consists of four main conditions:

- i) Moving in the arena center
- ii) Moving in the arena periphery
- iii) Stopping in the center
- iv) Stopping in the periphery.

When stopping, the mean waiting time is influenced by the number of perceived neighbors (for more details, see [71.6]). The group behavior resulting from the

**Fig. 71.2a–d** Aggregation process based on variable probability of stopping within an aggregate. **(a)** Agents move randomly and may stop for some time (gray agent). **(b)** When encountering a stopped agent, other agents stop as well, therefore increasing the size of the aggregate. **(c)** The probability of meeting an aggregate increases with the aggregate size for geometric reasons. Social interactions modulate the probability of leaving the aggregate, which diminishes with the increasing number of individuals. **(d)** Eventually, all agents are in the same aggregate

interaction among Alice robots was analyzed with the same tools used for cockroaches [71.5, 6]. The comparison of the robotic system with the biological model shows a very good correspondence, demonstrating that the mechanisms identified by the behavioral model are sufficient to support aggregation in a group of robots, with dynamics that are comparable to that observed in the biological system. Additionally, the robotic model constitutes a constructive proof that the identified mechanisms really work as suggested.

This study demonstrates, in terms of simple rules, the approach of distilling the relevant mechanisms that produce a given self-organizing behavior. A different approach consists in exploiting artificial evolution to synthesize the controllers for the robotic swarm. This allows the user to simply define some performance metric for the group and let the evolutionary algorithm find the controllers capable of producing the desired behavior. This generic approach has been exploited to evolve various self-organizing behaviors, including aggregation [71.8]. In this case, robots were rewarded to minimize their distance from the geometric center of the group and to keep moving. The analysis of the evolved behavior revealed that in all cases robots are attracted by teammates and repelled by obstacles. When a small aggregate forms, robots keep on moving thanks to the delicate balance between attractive and repulsive forces. This makes the aggregate continuously expand and shrink, moving slightly across the arena. This slow motion of the aggregate makes it possible to attract other robots or other aggregates formed in the vicinity, and results in a very good scalability of the ag-

gregation behavior with respect to the group size. This experiment revealed a possible alternative mechanism for aggregation, which is not dependent on the probability of joining or leaving an aggregate. In fact, robots here never quit an aggregate to which they are attracted. Rather, the aggregates themselves are dynamic structures capable of moving within the environment, and in doing so they can be attracted by neighboring aggregates, until all robots belong to the same group.

### 71.2.4 Other Studies

The seminal papers described above are representative of other studies, which either exploit a probabilistic approach [71.9, 10], or rely on artificial evolution [71.11]. Approaches grounded on mathematical models and control theory are also worth mentioning [71.12, 13]. Other variants of the aggregation behavior can be considered. The aggregate may be characterized by an internal structure, that is, agents in the aggregate are distributed on a regular lattice or form a specific shape. In such cases, we talk about *pattern/shape formation* [71.14]. Another possibility is given by the admissibility of multiple aggregates. In the studies mentioned so far, multiple aggregates may form at the beginning of the aggregation process, but as time goes by smaller aggregates are disbanded in favor of larger ones, eventually leading to a single aggregate for the whole swarm. However, it could be desirable to obtain multiple aggregates forming functional groups of a specific size. In this case, it is necessary to devise mechanisms for controlling the group size [71.15].

## 71.3 Acting Together: Synchronization

Synchronization is a common phenomenon observed both in the animate and inanimate world. In a synchronous system, the various components present a strong time coherence between the individual types of behavior. In robotics, synchronization can be exploited for the coordination of actions, both within a single or a multi-robot domain. In the latter case, synchronization may be particularly useful to enhance the system efficiency and/or to reduce the interferences among robots.

### 71.3.1 Variants of Synchronization Behavior

Synchronization in a multi-agent system can be of mainly two forms: *loose* and *tight*. In the case of loose

synchronization, we observe a generic coordination in time of the activities brought forth by different agents. In this case, single individuals do not present a periodic behavior, but as a group it is possible to observe bursts of synchronized activities. Often in this case there are external cues that influence synchrony, such as the day-light rhythm. On the other hand, it is possible to observe tight synchronization when the individual actions are perfectly coherent. To ensure tight synchronization in a group, it is possible to rely on either a centralized or a distributed approach. In the former, one agent acts as a reference (e.g., a conductor for the orchestra or the music theme for a ballet) and drives the behavior of the other system components. In the latter, a self-organizing

process is in place, and the system shows the ability to synchronize without an externally-imposed rhythm. It is worth noting that tight synchronization does not necessitate individual periodic behavior, neither in the centralized nor in the self-organized case. For instance, synchronization has also been studied between coupled chaotic systems [71.16]. In the following, we focus on self-organized synchronization of periodic behavior, which is the most studied phenomenon as it is commonly observed in many different systems.

### 71.3.2 Self-Organized Synchronization in Biology

Although synchronization has always been a well-known phenomenon [71.17], its study did not arouse much interest until the late 1960s, when Winfree began investigating the mechanisms underlying biological rhythms [71.18]. He observed that many systems in biology present periodic oscillations, which can get entrained when there is some coupling between the oscillators. A mathematical description of this phenomenon was first introduced by Kuramoto [71.19], who developed a very influential model that was afterwards refined and applied to various domains [71.17].

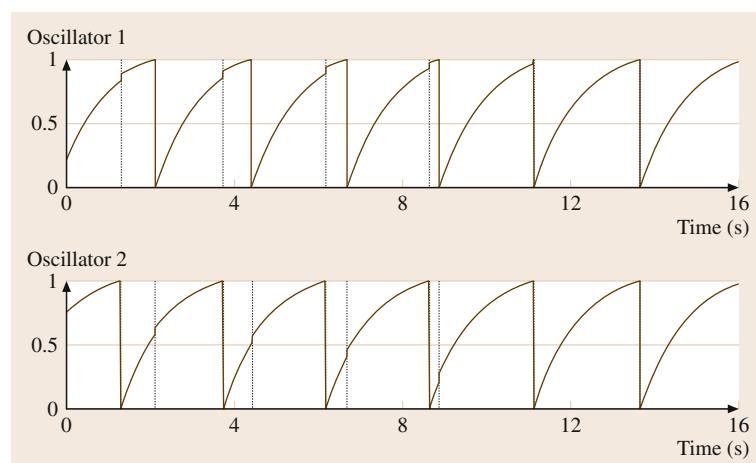

Similar mechanisms are at the base of the synchronous signaling behavior observed in various animal species [71.3]. *Chorusing* is a term commonly used to refer to the coordinated emission of acoustic communication signals by large groups of animals. To cite a few examples, chorusing has been observed in frogs, crickets, and spiders. However, probably the most fascinating synchronous display is the synchronous flashing of fireflies from South-East Asia. This phenomenon was

thoroughly studied until a self-organizing explanation was proposed to account for the emergence of synchrony [71.20].

A rather simple model describes the behavior of fireflies as the interactions between pulse-coupled oscillators [71.21]. In Fig. 71.3, the activity of two oscillators is represented as a function of time. Each oscillator is of the integrate-and-fire type, which well represents a biological oscillator such as the one of fireflies. The oscillator is characterized by a voltage-like variable that is integrated over time until a threshold is reached. At this point, a pulse is fired and the variable is reset to the base level (Fig. 71.3). Interactions between oscillators take the form of constant phase shifts induced by incoming pulses, which bring other oscillators close to the firing state, or make them directly fire. These simple interactions are sufficient for synchronization; in a group of similarly pulse-coupled oscillators, constant adjustments of the phase made by all the individuals lead to a global synchronization of pulses (for a detailed description of this model, see [71.21]).

### 71.3.3 Self-Organized Synchronization in Swarm Robotics

The main purpose of synchronization in swarm robotics is the coordination of the activities in a group. This can be achieved in different ways, and mechanisms inspired by the behavior of pulse-coupled oscillators have been developed. In [71.15], synchronization is exploited to regulate the size of traveling robotic aggregates. Robots can emit a short sound signal (a chirp), and enter a refractory state for a short time after signaling. Then, robots enter an active state in which they may signal

**Fig. 71.3** Synchronization between pulse-coupled oscillators. The oscillator emits pulses each time its state variable reaches the threshold level (corresponding to 1 in the plot). When one oscillator emits a pulse, its state is reset while the state of the other oscillator is advanced by a constant amount, which corresponds to a phase shift, or to the oscillator firing if it overcomes the threshold

at any time, on the basis of a constant probability per time-step. Therefore, the chirping period is not constant and depends on the chirping probability. In this state, robots also listen to external signals and react by immediately emitting a chirp. This mechanism, similar to chorusing in frogs and crickets, leads to synchronized emission of signals. Thanks to this simple synchronization mechanism, the size of an aggregate can somehow be estimated. Given the probabilistic nature of chirping, a robot has a probability of independently initiating signaling that depends on the number of individuals in the group; estimating this probability by listening to own and others' chirps allows an approximate group size estimation. Synchronization, therefore, ensures a mechanism to keep coherence in the group, which is the precondition for group size estimation.

In [71.22], synchronization is instead necessary to reduce the interferences between robots, which periodically perform foraging and homing movements in a cluttered environment. Without coordination, the physical interferences between robots going toward and away from the home location lead to a reduced overall performance. Therefore, a synchronization mechanism based on the firefly behavior was devised. Robots emit a signal in correspondence to the switch from foraging to homing. This signal can be perceived by neighboring robots within a limited radius and induces a reset of the internal rhythm that corresponds to a behavioral shift to homing. Despite the limited range of communication among robots, a global synchronization is quickly achieved, which leads the group to reduce interferences and increase the system performance [71.22].

A different approach to the study of synchronization is described in [71.23]. Here, artificial evolution is exploited to synthesize the behavior of a group of robots, with the objective of obtaining minimal communication strategies for synchronization. Robots were rewarded to present an individual periodic movement and to signal in order to synchronize the individual oscillations. The results obtained through artificial evolution are then analyzed to understand the mechanisms that can support

synchronization, showing that two types of strategies are evolved: one is based on a modulation of the oscillation frequency, the other relies on a phase reset. These two strategies are also observed in biological oscillators: for instance, different species of fireflies present different synchronization mechanisms, based on delayed or advanced phase responses [71.20].

### 71.3.4 Other Studies

While self-organized synchronization is a well-known phenomenon, its application in collective and swarm robotics has not been largely exploited. The coupled-oscillator synchronization mechanism was applied to a cleaning task to be performed by a swarm of micro robots [71.24]. Another interesting implementation of the basic model can be found in [71.25]. Here, synchronization is exploited to detect and correct faults in a swarm robotics system. It is assumed that robots can synchronize a periodic flashing behavior while moving in the arena and accomplishing their task. If a robot incurs some fault, it will forcibly stop synchronizing. This fault can be detected and recovered by neighboring robots. Similar to the heartbeat in distributed computing, correct synchronization corresponds to a well-functioning system, while the lack of synchronization corresponds to a faulty condition.

Finally, synchronization behavior may emerge spontaneously in an evolutionary robotics setup, even if they are not explicitly rewarded. In [71.26], synchronization of group activities evolved spontaneously as a result of the need to limit the interferences among robots in a foraging task. In [71.27], robots were rewarded to maximize the mean mutual information between their motor actions. Mutual information is a statistical measure derived in information theory, and roughly corresponds to the correlation between the output of two stochastic processes. Evolution, therefore, produced synchronous movements among the robots, which could actually maximize the mutual information while maintaining a varied behavior.

## 71.4 Staying Together: Coordinated Motion

Another fundamental problem for a swarm is ensuring coherence in space. This means that the individuals in the swarm must display coordinated movement in order to maintain a consistent spatial structure. Coordinated motion is often observed in groups of animals. Flocks of

birds or schools of fish are fascinating examples of self-organized behavior producing a collective motion of the group. Similar problems need to be tackled in robotics, for instance for moving in formation or for distributedly deciding a common direction of motion.

### 71.4.1 Variants of the Coordinated Motion Behavior

The coordinated motion of a group of agents can be achieved in different ways. Also in this case, we can distinguish mainly between a centralized and a distributed approach. In a centralized approach, one agent can be considered the leader and the other agents follow (e.g., the mother duck with her ducklings). In the distributed approach, instead, there is no single leader and some coordination mechanism must be found to let the group move in a common direction. Of particular interest for swarm robotics are the coordinated motion models based on self-organization. Such models consider multi-agent systems that are normally homogeneous and characterized by a uniform distribution of information: no agent is more informed than the others, and there exists no a priori preference for any direction of motion (i.e., agents start being uniformly distributed in space). However, through self-organization and amplification of shared information, the system can break the symmetry and converge to a common direction of motion. A possible variant of the self-organized coordinated motion consists in having a non-uniform distribution of information, which corresponds to hav-

ing some agents that are more informed than the others on a preferred direction of motion. In this case, a few informed agents may influence the motion of the entire group.

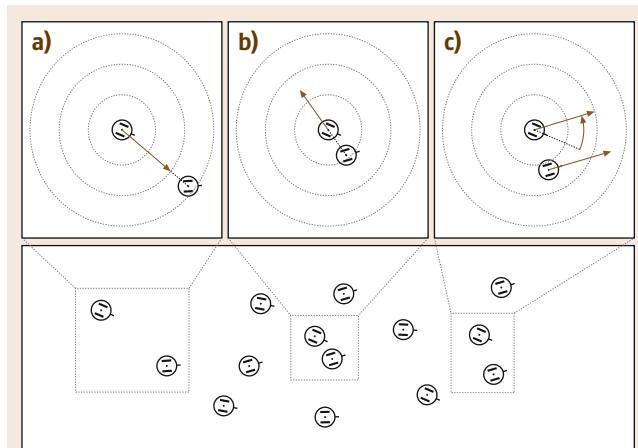

### 71.4.2 Coordinated Motion in Biology

Many animal species present coordinated motion behavior, ranging from bacteria to fish and birds. Not all animal species employ the same mechanisms, but in general it is possible to recognize various types of interactions among individuals that have a bearing on the choice of the motion direction. Coordinated motion has mainly been studied in various species of fish, in birds, and in insect swarms [71.29, 30]. The most influential model was introduced by *Huth and Wissel* to describe the behavior of various species of fish observed [71.28]. In this model, it is assumed that each fish is influenced solely by its nearest neighbor. Also, the movement of each fish is based on the same behavioral model, which also includes some inherent random fluctuation. According to the proposed behavioral model, each fish follows essentially three rules:

- i) Approach a far away individual
- ii) Get away from individuals that are too close
- iii) Align with the neighbor direction (Fig. 71.4).

When the nearest neighbor is within the closest region, the fish reacts by moving away. When the nearest neighbor is in the farthest region, the fish reacts by approaching. Otherwise, if the neighbor is within the intermediate region, the fish reacts by aligning. These simple rules are sufficient to produce collective group motion, and the final direction emerges from the interactions among the individuals.

Starting from the above model, a number of variants have been proposed, which take into account different parameters and different numbers of individuals. In [71.31], a model including all individuals in the perceptual range was introduced, and a broad analysis of the parameters was performed, showing how minor differences at the individual level correspond to large differences at the group level. In [71.32], an experimental study on bird flocks in the field was performed, and position and velocity data were obtained for each bird in a real flock through stereo-photography and 3-D mapping. The data obtained data were used to verify the assumption about the number of individuals that each bird monitors during flocking, showing that this number is constant (and corresponds to about 7 individuals)

**Fig. 71.4a–c** Self-organized coordinated motion in a group of agents. In the bottom part, a group of agents is moving in roughly the same direction. According to the model presented in [71.28], agents react to the closest neighbor within their perception range and follow three main rules: (a) agents move toward a neighbor when it is too far; (b) agents move away from a neighbor when it is too close; (c) agents rotate and align with a neighbor situated at intermediate distances. The iterated application of these rules leads the group to move in a same direction

notwithstanding the varying density of the flock. Finally, in [71.33], a model was developed in which some of the group members have individual knowledge on a preferential direction. The model describes the outcome of a consensus decision in the flock as a result of the interaction between informed and uninformed individuals.

### 71.4.3 Coordinated Motion in Swarm Robotics

The models introduced for characterizing the self-organized behavior of fish schools or bird flocks have also inspired a number of interesting studies. The most influential work is definitely that of *Reynolds*, who developed virtual creatures called *boids* [71.34]. In this work, each creature executes three simple types of behavior:

- i) Collision avoidance, to avoid crashing with nearby flockmates
- ii) Velocity matching, to move in the same way of nearby flockmates
- iii) Flock centering, to stay close to nearby flockmates.

Notice that the behavioral model corresponds to the models proposed in biological studies. The merit of this work is that it is the first implementation of the rules studied for real flocks in a virtual 3-D world, showing a close correspondence of the behavior of boids with that of flocks, herds, and schools. Reynolds' research has been taken as inspiration by many other studies on coordinated motion, mainly in simulation. In [71.35], an implementation of the flocking behavioral model was proposed and tested on real robots. Robots use infrared proximity sensors to recognize the presence of other robots and their distance, which is necessary for collision avoidance and flock centering behavior. Additionally, a dedicated sensor to perceive the heading of neighbors was developed to support aligning behavior. This system, called the virtual heading system (**VHS**), is based on a digital compass and wireless communication. Despite the fact that a digital compass cannot reliably work in an indoor environment, it is assumed that neighboring robots have similar perceptions. The heading perceived with respect to the local north is communicated over the wireless channel, and it is exploited for alignment behavior. This system al-

lowed testing the flocking behavior of small robotic groups in a physical setting and studying the dynamics of flocking with up to 1000 simulated robots. This work was later extended in [71.36], by having a subgroup of informed individuals which could steer the whole flock, following the model presented in [71.33]. The dynamics of steered flocking have been studied by varying the percentage of informed robots in simulation, and tests with real robots have been performed as well.

### 71.4.4 Other Studies

As mentioned above, there exist numerous studies that were inspired by the schooling/flocking models. All these studies adopt some variants of the behavioral rules described above, or analyze the group dynamics under some particular perspective. A different approach to coordinated motion can be found in [71.37]. In this work, robots have to transport a heavy object and have imperfect knowledge of the direction of motion. They can, however, negotiate the goal direction by displaying their own preferred direction of motion and by adjusting it on the basis of the direction displayed by others. On the whole, this mechanism implements similar dynamics to the alignment behavior of the classical flocking model. Here, however, robots are connected together to the object to be transported, adding a further constraint to the system that obliges a good negotiation to allow motion. A similar constraint characterizes the coordinated motion studies with physically assembled robots presented in [71.38, 39]. Here, robots form a physical structure of varying shape and can rotate their chassis in order to match the direction of motion of the other robots. In this case, there is no direct detection of the motion direction of neighbors. Instead, robots can sense the pulling and pushing forces that are exerted by the other connected robots through the physical connections. These pulling/pushing forces are naturally averaged by the force sensor, which returns their resultant. Artificial evolution was exploited to synthesize an artificial neural network that could transform the forces sensed to motor commands. The results obtained show the impressive capability of self-organized coordination between the robots, as well as scalability and generalization to different size and shapes [71.38], and the ability to cope with obstacles and to avoid falling outside the borders of the arena [71.39].

## 71.5 Searching Together: Collective Exploration

Exploring and searching the environment is an important behavior for robot swarms. In many tasks, the swarm must interact with the environment, sometimes only to monitor it, but sometimes also to process materials or other kinds of resources. Usually, the swarm cannot completely perceive the environment, and the environment may also change during the operation of the robots. Hence, robots need to explore and search the environment to monitor for changes or in order to detect new resources.

To cope with its partial perception of the environment, a swarm can move, for instance using flocking, in order to explore new places (some locations may be unavailable, though). Hence, most of the environment can be perceived, but not at the same time. As in many other artificial systems, a tradeoff between exploration and exploitation exists and requires careful design choices.

### 71.5.1 Variants of Collective Exploration Behavior

There is no perfect exploration and search strategy because the structure of the environment in which the swarm is placed can take many different shapes. Strategies only perform more or less well as a function of the situation with which they are faced [71.40]. For instance, the swarm could be in a maze, in a open environment with few obstacles, or in an environment with many obstacles.

We identified a restricted number of environmental characteristics that play an important role in the choice of searching behavior in swarm robotics. These characteristics are commonly found in swarm robotics scenarios, and are the presence of a central place, the size of the environment, the presence of obstacles.

The central place is a specific location where robots must come back regularly, for instance for maintenance or to deposit foraged items. A scenario that involves a central place requires a swarm able to either remember or keep track of that location.

If the environment is closed (finite area) and not too large, the swarm may use random motion to explore, with fair chances to rapidly locate resources (or even the central place). In an open environment, robots can get lost very quickly. In this type of environment, it is necessary to use a behavior that allows robots to stay together and maintain connectivity.

Obstacles are environmental elements that constrain the motion of the swarm. If the configuration of the ob-

stacles is known in advance, the swarm can move in the environment following appropriate patterns. In most cases, however, obstacles are unexpected or might be dynamic and may prevent the swarm from exploring parts of the environment.

### 71.5.2 Collective Exploration in Biology

In nature, animals are constantly looking for resources such as food, sexual partners, or nesting sites. Animals living in groups may use several types of behavior to explore their environment and locate these resources.

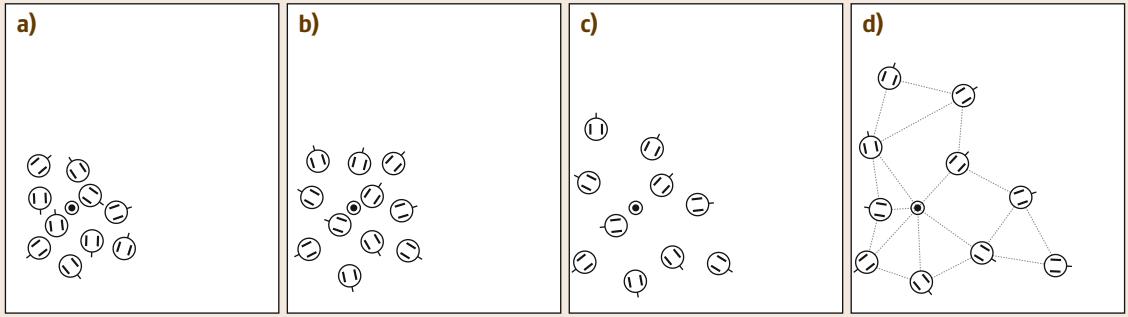

For instance, fish can take advantage of the number of individuals in a shoal to improve their capabilities to find food [71.41–43]. To do so, they move and maintain large interdistances between individuals. In this way, fish increase their perceptual coverage as well as their chances to find new resources.

Animals also heavily rely on random motion to explore their environment [71.44–46]. Usually the exploratory pattern is not fully random (that is, isotropic), because animals use all possible environmental cues at hand to guide themselves. Random motion can be biased towards a given direction, or it can be constrained in a specific area, for instance around a previously memorized location [71.47]. Some desert ants achieve high localization performance with odometry (counting their footsteps) and relying on gravity and the polarization of natural light. They may move randomly to look for resources but they are able to quickly return to their nest and also to return to an interesting location previously identified.

### 71.5.3 Collective Exploration in Swarm Robotics

One of the most common exploration strategies used in robotics is random exploration. In a typical implementation, robots wander in the environment until they perceive a feature of interest [71.48–50]. By doing this, robots possibly lose contact with each other and, therefore, their ability to work together. Hence this strategy is not suited for large or open environments. Due to the stochastic nature of the strategy, its performance can only be evaluated statistically. On average, the time to locate a feature is proportional to the squared distance with robots [71.44].

Systematic exploration strategies are very different. Robots use some a priori knowledge about the structure

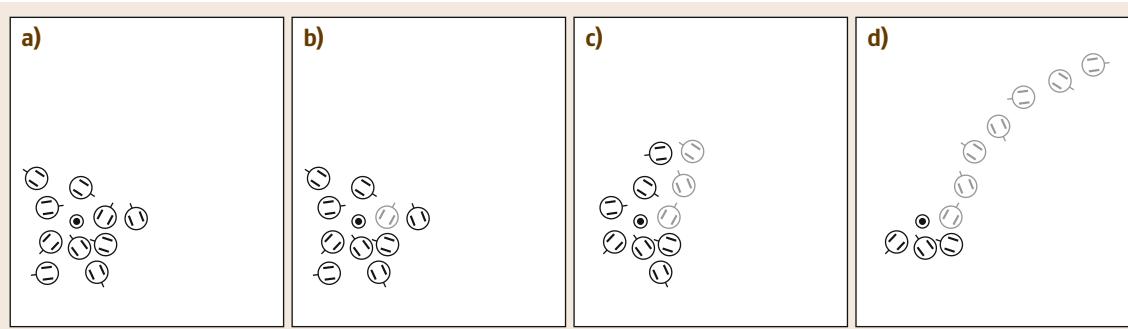

**Fig. 71.5a–d** Gas expansion behavior to monitor the surroundings of a central place. (a) The swarm starts aggregated around a central place (represented by a *black spot*). (b,c) Robots try to move as far as possible from their neighbors, while maintaining some visual or radio connection. (d) As a result, the whole swarm expands in the environment, like a gas, covering part of the environment

of the environment in order to methodically sweep it and find features. To ensure that robots do not repeatedly cover the same places, they may need to memorize which places have already been explored. This is often implemented with localization techniques and mapping of the environment [71.51]. The advantage of this technique is that an answer will be found with certainty, and the time of exploration has a lower and upper bound if the environment is not open. However, memory requirements may be excessive, and the strategy is not suited for open environments.

Between the two extreme strategies reported in the previous paragraph lie a number of more specialized strategies that present advantages and drawbacks depending on the structure of the environment and the distribution of the resources.

Collective motion (which has already been detailed in Sect. 71.4) allows swarms to maintain their cohesion while moving through the environment. Flocking behavior can be employed in an open environment with a limited risk of losing contact between robots. The swarm behaves like a sort of physical mesh that covers part of the environment; to maximize the area covered during exploration robots can increase their interdistance during motion as much as possible.

Gas expansion behavior (Fig. 71.5) allows robots to quickly and exhaustively explore the surroundings of a central place [71.52–55]. While one or several robots keep track of a central place, other robots try to move as far as possible from their neighbors, while still maintaining direct line of sight with at least one of them. The swarm behaves like a fluid or gas that penetrates

**Fig. 71.6a–d** Chaining behavior in action with a central place represented by a *large black dot*, bottom left. (a) Robots start aggregated around the central place. (b) While maintaining visual or radio contact with neighbors, some robots change role and become part of a chain (grayed out). (c) Other robots move around the central place and encounter the early chain of robots. With some probability, they also turn into new parts of the chain. (d) At the end of the iterative process, robots form a long chain that spans through the environment and maintains a physical link to the central place

the asperities of the environment. The exploration is very effective and any change or new resource within the perception range of the swarm is immediately perceived. However, since robots are bound to the central place, the area that they can explore is limited by the number of robots in the swarm. If robots do not stick to a central place, the resulting behavior shifts to a type of flocking or moving formation.

With chaining behavior, swarms can form a chain with one end that sticks to a central place and the other end that freely moves through the environ-

ment (Fig. 71.6). In [71.56], minimalistic behavior produces a static chain, but different types of chain motions can be imagined. In [71.57], for instance, chains can build up, move, and disaggregate until a resource is found. Contrary to gas expansion behavior, a chaining swarm may not immediately perceive changes in the environment because it has to constantly sweep the space. Chaining allows robots to cover a more important area than gas expansion behavior, ideally a disc of radius proportional to the number of robots.

## 71.6 Deciding Together: Collective Decision Making

Decision making is a behavior used by any artificial system that must produce an adapted response when facing new or unexpected situations. Because the best action depends on the situation encountered, a swarm cannot rely on a pre-programmed and systematic reaction. Monolithic artificial systems make decisions all the time, by gathering information and then evaluating the different options at hand. However, when it comes to swarms, each group member might have its own opinion about the correct decision. If all individuals perceive the same information and process it in the same way, then they might independently make the same decision. However, in practice, the more common case is that individuals perceive partial and noisy information about the situation. Thus, if no coordination among group members occurs, a segregation based on differing opinions might take place, thereby removing the advantages of being a swarm. Therefore, the challenge is to have the whole group collaborate to make a collective decision and take action accordingly.

### 71.6.1 Variants of Collective Decision Making Behavior

There are mainly three mechanisms reported in the literature that allow swarms to make collective decisions. The first and most simple mechanism is based on opinion propagation. As soon as a group member has enough information about a situation to make up its mind, it propagates its opinion through the whole group.

The second mechanism is based on opinion averaging. All individuals constantly share their opinion with their neighbors and also adjust their own opinion in consequence. This iterative process leads to the emergence of a collective decision. The adjustment of the opinion

is typically achieved with an average function, especially if opinions are about quantitative values such as a location, a distance, or a weight, for instance.

The third and last mechanism relies on amplification to produce a collective decision. In a nutshell, all individuals start with an opinion, and may decide to change their opinion to another one. The switch to a new opinion happens with a probability calculated on the basis of the frequency of this opinion in the swarm. Practically, this means that if an opinion is represented often in the group, it has also more chances of being adopted by an individual, which is why the term amplification is used.

Each of the three aforementioned mechanisms has some advantages over the others and may be preferred, depending on the situation faced. The factors that play an important role in collective decision processes include the speed and the accuracy needed to make the choice, the robustness of communication, and the reliability of individual information.

In terms of speed, opinion propagation allows fast collective decisions, in contrast with the two other mechanisms, which require numerous interactions among individuals. However, this speed generally comes at the cost of robustness or accuracy [71.58–60]. If communication is not robust enough, messages can be corrupted. The mechanism of opinion propagation is particularly sensitive to such effects, and a wrong or random collective decision might be made by a swarm in that case.

The averaging mechanism would produce a more robust decision because wrong information from erroneous messages is diluted in the larger amount of information present in the swarm [71.61]. However, opinion averaging works best if all individuals have roughly

identical knowledge. If a small proportion of individuals have excellent knowledge to make the decision, while the remaining individuals have poor information, opinion propagation may produce better results than opinion averaging [71.33].

Lastly, the amplification mechanism is the main choice for a gradually emerging collective decision if opinions cannot be merged with some averaging function. Instead of adjusting opinions, individuals simply adopt new opinions with some probability. It is worth noting that this mechanism can produce good decisions even if individuals have poor information.

### 71.6.2 Collective Decision Making in Biology

The powerful possibilities of decision making in groups were already suggested by *Galton* back in 1905 [71.62]. In that paper, Galton reports the results of a weight-judging competition in which competitors had to estimate the weight of a fat ox. With slightly less than 800 independent estimates, Galton observed that the average estimate was accurate to 1% of the real weight of the ox. This early observation opened interesting perspectives about the accuracy of collective estimations, but it did not describe a collective decision mechanism, since Galton himself had to gather the estimates and apply some calculation to evaluate the estimate of the crowd.

More recent studies about group navigation have shown that groups of animals cohesively moving together towards a goal direction reach their objective faster than independent individuals [71.63, 64]. The mechanism of collective navigation not only allows the individuals to move and stay together, but it also acts as a distributed averaging function that locally fuses the opinions of individuals about the direction of motion, allowing them to improve their navigation performance.

In the last decades, the amplification mechanism has been identified as a source of collective decision in a broad range of animal species such as ants [71.65, 66], honeybees [71.67, 68], spiders [71.69], cockroaches [71.70], monkeys [71.71], and sheep [71.72].

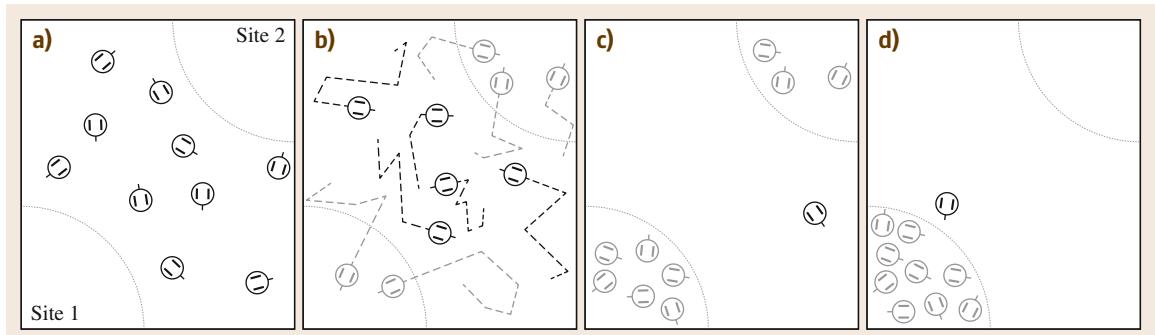

Ants that choose one route to a resource probably constitute the most well-known example of the amplification mechanism. In [71.66], an ant colony is offered two paths to two identical resource sites. Initially, the two resources are exploited equally, but after a short time ants focus on a single resource. This collective choice happens because ants that have found the resource come back to the nest, marking the ground with a pheromone trail. The next ants that try to reach the

resource are sensitive to this odor and have higher chances of following the path with higher pheromone concentration. As a result of this amplified response, a collective decision rapidly emerges. In addition, it was shown in [71.73] that when ants are presented two paths of different lengths to the same resource, the same pheromone-based mechanism allows them to choose the shortest path. This can be explained by the fact that ants using the shortest path need less time to make round trips, making the pheromone concentration on this path grow faster.

Quorum sensing is a special case of the amplification mechanism which has been notably used to explain nest site selection in ants and bees [71.74–76]. The most basic example of quorum sensing uses a threshold to dictate if individuals should change their opinion. If an individual perceives enough neighbors (above the threshold) that already share the opposite opinion, then it will in turn adopt this opinion. It has been shown that this threshold makes quorum sensing more robust to the propagation of erroneous information during the decision process. In addition, the accuracy of collective decisions made with quorum sensing may improve with group size, and cognitive capabilities of groups may outperform the ones of single individuals [71.77, 78]. In the case of nest site selection, cohesion is mandatory for the group. A cross inhibition mechanism complementing amplification was identified as a key feature to ensure that groups do not split [71.79].

### 71.6.3 Collective Decision Making in Swarm Robotics

In swarm robotics, opinion averaging has been used to improve the localization capabilities of robots. In [71.50], a swarm of robots carries out a foraging task between a central place and a resource site. The robots have to navigate back and forth between the two places and use odometry to estimate their location. As odometry provides noisy estimates, robots using solely this technique may quickly get lost. Here, robots can share and merge their localization opinions when they meet, by means of local infrared communication. By doing so, robots manage better localization and improve their performance in the foraging task. Moreover, robots associate a confidence level to their estimates, which is used to decide how information is merged. If a robot advertises an opinion with very high confidence, then the mechanism produces opinion propagation. Hence the two mechanisms of averaging and propagation are

**Fig. 71.7a–d** A swarm of robots is presented with two resource sites in its environment and must collectively choose one. (a) Initially, robots are randomly scattered. (b) Using a random walk, they move until a resource site is found. On average, the swarm is split in the two sites. (c) The more neighbors they perceive, the longer the robots stay. A competition between the two sites takes place and any random event may change the situation. Here a robot just left the *top right site*, further reducing the chances that other robots stay there. (d) The swarm has made a choice in favor of the *bottom left site*. The choice is stable, although some robots may frequently leave the site for exploration

blended in a single behavior, and the balance between them is tuned by the user with a control parameter.

The aggregation behavior previously mentioned in Sect. 71.2.3 can be exploited to trigger collective decision making in situations where there are several environmental heterogeneities. In [71.80], the robots are presented two shelters and they choose one of them as a resting site by aggregating there. The behavior of the robots closely follows the one observed in cockroaches (Fig. 71.7). In [71.81], both robots and cockroaches are introduced in an arena with two shelters, demonstrating the influence of the two groups on each other when making the collective decision. The collective decision is the result of an amplification mechanism, implemented via the probability of a robot leaving an aggregate. This probability diminishes with the number of perceived neighbors, allowing larger aggregates to attract more robots.

#### 71.6.4 Other Studies

The opinion averaging mechanism was deeply investigated with a general mathematical approach in [71.82,

83]. These studies demonstrate convergence of the mechanism and emphasize the importance of the topology of the communication network through which interactions take place.

Another amplification mechanism inspired from the behavior of honeybees was implemented in [71.84]. With this mechanism, it was shown that robots are able to make a collective decision and between two sites reliably choose the one offering the best illumination conditions.

The amplification mechanism based on pheromone trails, which is used by ants, has also inspired several swarm robotics studies. In [71.85, 86], the pheromone is replaced by light projected by a beamer. This implementation is limited to laboratory studies, but it allowed demonstrating path selection with robot swarms. In [71.87], the process is abstracted inside a network of robots that are deployed in the environment. Virtual ants hop from robots to robots and deposit pheromone inside them. Eventually, the shortest path to a resource is marked out by robots with high and sustained levels of pheromone.

## 71.7 Conclusions

In this chapter, we have presented a broad overview of the common problems faced in a swarm robotics context, and we pointed to possible approaches to obtain solutions based on a self-organizing process. We have discussed aggregation, synchronization, co-

ordinated motion, collective exploration, and decision making, and we argued that many application scenarios could be solved by a mix of the above solutions. So, are we done with swarm robotics research? Definitely not.

First of all, the fact that possible solutions exist does not mean that they are the most suitable for any possible application scenario. Hardware constraints, miniaturization, environmental contingencies, and performance issues may require the design of different solutions, which may strongly depart from the examples given above. Still, the approaches we presented constitute a logical starting point, as well as a valid benchmark against which novel approaches can be compared.

Another important research direction consists in characterizing the self-organizing behavior we presented in terms of abstract properties, such as the time of convergence toward a stable state, sensitivity to parameter changes, robustness to failures, and so forth. From this perspective, the main problem is to ensure a certain functionality of the system with respect to the needs of the application and to predict the system features before actual development and testing. In many cases, a precise characterization of the system is not possible, and only a statistical description can be achieved. Still, such an enterprise would bring swarm robotics closer to an engineering practice, eventually allowing us to guarantee a certain performance of the developed system, as well as other properties that engineering commonly deals with.

The examples we presented all refer to homogeneous systems, in which all individuals are physically

identical and follow exactly the same rules. This is, however, a strong simplification, which follows the tradition of biological modeling of self-organizing behavior. However, instead of being a limitation, heterogeneity is potentially a richness to be exploited in a swarm robotics system, which can lead to more complex group behavior. For instance, different individual reactions to features in the environment can be at the basis of optimal decision making at the group level [71.88]. Otherwise, heterogeneity between groups of individuals can be exploited for performing tasks that require specialized abilities, but maintaining an overall redundancy of the system that ensures robustness and scalability [71.89].

In conclusion, swarm robotics research still has many challenges to address, which range from the need for a more theoretical understanding of the relation between individual behavior and group dynamics, to the autonomy and adaptation to varied real-world conditions in order to face complex application scenarios (e.g., due to harsh environmental conditions such as planetary or underwater exploration, or to strong miniaturization down to the micro scale). Whatever the theoretical or practical driver is, we believe that the studies presented in this chapter constitute fundamental reference points that teach us how self-organization can be achieved in a swarm robotics system.

## 72. Collective Manipulation and Construction

# Collective Manipulation and Construction

Lynne Parker

Many practical applications can make use of robot collectives that can manipulate objects and construct structures. Examples include applications in warehousing, truck loading and unloading, transporting large objects in industrial environments, and assembly of large-scale structures. Creating such systems, however, can be challenging. When collective robots work together to manipulate physical objects in the environment, their interactions necessarily become more tightly coupled. This need for tight coupling can lead to important control challenges, since actions by some robots can directly interfere with those of other robots. This chapter explores techniques that have been developed to enable robot swarms to effectively manipulate and construct objects in the environment. The focus in this chapter is on decentralized manipulation and construction techniques that would likely scale to large robot swarms (at least 10 robots), rather than approaches aimed primarily at smaller teams that attempt the same objectives. This chapter first discusses the swarm task of object transportation; in this domain, the objective is for

robots to collectively move objects through the environment to a goal destination. The chapter then discusses object clustering and sorting, which requires objects in the environment to be aggregated at one or more locations in the environment. The final task discussed is that of collective construction and wall building, in which robots work together to build a prespecified structure. While these different tasks vary in their specific objectives for collective manipulation, they also have several commonalities. This chapter explores the state of the art in this area.

### 72.1 Object Transportation

Some of the earliest work in swarm robotics was aimed at the object transportation task [72.1–6], which requires a swarm of robots to move an object from its current position in the environment to some goal destination. The primary benefit of using collective robots for this task is that the individual robots can combine forces to move objects that are too heavy for individual robots working alone or in small teams. However, the task is not without its challenges; it is nontrivial to design decentralized robot control algorithms that can effectively coordinate robot team members during object transportation. A further complication is that the interaction dynamics of the robots with the object can

be sensitive to certain object geometries [72.7, 8] and object rotations during transportation [72.8], thus exacerbating the control problem.

There are many ways to compare and contrast alternative distributed techniques to collective object transport. The most common distinctions are:

- Local knowledge only versus some required global knowledge (e.g., of team size, state, position).
- Homogeneous swarms versus heterogeneous swarms (e.g., teams with leaders and followers).
- Manual controller design versus autonomously learned control.

- 2-D (two-dimensional) vs. 3-D (three-dimensional) environments.
- Obstacle-free environments versus cluttered environments.
- Static environments versus dynamic environments.
- Dependent on fully functioning robots versus systems robust to error.

Alternatively, we can compare transportation techniques by focusing on the specific manipulation technique employed. The manipulation techniques used for collective object transportation can be grouped into three primary methods [72.9]: pushing, grasping, and caging. The pushing approach requires contact between each robot and the object, in order to impart force in the goal direction; however, the robots are not physically connected with the object. In the grasping approach, each robot in the swarm is physically attached to the object being transported. Finally, the caging approach involves robots encircling the object so that the object moves in the desired direction, even without the constant contact of all the robots with the object.

This section outlines some of the key techniques developed to address this object transportation task, organized according to these three main techniques.

### 72.1.1 Transport by Pushing

A canonical task often used as a testbed in distributed robotics is the box pushing task. The number, size, or weight of the boxes can be varied to explore different types of multirobot cooperation. This task typically involves robots first locating a box, positioning themselves at the box, and then moving the box cooperatively toward a goal position. Typically, this task is explored in 2-D. The domain of box pushing is also popular because it has relevance to several real-world applications [72.10], including warehouse stocking, truck loading and unloading, transporting large objects in industrial environments, and assembling of large-scale structures.

The pushing technique was first demonstrated in the early work of *Kube* and *Zhang* [72.1], inspired by the cooperative transport behavior in ants [72.7]. They proposed a behavior-based approach that combined behaviors for seeking out the object (illuminated by a light), avoiding collisions, following other robots, and motion control. An additional behavior to detect stagnation was used to ensure that the collective did not work consistently against each other. In this approach, all robots acted similarly; there was no concept

of a leader and followers. While some of the robots in the swarm might not contribute to the pushing task due to poor alignment or positioning along the nondominant pushing direction, *Kube* and *Zhang* showed that careful design of these behaviors enabled the robot swarm to distribute along the boundary of the object and push it. Figure 72.1 shows five robots cooperatively pushing a lighted box.

Other researchers have explored different aspects of box pushing in multirobot systems. While much of this early work involved demonstrations of smaller robot teams, many of these techniques could theoretically scale to larger numbers of robots. Task allocation and action selection are often demonstrated using collective box pushing experiments; examples of this work include that of *Parker* [72.11, 12], who illustrated aspects of adaptive task allocation and learning; *Gerkey* and *Mataric* [72.13], who present a publish/subscribe dynamic task allocation method; and *Yamada* and *Saito* [72.14], who develop a behavior-based action selection technique that does not require any communication.

Other work using box pushing as an implementation domain for multirobot studies includes *Donald* et al. [72.15], who illustrates concepts of information invariance and the interchangeability of sensing, communication, and control; *Simmons* et al. [72.16], who demonstrate the feasibility of cooperative control for building planetary habitats, *Brown* and *Jennings* [72.17], and *Böhringer* et al. [72.18], who explored notions of strong cooperation without communication in pusher/steerer models, *Rus* et al. [72.19], who

**Fig. 72.1** Demonstration of five robots collectively pushing a lighted box (after [72.7])

studied different cooperative manipulation protocols in robot teams that make use of different combinations of state, sensing, and communication, and *Jones and Mataric* [72.20], who developed general methods for automatically synthesizing controllers for multirobot systems.

Most of this existing work in box pushing has focused, not on box pushing as the end objective, but rather on using box pushing for demonstrating various techniques for multirobot control. However, for studies whose primary objective is to generate robust cooperative transport techniques, work has more commonly focused on manipulation techniques involving grasping and caging, rather than pushing, since grasping and caging provide more controllability by the robot team.

### 72.1.2 Transport by Grasping

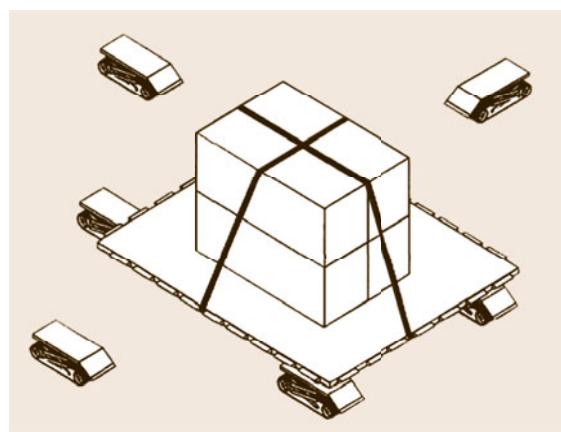

Grasping approaches for object transportation in swarm robotics typically make use of form closure and force closure properties [72.21]. In *form closure*, the object motion is constrained via frictionless contact constraints; in *force closure*, frictional contact forces exerted by the robots prevent unwanted motions of the manipulated object. The earliest work representing the grasping technique is that of *Wang et al.* [72.4]. This approach uses form closure, along with a behavior-based control approach that is similar to the early swarm robot pushing technique of *Kube and Zhang* [72.1]. The technique of *Wang et al.* called **BeRoSH** (for Behavior-based Multiple Robot System with Host for Object Manipulation), incorporates behaviors for pushing, maintaining contact, moving, and avoiding objects. In this approach, the goal pose of the object is provided directly to each robot from an external source (i.e., the Host); otherwise, the robots work independently according to their designed behaviors. As a collective, the swarm exhibits form closure. *Wang et al.* showed that this form closure technique can successfully transport an object to its desired goal pose from a variety of different starting locations.

Another early work using the force closure grasping technique is that of *Stilwell and Bay* [72.2] and *Johnson and Bay* [72.3]. They developed distributed leader-follower techniques that enable swarms of tank-like robots to transport pallets collectively while maintaining a level height of the pallet during transportation (Fig. 72.2). In their approaches, a pallet sits atop several tank-like robots; the weight of the pallet creates a coupling with the robots that could be viewed similar to a grasp. To transport the pallet, one vehicle is

designated as the leader. This leader then perturbs the dynamics of the system to move the swarm in the desired direction, and with the desired pallet height. The remaining robots in the swarm react to the perturbations to stabilize the forces in the system. The system is fully distributed, and requires robots to only use local force information to achieve the collective motion. The individual robots do not require knowledge of the pallet mass or inertia, the size of the collective, or the robot positions relative to the pallet's center of gravity. They showed the control stability of their approach for this application, even in the presence of inaccurate sensor data.

A related approach is that of *Kosuge and Oosumi* [72.5], who also used a decentralized leader-follower approach for multiple holonomic robots grasping and moving an object, in a manner similar to that of [72.2]. Their approach defines a compliant motion control algorithm for each velocity-controlled robot. The main difference of this work compared to [72.2] is that the control algorithm specifies the desired internal force as part of the coordination algorithm. This approach was validated in simulation for robots carrying an aluminum steel pipe.

Another related approach is that of *Miyata et al.* [72.6], who addressed the need for nonholonomic vehicles to regrasp the object during transport. Their approach includes a hybrid system that makes use of both centralized and decentralized planners. The centralized planner develops an approximate motion plan for the object, along with a regrasping plan at low resolution; the decentralized planner precisely estimates object motion and robot control at a much higher resolution.

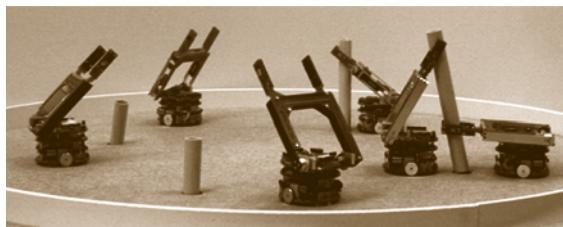

**Fig. 72.2** Cooperative transport of a pallet using tank-like robots (after [72.2])

They demonstrated the effectiveness of this approach in simulation.

*Sugar* and *Kumar* [72.22] developed distributed control algorithms enabling robots with manipulators to grasp and cooperatively transport a box. In this work, a novel manipulator design enables the locomotion control to be decoupled from the manipulation control. Only a small number of the team members need to be equipped with actively controlled end effectors. This approach was shown to be robust to positioning errors related to the misalignment between the two platforms and errors in the measurement of the box size.

Cooperative stick pulling [72.23, 24] was explored by *Ijspeert* et al.; this task requires robots to pull sticks out of the ground (Fig. 72.3). The robot controllers are behavior-based, and include actions such as looking for sticks, detecting sticks, gripping sticks, obstacle avoidance, and stick release. Experiments show that the dynamics are dependent on the ratio between the number of robots and sticks; that collaboration can increase superlinearly with certain team sizes; that heterogeneity in the robots can increase the collaboration rate in certain circumstances; and that a simple signalling scheme can increase the effectiveness of the collaboration for certain team sizes. A main objective of this research was to explore the effectiveness of various modeling techniques for group behavior. These modeling techniques are discussed in more detail in a separate chapter.

The SWARM-BOTS project is a more recent example of the use of grasping for collective transport; it also makes use of self-assembly as a novel approach for achieving distributed transport. In this work [72.25], *s-bot* robots are developed that have grippers enabling the robots to create physical links with other *s-bots* or objects, thus creating assemblies of robots. These assemblies can then work together for navigation across rough terrain, or to collectively transport objects. The *s-bots* are cylindrical, with a flexible arm

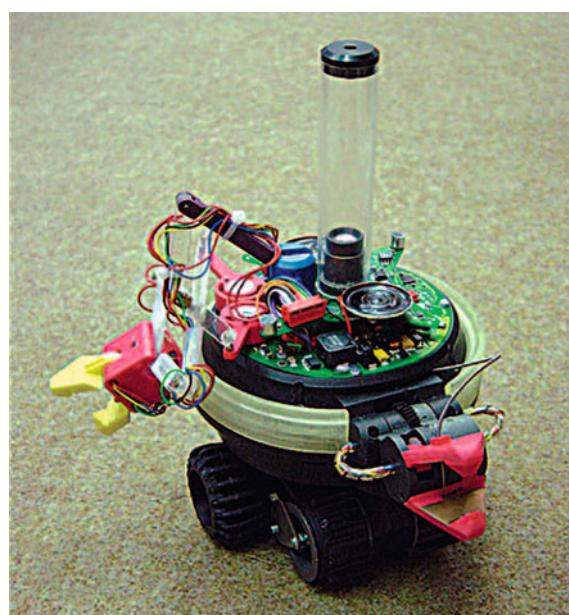

**Fig. 72.3** Stick pulling experiment using robot collectives (after [72.23])

and toothed gripper that can connect one *s-bot* to another (Fig. 72.4).

The decentralized control of the SWARM-BOT robots is learned using evolutionary techniques in simulation, then ported to the physical robots. The learned *s-bot* control [72.26] consists of an assembly module, which is a neural network that controls the robot prior to connection, and a transport module, which is a neural network that enables the *s-bot* to move the object toward the goal after a grasp connection is made. The self-assembly process involves the use of a red-colored seed object, to which other *s-bots* are attracted. *S-bots* initially light themselves with a blue ring, and then are attracted to the red color, while being repulsed by the blue color. Once robots make a connection, they color themselves red.

The interaction of these attractive and repulsive forces across the *s-bots* enables the robots to self-assemble into various connection patterns. Once the *s-bots* have self-assembled, they use the transport module to align toward a light source, which indicates the target position. The *s-bots* then apply pushing and pulling motions to transport the object to the destination. Similar to the approach of *Kube* and *Zhang* [72.1], the *s-bots* also check for stagnation and execute a recovery move when needed. The authors demonstrate [72.8] how the evolutionary learning approach allows the collective

**Fig. 72.4** An *s-bot*, developed as part of the SWARM-BOTS project (after [72.25])

to successfully deal with different object geometries, adapt to changes in target location, and scale to larger team sizes.

This technique for collective transport using self-assembly was demonstrated [72.25] in an interesting application of object transport, in which 20 s-bots self-assembled into four chains in order to pull a child across the floor (Fig. 72.5). In this experiment, the user specifies the number of assembled chains, the distribution of the s-bots into the chains, the global localization of the child, and the global action timing. The s-bots then autonomously form the chains using self-assembly and execute the pull.

Several additional interesting phenomena regarding collective transport were discovered in related studies with the SWARM-BOTS. Nouyan et al. [72.27] showed that the different collective tasks of path formation, self-assembly, and group transport can be solved in a single system using a homogeneous robot team. They further introduce the notion of *chains with cycle directional patterns*, which facilitate swarm exploration in unknown environments, and assist in establishing paths between the object and goal. The paths established by the robot-generated chains mimic pheromone trails in ants. In [72.28], Groß and Dorigo determined that, while robots that behave as if they are solitary robots can still collectively move objects, robots that learn transport behaviors in a group can achieve a better performance. In [72.29], Campo et al. showed that the SWARM-BOTS robots could effectively transport ob-

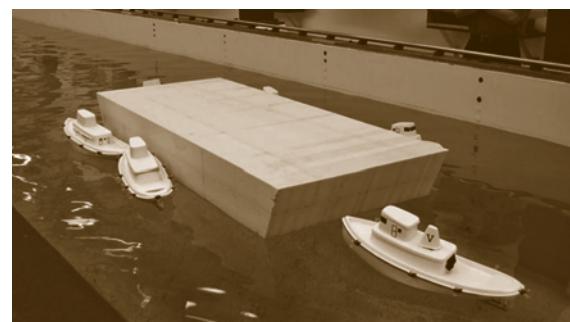

jects even with only partial knowledge of the direction of the goal. They investigated four alternative control strategies, which vary in the degree to which the robots negotiate regarding the goal position during transport. Their results showed that negotiating throughout object transport can improve motion coordination. All of these works are based on inspiration from biological systems.

The work of Berman et al. [72.31] is not only bio-inspired, but also seeks to directly model the group retrieval behavior in ants. Their studies examined the ants' roles during transport in order to define rules that govern the ants' actions. They further explored measurements of individual forces used by the ants to guide food to their nest. They found that the distributed ant transport behavior exhibits an initial disordered phase, which then transitions to a more highly coordinated phase of increased load speed. From these studies, a computational dynamic model of the ant behavior was designed and implemented in simulations, showing that the derived model matches ant behavior. Ultimately, this approach could be adapted for use on physical robot teams.

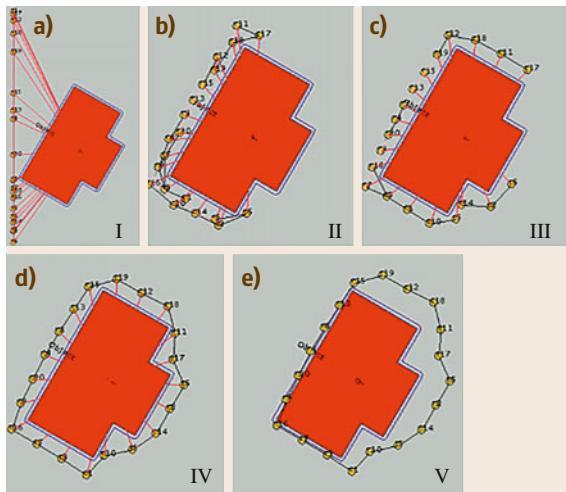

Once a robot collective has begun transporting an object, the question arises as to how new robots can join the group to help with the transport task. Esposito [72.30] addresses this challenge by adapting a grasp quality function from the multifingered hand literature. This approach assumes that robots know the object geometry, the total number of robots in the swarm, and the actuator limitation. Individual robot contact configurations are defined relative to the object center and object boundary. The objective is to find an optimal position for a new robot by optimizing across the grasping wrench space. A numerical algorithm was developed to address this problem, which incorporates the force closure criteria. This ap-

proach was demonstrated on unmanned tugboats collectively moving a barge, as illustrated in Fig. 72.6. In this demonstration, the robots are equipped with articulated magnetic attachments that allow them to grasp the barge. This approach is scalable to larger numbers of robots, with constant best case runtime,

and median runtimes polynomial in the number of robots.

### 72.1.3 Transport by Caging

The caging approach simplifies the object manipulation task, compared to the grasping approach, by making use of the concept of *object closure* [72.34]. In object closure, a bounded movable area is defined for the object by the robots surrounding it. The benefit of this approach is that continuous contact between the object and the robots is not needed, thus making for simpler motion planning and control techniques, compared to grasping techniques based on the form or force closure. Wang and Kumar [72.32] developed this object-closure technique under the assumptions that the robots are circular and holonomic, the object is star-shaped, the robots know the number of robots in the collective, and can estimate the geometric properties of the object, along with the distance and orientation to other robots and the object. Their approach causes the robots to first approach the object independently, and then search for an *inescapable formation*, which is a configuration of the robots from which the object cannot escape. Finally, the robots execute a formation control strategy to guide the object to the goal destination. The object approach technique is based on potential fields, in which force vectors attract the robot toward the object and generally away from other robots. Song and Kumar [72.35] proved the stability of this potential field approach for collective transport. Robots search for proper configurations around the object by representing the problem as a path finding problem in configuration space. This work describes a necessary and sufficient condition for testing for object closure. Later work [72.36] presents a fast algorithm to test for object closure. Experiments with 20 robots validate the proposed approach (Fig. 72.7).

A further enhancement of this vector-based control strategy was developed in [72.33], which can account for inter-robot collisions. This latter strategy implements three primary behaviors – approach, surround, and transport. In this variant of the work, robots converge to a smooth boundary using control-theoretic techniques. This work was implemented on a collective of physical robots, as illustrated in Fig. 72.8.

## 72.2 Object Sorting and Clustering

Collective object sorting and clustering requires robot teams to sort objects from multiple classes, typically into separate physical clusters. There are different types of related tasks in this domain [72.37], including clustering, segregation, patch sorting, and annular sorting. Early discussions of this task in robot swarms were given by Deneubourg et al. [72.38], with the ideas inspired by similar behaviors in ant colonies. The objective is to achieve clustering and sorting behaviors without any need for hierarchical decision making, inter-robot communication, or global representations of the environment. Deneubourg et al. showed that stigmergy could be used to cluster scattered objects of a single type, or to sort objects of two different types. To achieve the sorting behavior, the robots sensed the local densities of the objects, as well as the type of object they were carrying. Clustering resulted from a similar mechanism operating on a single type of object. Beckers et al. [72.39] achieved clustering from even simpler robots and behaviors, via stigmergic threshold mechanisms.

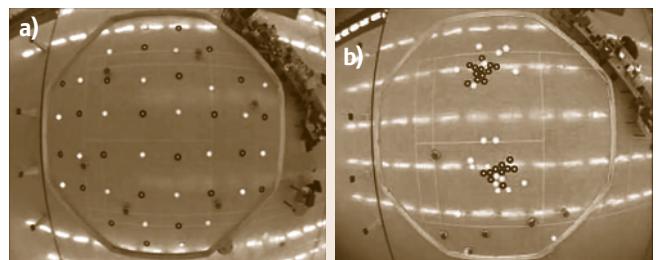

Holland and Melhuish [72.37] explored the effect of stigmergy and self-organization in swarms of homogeneous physical robots. The robots are programmed with simple rule sets with no ability for spatial orientation or memory. The experiments show the ability of the robots to achieve effective sorting and clustering, as illustrated in Fig. 72.9. In this work, a variety of influences were explored, including boundary effects and the distance between objects when deposited. The authors concluded that the effectiveness of the developed sorting behaviors is critically dependent on the exploitation of real-world physics. An implication of this finding is that simulators must be used with care when exploring these behaviors.

Wang and Zhang [72.40, 41] explored similar aims, but focused on discovering a general approach to the sorting problem. They conjecture that the outcome of the sorting task is dependent primarily on the capabilities of the robots, rather than the initial configuration. This conjecture is validated in simulation experiments, as illustrated in Fig. 72.10.

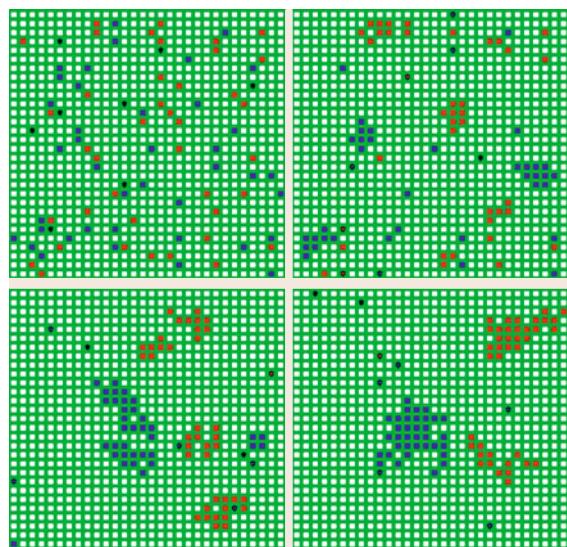

Other work on this topic includes that of Yang and Kamel [72.42], who present research using three colonies of ants having different speed models. The approach is a two-step process. The first step is for clusterings to be visually formed on the plane by agents walking, picking up, or setting down objects according

to a probabilistic model, which is based on Deneubourg et al. [72.38]. The second step is for clusters to be combined using a hypergraph model. Experiments were conducted in simulation to show the viability of the approach. The authors also discovered that having too many agents can lead to a deterioration in the swarm performance.

Martinoli and Mondada [72.43] implemented another bio-inspired approach to clustering, in which the robot behavior is similar to that of a Braatenberg vehicle. They also discovered that large numbers of robots can cause interference in this task, concluding that non-cooperative task cannot always be improved with more robots.

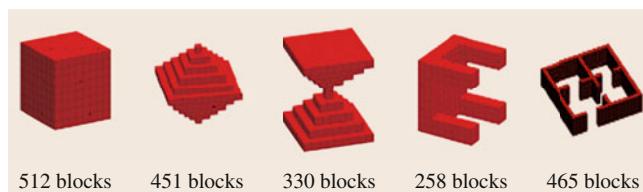

**Fig. 72.9** Results of physical robot experiments in sorting. Panel (a) shows the starting configuration, while (b) shows the sorting results after 1.75 h (after [72.37])

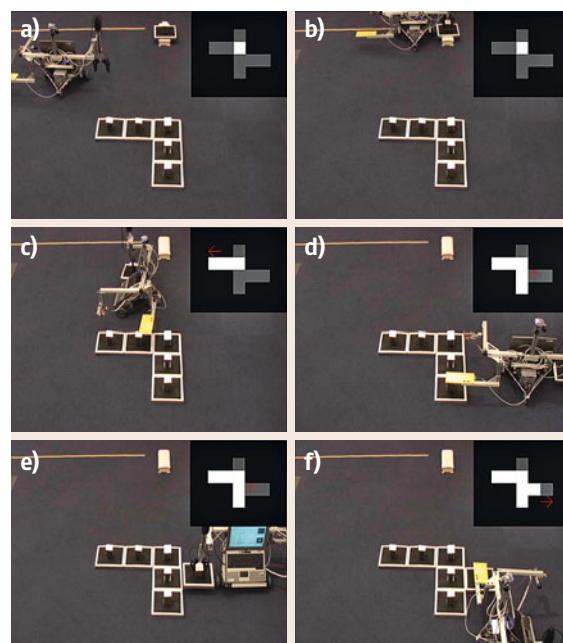

**Fig. 72.10** Results of simulations of sorting tasks, with 8 robots and 40 objects of two types (after [72.40])

## 72.3 Collective Construction and Wall Building

The objective of the collective construction and wall building task is for robots to build structures of a specified form, in either 2-D or 3-D. This task is distinguished from self-reconfigurable robots, whose bodies themselves serve as the dynamic structure. This section is focused on the former situation, in which manipulation is required to create the desired structure. The argument in favor of this separation of mobility and structure is that, once formed, the structure does not need to move again, and thus the ability to move could serve as a liability [72.44]. Furthermore, robotic units that serve both as mobility and structure might not be effective as passive structural elements.

**Fig. 72.11** Experiments for a variety of 3-D structures, built autonomously by a system of simple robots and blocks (after [72.44])

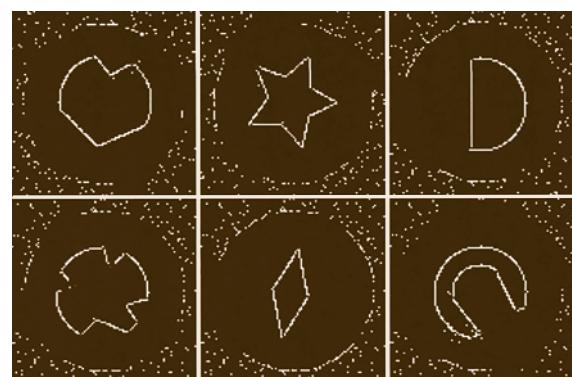

**Fig. 72.12a–f** Proof-of-principle experiments for 2-D construction, using a single robot (after [72.45])

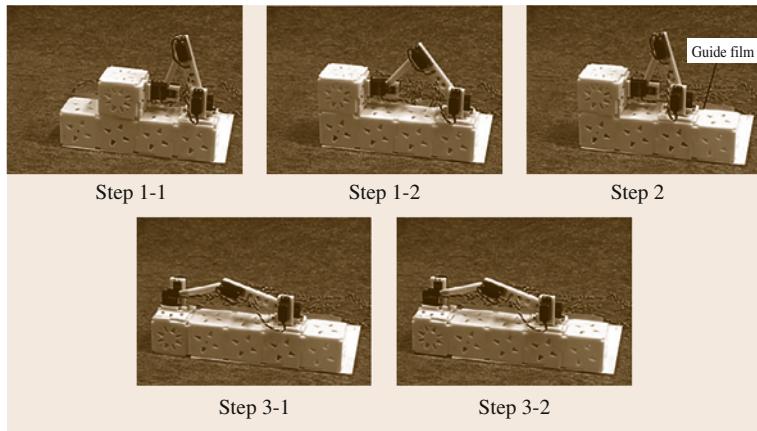

Werfel et al. have extensively explored this topic, developing distributed algorithms that enable simplified robots to build structures based on provided blueprints, both in 2-D [72.45–47] and in 3-D [72.44]. In their 3-D approach, the system consists of idealized mobile robots that perform the construction, and smart blocks that serve as the passive structure. The robots' job is to provide the mobility, while the blocks' role is to identify places in the growing structure at which an additional block can be placed that is on the path toward obtaining the desired final structure. The goal of their work is to be able to deploy some number of robots and free blocks into a construction zone, along with a single block that serves as a seed for the structure, and then have the construction to proceed autonomously according to the provided blueprint of the desired structure.

Several simplifying assumptions are made in this work [72.44], such as the environment being weightless and the robots being free to move in any direction in 3-D, including along the surface of the structure under construction. This work does not address physical robot navigation and locomotion challenges, grasping challenges, etc.

In this approach, blocks are smart cubes; they can communicate with attached neighbors, they share a global coordinate system, and they can communicate with passing robots regarding the validity of block attachments to exposed faces. Once robots have transported a free block to the structure, they locate attachment points in one of three ways: random movement, systematic search, or gradient following. A significant contribution of this work is the development of the block algorithm that enables the blocks to specify

**Fig. 72.13** Geometric structures built by a team of 30 robots, in simulation (after [72.48])

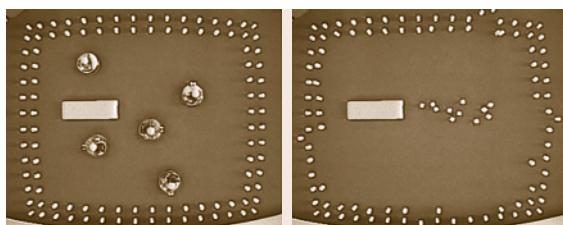

**Fig. 72.14** Experiments with prototype hardware designed for multirobot construction tasks (after [72.49])

how to grow the developing structure with guarantees, and with only limited required communication. More specifically, the communication requirement between blocks scales linearly in the size of the structure, while no explicit communication between the mobile robots is needed.

Experiments using this approach have shown the ability of the system to build a variety of structures in simulation, as illustrated in Fig. 72.11. A proof-of-principle physical robot experiment using a single robot in the 2-D case [72.45] is illustrated in Fig. 72.12.

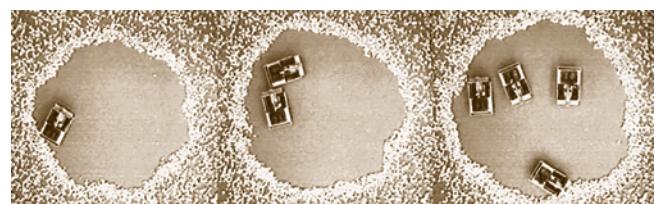

*Werfel* [72.48] also describes a system for arranging inert blocks into arbitrary shapes. The input to the robot system is a high-level geometric program, which is then translated by the robots into an appropriate arrangement of blocks using their programmed behaviors. The desired structure is communicated to the robots as a list of corners, the angles between corners, and whether the connection between corners is to be straight or curved. Robots are provided with behaviors such as *clearing*, *doneClearing*, *beCorner*, *collect*, *seal*, and *off*. Figure 72.13 shows some example structures built using this system in simulation.

**Fig. 72.15** Experimental trial demonstrating a swarm building a loose wall via a spatiotemporal varying template (after [72.50])

Hardware challenges of collective robot construction are addressed by *Terada* and *Murata* [72.49]. In this work, a hardware design is proposed that defines passive building blocks, along with an assembler robot that constructs structures with the robots. Figure 72.14 shows the prototype hardware completing an assembly task. In principle, multiple assembler robots could work together to create larger construction teams more closely aligned with the concept of swarm construction.

Other related work on the topic of collective construction includes the work of *Wawerla* et al. [72.51], in which robots use a behavior-based approach to build a linear wall using blocks equipped with either positive or negative Velcro, distinguished by block color. Their results show that adding 1 bit of state information to communicate the color of the last attached block provides a significant improvement in the collective performance. The work by *Stewart* and *Russell* [72.50, 52] proposes a distributed approach to building a loose wall structure with a robot swarm. The approach makes use of a spatiotemporal varying light-field template, which is generated by an organizer robot to help direct the actions of the builder robots. Builder robots deposit objects in locations indicated by the template.

**Fig. 72.16** Experiments of blind bulldozing for site clearing using physical robots (after [72.53])

Figure 72.15 shows the results from one of the experiments using this approach on physical robots.

Another type of construction is called *blind bulldozing*, which is inspired by a behavior observed in certain ant colonies. Rather than constructing by accumulating materials, this approach achieves construction by removing materials. This task has practical application in site clearing, such as would be needed for planetary exploration [72.54]. Early ideas of this concept were discussed by Brooks et al. [72.55], which argues for large numbers of small robots to be delivered to the lunar surface for site preparation. Parker et al. [72.53],

further developed this idea by proposing robots using force sensors to clear an area by pushing material to the edges of the work site. In this approach, the robot system collective behavior is modeled in terms of how the nest grows over time. Stigmergy is used to control the construction process, in that the work achieved by each robot affects the other robots' behaviors through the environment. Figure 72.16 shows some experiments using this approach on physical robots. The authors argue that blind bulldozing is appropriate in applications where the cost, complexity, and reliability of the robots is a concern.

## 72.4 Conclusions

This chapter has surveyed some of the important techniques that have been developed for collective object transport and manipulation. While many advances have been made, there are still many open challenges that remain. Some open problems include: How to deal with faults in the robot team members during task execution; how to address construction in dynamic and cluttered

environments; how to enable humans to interact with the robot swarms; how to extend more of the existing techniques to 3-D applications; how to design formal techniques for predicting and guaranteeing swarm behavior; how to realize larger scale systems on physical robots; and how to apply swarm techniques for manipulation and construction to practical applications.

# Reconfigurable Robots

Kasper Støy

Reconfigurable robots are robots built from mechatronics modules that can be connected in different ways to create task-specific robot morphologies. In this chapter we introduce reconfigurable robots and provide a brief taxonomy of this type of robot. However, the main focus of this chapter is on the four most important challenges in realizing reconfigurable robots. The first two are mechatronics challenges, namely the challenge of connector design and energy. Connectors are the most important design element of any reconfigurable robot because they provide it with much of its functionality, but also many of its limitations. Supplying energy to a connected, distributed multi-robot system such as a reconfigurable robot is an important, but often underestimated problem. The third challenge is distributed control of reconfigurable robots. It is examined both how reconfigurable robots can be controlled in static configurations to produce locomotion and manipulation and how configurations can be transformed through a self-reconfiguration process. The fourth challenge that we will discuss is programmability and debugging of reconfigurable robot systems. The chapter is concluded with a brief

perspective. Overall, the chapter provides a general overview of the field of reconfigurable robots and is a perfect starting point for anyone interested in this exciting field.

Reconfigurable robots are a kind of robot built from modules that can be connected in different ways to form different morphologies for different purposes. The motivation for this is that conventional robots are limited by their morphology. E.g., the size of the wheels of a wheeled robot determines what terrain it can traverse. If it has small wheels it can operate in confined spaces, but not traverse rugged terrain and, vice versa, if it has large wheels. A robot arm may be limited in terms of reach or inability to move around in the environment. Reconfigurable robots aim to solve this problem by providing a robotic system that can be manually reconfigured to be physically suited for the specific task at hand. It is conceivable that a reconfigurable robot on-

site can be fitted with several types of wheels, different segments can be added to form the body or arms. In this way, the reconfigurable robot can be a perfect physical fit for its task despite the task not being known or defined in advance.

While this practically oriented motivation is sufficient for developing and working with reconfigurable robots, the vision for the field is much deeper. The underlying, long-term vision is to develop robots that are robust, self-healing, versatile, cheap, and autonomous. Hence most research in the field of reconfigurable robots has been on self-reconfigurable robots. These robots consist of modules just like reconfigurable robots, but in addition the modules can automatically

**Fig. 73.1** A gathering of *Dictyostelium discoideum* amoebae cells can be seen migrating (some individually, and some in streams) toward a central point. Aggregation territories can be as much as a centimeter in diameter (after [73.2])

connect, disconnect, and move with respect to neighboring modules, and thus the robot as a whole can change shape not unlike the robot systems envisioned in science fiction movies such as Terminator and Transformers or the children's cartoon Barbapapa. Another way to view self-reconfigurable robots is as multi-cellular robots [73.1]. In this case, each module is comparable to a cell in an organism. In fact, the small animal hydra is able to self-reconfigure in the sense that if it is cut in half, the two sections each form a smaller, but complete hydra. While not strictly a multi-cellular organism, the slime mold *Dictyostelium* has also been of significant inspiration to the self-reconfigurable robot community. In this slime mold individual cells search for food in a local area, but once the food sources are used up the cells aggregate, as is shown in Fig. 73.1, to form slugs that number in the hundreds of thousands of cells, however, is still able to function as one organism whose mission it is in fact to find a suitable place to disperse spores for the next generation of slime molds.

The modular design gives reconfigurable robots a number of useful features. First of all the robots are robust since if modules fail, the rest of the modules will still continue working and thus the robot can maintain

**Fig. 73.2** The CKbot in a chain configuration with wheels attached (courtesy of Modlab at University of Pennsylvania)

a level of functionality, although it is slightly reduced. Self-reconfigurable robots extend on this by being able to eject failed modules from the robot and replace them with modules from other parts of their bodies and effectively achieve self-healing. A powerful demonstration of this is the CKBot shown in Fig. 73.2, which after a kick has broken into several clusters of modules. These clusters are able to locate each other again and recreate the original structure [73.3]. Another vision of reconfigurable robots is that they are versatile due to their modular structure. Reconfigurable robots are not limited by a fixed shape, but the number and capabilities of the modules are available. A final feature is that the individual modules can be produced relatively cheaply due to production at scale. The implication is that even though the individual module can be quite complex they can be mass produced and thus their cost can be relatively low compared to their complexity.

It is also important to point out that reconfigurable robots can never be a universal robot that can take on the functionality of any robot. It is, of course, the ultimate dream, but given a known task-environment a robot can be custom-designed for this and thus will be simpler and better performing than a comparable reconfigurable robot. Thus reconfigurable robots are best suited for situations where the task or environment is not known in advance or in locations where many different types of robots are needed, but it is not possible to bring them all. Optimal applications for reconfigurable robots are thus in extra-planetary missions, disaster areas, and so on. However, they may also find their use in more down to earth applications such as educational robotics [73.4] or as robot construction kits [73.5].

It is important to note that these are all visions that the reconfigurable robot community is striving towards, but has only realized in limited ways. However, it is the vision of these truly amazing reconfigurable robots that drives us forward.

## 73.1 Mechatronics System Integration

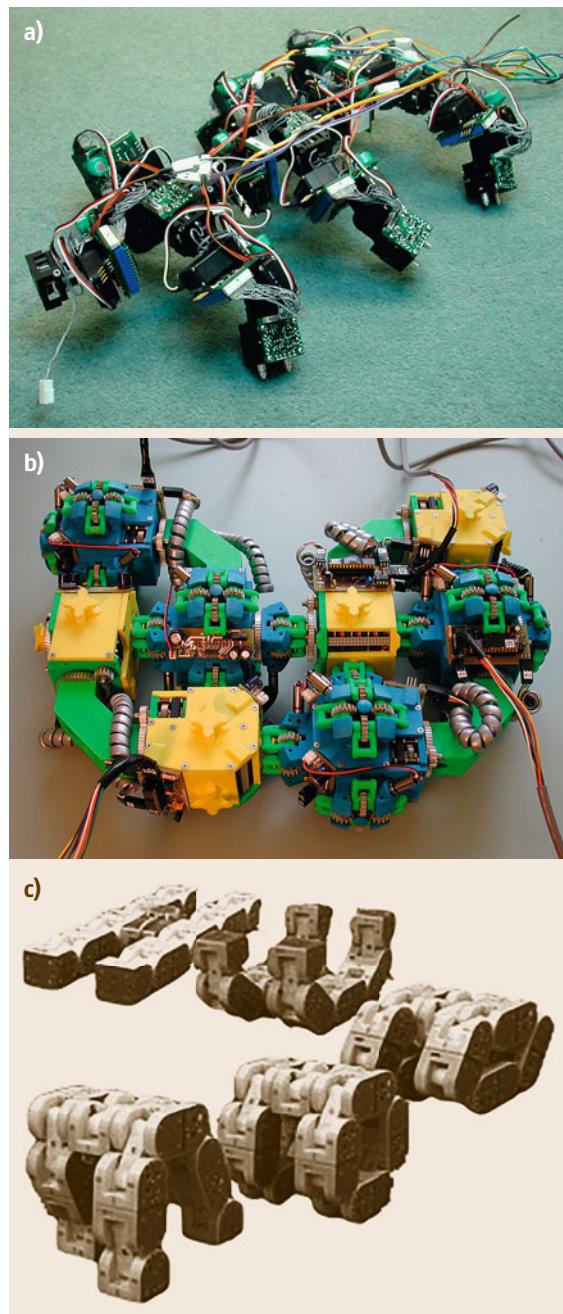

In mechatronics system integration the main challenge is how to make a trade-off between different potential features of a module and the need to fit everything in a mechatronics module, which typically has a radius on the order of centimeters. The different classes of reconfigurable robots reflect different trade-offs.

The oldest class is the *mobile* reconfigurable robot and can be traced back to the cellular robot (**CEBOT**) developed in the late 1980s [73.6], but new instantiations of this class, which are an order of magnitude smaller, have also recently been published [73.7–9]. This class of reconfigurable robots is characterized by the modules having a high-degree of self-mobility, typically obtained by providing each module with a set of wheels. Modules of other classes also have a limited degree of self-mobility, e.g., a module can perform inch-worm like gaits, but it is so limited that we do not consider it mobile.

*Chain-type* reconfigurable robots (Fig. 73.3a) were the first of the modern reconfigurable robots in the sense that they successfully demonstrated versatility: given the same reconfigurable robot several locomotion gaits could be implemented, including inch-worming, rolling, and even walking, as was demonstrated using the PolyPod robot [73.10, 11] and later its descendent PolyBot [73.12] and CONRO [73.13]. The chain-type modules are characterized by having a high degree of internal actuation which typically allow a module to bend or twist. However, there are examples of modules which provide for both bending and twisting [73.14]. These modules are also typically elongated, which makes them suitable for forming chains of modules with many degrees of freedom, making them appropriate for making limbs.

Another class of reconfigurable robots is the *lattice-type* robots (Fig. 73.3b). This class of robot addresses one of the short-comings of chain-type robots. Namely, that it is difficult for chains to align and connect because this requires precision that they often do not have. This makes it difficult to achieve self-reconfiguration with chain-type modular robots. The solution lattice-type reconfigurable robots represents is to have a geometric design that allows them to fit in a lattice just

like atoms in a crystal. The movement of the modules is then limited to moving from lattice to lattice position, a task that only requires limited precision, sensing,

**Fig. 73.3a–c** Examples of the three main types of reconfigurable robots: (a) CONRO chain-type, (b) molecule lattice-type, (c) M-TRAN hybrid, courtesy of USC's Information Sciences Institute (a); Distributed Robotics Laboratory, MIT (b); AIST, Japan (c) ►

and actuation. However, this often means that modules have limited functionality outside of the lattice. Early two-dimensional lattice-type robots include the Fracta and Metamorphic robots [73.15, 16]; the first three-dimensional lattice-type robots were the Molecule and the 3-D-Unit [73.17, 18].

Chain-type and lattice-type robots (Fig. 73.3c) have largely been superseded by the *hybrid* reconfigurable robots. These robots combine the characteristics of chain-type and lattice-type robots in one system. That is, they can both fit in a lattice structure, which allows for relatively easy self-reconfiguration, and out-of-lattice, which allows for efficient locomotion or manipulation. The recent generation of self-reconfigurable robots, including M-TRAN III, ATRON shown in Fig. 73.8, and SuperBot, are all of the hybrid type [73.14, 19, 20].

A final type of reconfigurable robot are the actuation-less robots. These robots depend on external forces to provide reconfiguration capabilities and are not able to move once they are in a lattice. There are stochastic versions of actuation-less modules that are suspended in a fluid [73.21] or float on an air-hockey table [73.22], and the random movements of the modules in the medium allow them by chance to get close enough to form connections. A slight twist of this approach is that modules only use the external forces to swing from lattice position to lattice position, but maintain control of when to disconnect and connect themselves [73.23]. There are also deterministic versions, which employ an

assembly-by-disassembly process where modules start connected in a lattice and modules that are not needed in the specific configuration can then deterministically decide to disconnect from the structure (typically based on electro-magnetic forces) [73.24]. Finally, there are the manually reconfigurable robots that depend on the human user (or another robot) to perform the reconfiguration [73.25, 26].

An orthogonal classification of reconfigurable robots is according to whether they are homogeneous or heterogeneous. Homogeneous modular robots consist of identical modules and have been favored in the community because they lend themselves to self-reconfiguration. However, it is becoming clear that if we want to keep modules simple and provide a certain level of functionality, we need to focus more on heterogeneous systems. It is not cost effective to provide all modules with the same level of functionality, and more importantly, the modules become too complex, heavy, and large if they are to contain all the functionality needed, which in practice make them unsuited for practical applications [73.27].

Another emerging idea is that of soft modules. In fact, quite a number of rigid modules that have been built come out of projects that aimed to build soft reconfigurable robots. The motivation for soft modules is that they provide a certain level of compliance in the interaction with the environment and also within the robot. However, a good way to realize soft reconfigurable robots has not yet been discovered.

## 73.2 Connection Mechanisms

An element of the mechatronic design of reconfigurable modular robots that has turned out to be a significant challenge is the mechanism that connects modules to one another. This may appear puzzling at first, but individual modules are functionally limited and, hence, reconfigurable robots perform most tasks using groups of modules. This means that everything has to be passed across connectors from module to module, including forces, communication, and energy. For self-reconfigurable robots connector design is even more difficult because the connector also has to be able to actively connect and disconnect. The optimal connector would have the following features:

- Small size
- Fast

- Strong
- Robust to wear and tear
- High tolerance to alignment errors
- Energy use only in the transition phases
- Transferal of electrical and/or communication signals between modules
- Genderless
- Allows connection with different orientations
- Disconnects from both sides
- Dirt resistant.

While there are a few connectors that incorporate most of these features, none has implemented them all. It is easy to imagine that a solution is something along the lines of self-cleaning, conducting, with active velcro or gecko skin. Unfortunately, this does not exist (yet) and connector de-

signs are, therefore, based on conventional electro-magnetic, mechanical, or electro-static principles of connection.

Magnetic connectors and combinations with electro-magnets for active connection and disconnection have been quite successful given that they meet most of the above requirements except for being genderless and strong. The gender issue is normally solved by laying out magnets in a geometrical pattern on the surface of the connector that allow male connectors and female connectors to be connected at a discrete number of angles. However, the main shortcoming of the magnetic solution is the strength it provides. It is clear that if the magnetic force is too weak modules will fall apart easily. However, it is, in fact, also a problem if the magnetic force is too strong, because for active mechanisms the modules have to overcome the magnetic force to disconnect (or for manually reconfigurable robots, the human user has to overcome the magnetic force). Therefore, a compromise has to be found, which is not optimal for any of the situations. A recent solution to this problem is the use of switchable magnets. Switchable magnets come in simple mechanical forms where magnets are physically turned to change the direction of the magnetic flux and thus the connection strength. The more advanced type use electro-magnets to change the magnetic polarization of a permanent magnet achieving the same but in a much smaller form factor. These developments have opened up the possibility of using magnetic connectors again, but it remains largely unexplored in the community except for the robot pebbles system (where the technology originated) [73.24].

The most recent generations of self-reconfigurable robots have all favored mechanical solutions. A mechanical solution is based on hooks coming out of one connector surface attaching to holes in the opposing connector surface. A mechanical solution immediately solves the problem of having strong connectors, but unfortunately introduces others. The most important problems are they are large and slow, e.g., in the ATRON self-reconfigurable robots the connector mechanism and associated actuators and electronics account for up to 60% of the modules' size and weight and it takes 2 s to connect. However, the *Terada* connector [73.28] used in M-TRAN III and the SINGO connector [73.29] used in SuperBot appear to have provided potential solutions to the problem of size, but the time issue still remains.

A last class of connectors are based on electro-static forces [73.30]. The idea is to charge two opposing metal surfaces causing the two surfaces to connect strongly. While being an interesting option, the realized systems are impractical, because they are large and sensitive to the distance between the connection surfaces. This approach makes most sense at smaller scales, but despite some effort this has not been realized. Also, in this category of non-standard connector unisex velcro connectors [73.31] should also be mentioned, but here, of course, the main problem is to obtain enough connection strength.

Overall, connector technology is fairly advanced, but there is certainly room for improvement. However, at this point for significant progress to be made, new results probably have to emerge from material science and not from the reconfigurable robotic community itself.

## 73.3 Energy

Reconfigurable robots are typically designed for autonomy and hence rely on on-board batteries for power. The challenges here are to enable the modules to share the available energy and to allow the robot to recharge once batteries are depleted.

It is important for the modules of a reconfigurable robot to be able to share energy because modules may have very different activity levels and hence very different levels of energy consumption. Therefore, the life of the robot can be extended significantly by allowing inactive modules to donate their energy to more active ones. The issue is largely unexplored but there has been attempts of passing energy across connectors [73.32] through physical connections, and it has

been discussed in the context of electro-static connectors [73.30]. For self-reconfigurable robots there is also likely to be an algorithmic solution where modules change roles over time and, hence, distribute the energy consumption equally among modules over time.

For recharging, a solution is to run an energy bus through the robot that both allows modules to recharge their batteries and run off an external power supply [73.33]. It has also been proposed for more stationary applications that modules do not have onboard batteries, but are powered by the external power supply. A way to achieve this while still giving the modules some autonomy of movement is to charge them through the floor; this has been investigated both mechatroni-

cally [73.15, 34] and algorithmically [73.35]. A more flexible, but challenging approach is to allow a subset of robot modules to return to the charger and then return to charge the remaining modules [73.36].

At the more explorative end of the spectrum there may be interesting possibilities in wireless energy transfer [73.37], solar energy, or other alternative forms of obtaining or harvesting energy.

## 73.4 Distributed Control

Reconfigurable robots were born out of the distributed autonomous robot systems community and there has, therefore, been a focus on distributed control algorithms since the early beginning. The reason why distributed control is such a good match for reconfigurable robots is that, if designed well, they have characteristics such as robustness and scalability. Robustness in this context refers to the ability of the control system and, hence, the robot to continue to function despite module failures and communication errors. This may seem as a relatively modest advantage, however, it turns out to be crucial.

Communication systems on reconfigurable robots tend to be unreliable because communication in the case of wired communication has to be passed across the physical connector between modules and the connection may not have perfectly connected and, hence, the electrical terminals for passing the communication signals have not made a completely stable physical connection. It may also be that dust has temporarily ruined the physical interface between the two modules, not allowing electrical communication signals to pass through. For these reasons, reconfigurable robots often rely on wireless communication in the form of either infrared communication or more global forms of wireless communication such as Bluetooth. However, this does not solve the problem, it just changes it. For infrared communication the transmitter and receiver on modules that are to communicate may not be aligned perfectly. There may be crosstalk caused by reflections of signals that cause interference between signals and even cause modules to receive messages that were not for them in the first place [73.38]. Communication relying on electro-magnetic waves do not have these problems, but then often the interference between modules and even background wireless signals can cause communication to fail. The point here is that communication errors cannot only be attributed to poor design or the immature nature of module prototypes, but are fundamental problems that the algorithms have to be able to handle robustly.

Scalability is the other advantage of distributed control algorithms. The motivation here is that while current reconfigurable robots consist of tens of modules, the ambition is that eventually we will have robots consisting of hundreds, thousands, or maybe even millions of modules. It is, therefore, important that the controller does not rely on a central module for control, since this module would be both a bottleneck for the responsiveness of the system and also be a single point of failure. Therefore, scalability of control algorithms is crucial, and distributed control algorithms have the potential to provide just that. Also, it is important here to understand that algorithms also have to be able to deal with module failure, since as the number of modules increases the chance of module failures and communication errors increase. In fact, given a high enough number of modules, modules will fail. Assume that the probability that a single module fails is  $p_1$ , the probability that one module out of  $n$  fails,  $p_n$  is given by

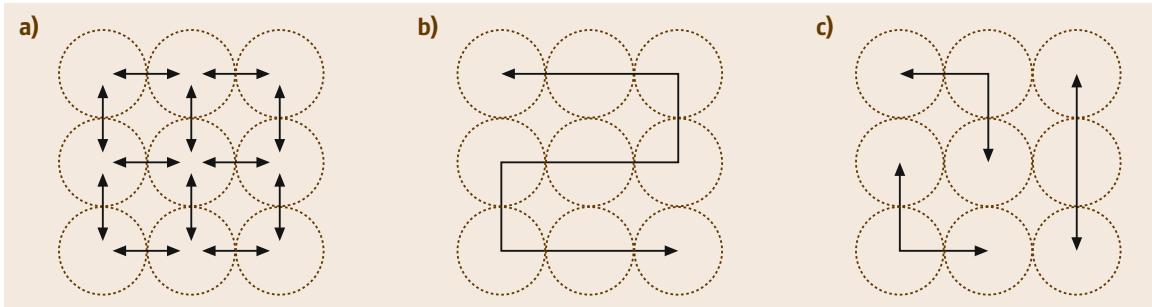

$$p_n = 1 - (1 - p_1)^n. \quad (73.1)$$

This is a very basic consideration, but it is important to understand that the probabilities are working against a controller that is not fault tolerant. For example, given ten modules with just a 1% probability of failing, the probably of one of them failing is 9.6%. Given this background we come to realize that distributed control algorithms are not just a luxury, but absolutely required if we are to realize reconfigurable robots.

### 73.4.1 Communication

A fundamental basis for all distributed control systems is the supporting communication system. In reconfigurable robots there are local, global, and hybrid communication systems, see Fig. 73.4a-c, respectively.

Local communication systems are based on module to module communication based on, for instance, infrared transceivers. While fairly primitive, this form of communication is essential in reconfigurable robots

**Fig. 73.4a–c** The underlying communication models used in reconfigurable robots are (a) local, (b) global, or (c) hybrid (after [73.39])

because it allows two modules to determine their relative positions and orientations. This is not possible using global communication systems independently of whether they are wired or wireless. Local communication also scales since there is no common communication medium that becomes saturated.

Global communication systems using wired bus systems or wireless communication are also useful for real-time control of the reconfigurable robot. Because in a purely local communication system there may significant lag even if the communication volume is low, because messages may have to travel many links to arrive. Hence, an optimal design is one that has both a local communication system to support topology discovery and a global communication system to perform high-speed global coordination.

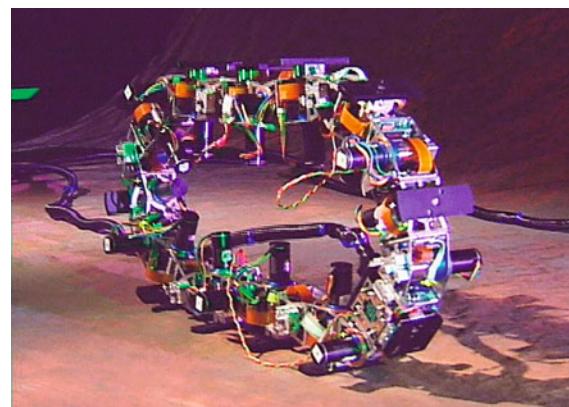

An alternative is hybrid communication [73.39]. The idea behind this is to make a bus system whose topology can be changed dynamically. Initially, modules can connect to neighbors to discover the local topology. As the need arises modules may connect or disconnect, i.e., reconfigure, their busses to match a given communication load and distribution across the system. While the idea seems to hold potential, it has not been thoroughly investigated.

### 73.4.2 Locomotion

One of the basic tasks of a reconfigurable robot is locomotion, hence let us take a look at some of the algorithms which have been proposed for controlling locomotion. One of the first distributed control algorithms was gait control tables [73.11, 40] (Fig. 73.5). Despite being very simple, the algorithm is a powerful demonstration that often practical and robust algorithms are more useful than theoretically sound algorithms.

Each cell in a control table corresponds to the position of one actuator of one module of a specific time interval. The column identifies the actuator and the row identifies the time interval. The algorithm is based on the assumption that all modules are synchronized. When the algorithm is activated each module moves its actuators to the position identified in the first row of the gait control table. It then waits until the time interval has passed and then move actuators to the position identified by the second row and so on. When the end of the gait control table is reached the controller loops back to the first row.

Gait control tables are a simple form of distributed control since they only work with the specific number of modules for which they were designed and they make the relatively large assumption that all modules' clocks are synchronized. There is no way around the first limitation; however, the second one in practice often holds long enough to make successful experiments relying on modules being initialized at the same time. While be-

**Fig. 73.5** The PolyBot robot in a loop configuration controlled by a gait control table (after [73.41])

ing fairly primitive the algorithm has been successful, and given our motivation above it is fairly clear why: it is very robust. It does not rely on communication and, in fact there is no communication between modules so the failure of one module does not influence the control of other modules, but may of course reduce the performance of the robot. However, it is often what we refer to as graceful degradation of performance, because the degradation is proportional to the number of failed modules.

Above we have described gait control tables in their most basic form, however, in reality each cell of a control table may refer to a general behavior instead of a specific actuator position. For example, it is possible that an actuator should implement a spring-like function, be turned off completely, or be completely stiff. In this way, the behavior of individual modules can be influenced by the behavior of other modules and the environment through which the robot is navigating.

Theoretically, the main problem of gait control tables is that modules have no mechanism to stay synchronized and, hence, over time modules will lose synchronization. Another more serious consequence of this is that the robot as a whole cannot react to the environment as a whole and, for instance, change locomotion pattern or shape. One solution to this problem is represented by hormone-based control algorithms [73.42]. Slightly simplified, the idea is that before each module executes a row of the gait control table a synchronizing hormone is passed through the robot. This ensures that modules stay synchronized and, in addition, it is also possible to pass different hormones to reflect different desired locomotion patterns. While theoretically well-developed hormone-based control slows down the robot due to the overhead of synchronization and even worse if synchronization hormones are lost the robot may stop for a while until a new hormone is generated. Role-based control [73.43] is a compromise between the two. The main idea of role-based control is to have a looser coupling between action and synchronization. The modules have autonomy like in gait control tables and achieve synchronization over time. However, the robot is not able to react globally as fast as hormone-based controllers because synchronization signals are slow compared to the movement of the robot.

These algorithms are mainly suited for open-looped control. However, an important challenge is to understand how to adapt locomotion patterns and configuration to the environment. This is a less explored

challenge [73.44, 45] and is a very important challenge for the future of reconfigurable robots.

### 73.4.3 Self-Reconfiguration

A challenge that has received significant attention is that of self-reconfiguration control. This challenge is, of course, tied to self-reconfigurable robots and not to reconfigurable robots in general. It turns out that the general problem of reconfiguring one configuration into another is computationally intractable. In fact, it is currently believed that to find the optimal solution is NP-hard [73.46]. However, it is not entirely clear if there exists a subspace of the problem where it is computationally more tractable. There may be special cases where this is the case, but we currently do not know. The current status is that self-reconfiguration control remains difficult, in particular because we also aim for distributed, not just centralized, algorithms for solving this believed-to-be NP-hard problem. In Fig. 73.6 we show an example of a short self-reconfiguration sequence.

#### Definition

One way to define the distributed self-reconfiguration problem is:

*Given a start configuration A and a final configuration B, distributedly find and execute a sequence of disconnections, moves, and connections that transforms A into B.*

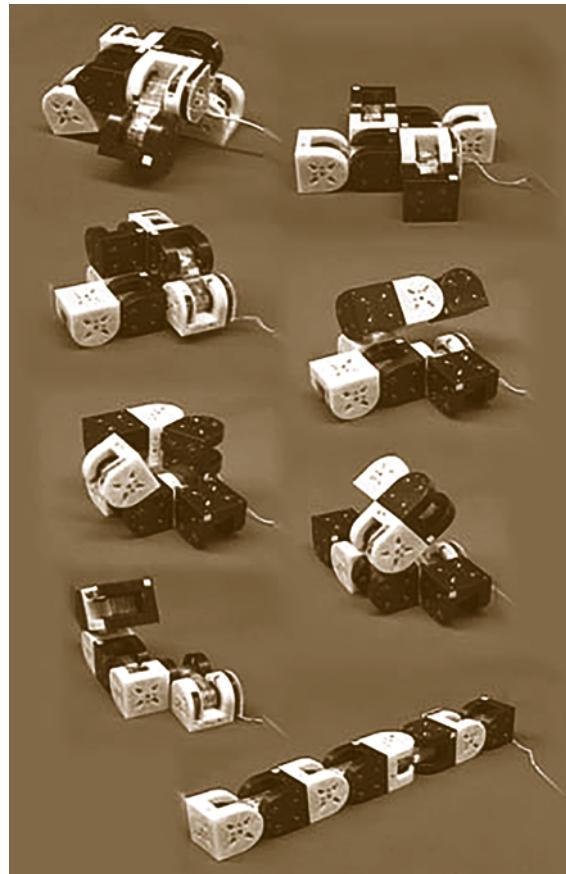

This formulation shies away from the optimality criteria because, in practice, good-enough solutions are what we are after. Of course, optimal solutions would be better, but given that the problem is NP-hard we cannot find them efficiently. A likely false assumption this formulation implies is that configurations A and B are known. While this is true for very simple cases where the self-reconfigurable robot is to transform itself into a pre-specified object like a chair, in general the robot should be able to distributedly discover suitable configurations. That is, the final configuration B is often not known beforehand. This leads to the flip-side of the self-reconfiguration problem, which has only been addressed to a limited degree:

*Given a start configuration A, a task T, and an environment E, distributedly find a configuration B better suited for task T in environment E.*

It is likely that the split between configuration discovery and self-reconfiguration control is not entirely productive and thus maybe a formulation like this is better:

*Given a start configuration A, a task T, and an environment E, distributedly find an action that makes configuration A better suited for task T in environment E.*

A final comment on the problem formulation is that we may need all three variations of the problem. The last formulation is useful for incremental improvement, but occasionally the robot has to go through a paradigm shift, e.g., from a snake to a walking robot, and to achieve this we need the first two formulations of the problem.

**Fig. 73.6** A self-reconfiguration sequence that transforms M-TRAN from a walker to a snake configuration (after [73.47])

### Algorithms

A self-reconfiguration algorithm consists of a representation of the final configuration and a movement strategy.

The movement strategies that have been researched so far are random movement [73.15], local rules [73.48], coordinate attractors [73.49], gradients [73.50], and recruitment [73.51]. The most conceptually simple algorithm is one where modules know the global coordinates of the positions contained in the goal configuration. In this case, modules can move around randomly and stop when they are at a coordinate which is contained in the goal configuration. While this strategy is attractive due to its simplicity, it has a number of drawbacks. In a three-dimensional self-reconfigurable robot random movement is dangerous because modules may by accident disconnect from the structure and fall down. While this problem may be solved by building sturdy, soft modules that are able to reattach to the structure after a fall it is a difficult solution (at least nobody has attempted it so far). Another problem is that when modules settle randomly hollow subspaces or sealed off caves may be created where modules cannot enter. Again, in practice this may not be a problem since these subspaces are likely to be relatively small. Finally, and this is probably the least problematic, random walk is inefficient for a large number of modules and self-reconfiguration sequences consisting of a large number of actions. In other words, a movement strategy based on random walk has scalability issues. Coordinate attractors, gradients, and recruitments are all designed to improve scalability. The idea behind coordinate attractors is that modules that have reached a coordinate contained in the goal configuration that through local sensing discover that an adjacent position in the goal configuration is unfilled and can broadcast this coordinate to all the modules to attract free modules to this location.

Gradients are again an improvement over this strategy because coordinate attractors are prone to local minima. That is, there may be no direct path from a free module to the free goal position. A gradient-based strategy does not broadcast a coordinate, but communicates an integer to neighbor modules; these communicate this integer minus 1 to their neighbors, and so on. Modules listen for integers and pass the highest one they have received minus 1 on. Once this process is complete, free modules can climb the gradient to find the location of the available goal position and, importantly, they can do so by following the structure of the robot and avoid local minima (this is the strat-

egy used in the self-reconfiguration sequence shown in Fig. 73.7).

Finally, the recruitment strategy is a more conservative version of gradients because here the module next to the goal position sends out a single message whose purpose it is to recruit a single free module for the un-filled goal position that it knows about. Whether it pays off to be conservative or not is a matter of priorities. However, it may often be a good strategy to attract more modules because where one module is needed probably more are needed later, and then accept the movement overhead when this is not the case. The final movement strategy is based on local rules. These rules only allow a module to move if the local configuration satisfies a rule in a rule set. In this case, the rule will fire and an action will be executed. By defining the local rules cleverly the resulting configurations can be constrained. The movement strategy of local rules is typically used to control cluster-flow or water-flow locomotion where modules from the back of the robot move towards the front, resulting in a forward locomotion of the robot [73.52].

All these movement strategies, except for local rules, rely on a representation of the goal configuration. A simple representation is to represent all the goal coordinates in the final configuration. However, given that all modules need a copy of this representation it is important that it is space efficient and, therefore, a direct representation like this is only suited for small configurations. Another representation used is one of overlapping cubes [73.50], but other representations could also be used. Typically, which representation to use depends on a trade-off between space and computational complexity. It is also possible to have indirect

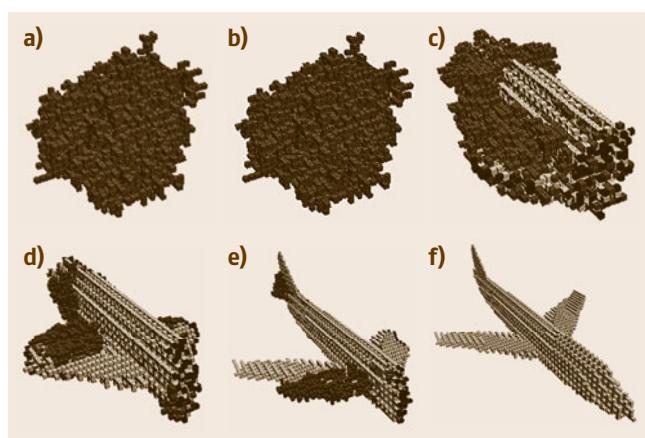

representations that code for growth patterns instead, but these are explored to a lesser degree.

The standing challenge for self-reconfiguration is to make algorithms that are practical to use on physical self-reconfigurable robots. The range of algorithms covered here is sufficient for robots consisting of tens of modules and, thus the self-reconfiguration challenge is currently more of a mechatronics problem than an algorithmic problem [73.53]; however there is certainly room for algorithmic improvements as well.

### 73.4.4 Manipulation

Manipulation is another task that is suitable for reconfigurable robots. If modules are connected in a chain configuration, they can form a serial manipulator with properties not unlike those of traditional robot manipulators. However, two important problems have to be solved before they can work as a traditional robot manipulator.

One problem is how to calculate the inverse kinematics for a chain of modules. The other is how to increase the strength of a modular manipulator since it is relatively weak because of the limited actuator strength of the individual module. Inverse kinematics provide a way to calculate the position of the internal joint angles of the module needed for the outermost module to reach a given position and orientation in space [73.54]. Several answers to the question of how to calculate inverse kinematics have been explored. One option is to fit the serial chain of modules to a curve [73.55]. Another is to use constrained optimization techniques [73.56]. A third option is to use a fast method based on what is defined as dexterous workspaces of subchains [73.57]. An important aspect of this work is also the potential for the robot to dis-

**Fig. 73.7a–f** Simulated, large-scale self-reconfiguration

**Fig. 73.8** The ATRON hybrid self-reconfigurable robot

cover its own kinematics [73.58]. However, maintaining a correspondences between the kinematic model and the physical robot remains a significant challenge for these approaches given that a chain of modules is often not rigid enough in part due to the connectors.

The other problem that needs to be addressed is the relative weakness of the modules and, as a consequence, the modular manipulator as a whole. We need to find a way to make modules work together to produce cooperative actuation that allows them to produce larger forces than those that the modules can produce individually. This question is a little harder to answer, but one option is to exploit the large mechanical advantages formed near singularities of the joints [73.59]. The idea is that a closed loop of modules forms a manipulator. If specific sets of modules are alternately moved and locked, the chain of modules can continually maintain a large mechanical advantage and then generate a much larger force than the one an individual module can provide. However, prob-

lems remain with internal forces of the chain and the weight of the modules involved. Alternative, mostly theoretical approaches include a biologically inspired approach to mechanical design where modules form the equivalent of bones, muscles, and tendons [73.60] and use these construction elements to propagate forces to where they are needed in the configuration. It may also be possible to coordinate the movement of all modules so that the movements add up to produce a larger movement on the global level, i.e., perform collective actuation [73.61].

Besides the traditional arm-based approach to manipulation, it is also possible to use reconfigurable robots as a distributed actuator array [73.62]. In this approach, modules are spread over a surface. When an object is placed on the surface, many modules can work together to manipulate it. The array can handle heavy objects as long as their surface area is relatively large. In combination with self-reconfiguration, it is also possible to use this approach in three dimensions [73.63].

## 73.5 Programmability and Debugging

An area that is receiving more and more focus in the community is the challenge of how to efficiently program and debug reconfigurable robots. In the previous section, we discussed how to control reconfigurable robots distributedly; while these distributed control algorithms are desired for their robustness and scalability they are notoriously difficult to implement and debug in general, but even more so on modular robots that are resource constrained, embedded platforms that often only allow for debugging output in the form of blinking LEDs.

### 73.5.1 Iterative, Incremental Programming and Debugging

Conventionally, the challenge is met by developing applications for reconfigurable robots using an iterative, incremental approach to programming and debugging. This ensures that we can locate errors relatively quickly and correct them before we introduce additional functionality and hence complexity. A good programming practice is also to develop an application programming interface that hides the low-level hardware interface for the programmer more interested in the higher-level control algorithms. This conventional approach is suitable for small demonstration programs, but as the complex-

ity of the task and thus the program increases, this approach becomes intractable. The main reason is that it becomes increasingly difficult to obtain reliable debugging information due to the distributed and dynamic nature of reconfigurable robots and also more often than not due to the immaturity of the physical platforms.

### 73.5.2 Simulation

Given the shortcomings of iterative, incremental development, researchers use simulations, e.g., [73.64], to ensure that the distributed and dynamic aspects of the controller are thoroughly debugged before being deployed on the physical platform. However, building a reliable simulator is a feat in its own right. The simplest form of simulators are logic in nature where events are discrete and instantaneous in time, e.g., the transmission of a message or the movement of a module from one lattice position to another. These logic-based simulators are useful for experimentally convincing oneself that the logic of the distributed algorithm under development is correct. If this algorithm is then transferred to the physical, reconfigurable robot and allowed to run on a carefully debugged application programming interface, it is only real-world issues and hardware limitations that stand in the way of success.

However, these issues and limitations should not be underestimated and include, but are not limited to: unreliable communication, limited communication bandwidth, time, parallelism, hardware failures, differences between modules in terms of actuation, sensing, and communication performance. These issues and limitations can to some degree be handled by proper simulation, but typically are not considered and thus leave algorithms stranded in simulation because they are unable to deal with the real-world constraints of a physical reconfigurable robot. The gap between the simulated world and the real world is often referred to as the reality-gap [73.65]. This gap is widened even more by using simulations based on simplified physics engines, because precise modeling of the physics of a reconfigurable modular robot is almost impossible due to the complex interactions between the modules themselves and the modules and the environment. While the physics-based simulations increase the reality gap, they do allow for a wider area of study, e.g., study of locomotion algorithms. However, often at the cost of reduced transfer of results to the physical reconfigurable robot.

### 73.5.3 Emerging Solutions

Above we have presented current approaches and their advantages and in particular their disadvantages. It is clear that we are far from meeting the challenge of efficient programming and debugging of physical reconfigurable robots. However, there are currently two approaches under investigation that may provide some solutions.

One is the use of domain specific programming languages [73.66, 67]. The fundamental idea is to expose programming primitives at the level of abstraction preferred by the programmer and hide the implementation of the primitives. For instance, communication

is not necessarily central to the programmer and can, therefore, be implicitly handled by the programming language. The advantage of this approach is that it frees the programmer from error-prone, repetitive programming and allows him to focus more energy on the programming challenges related to the task at hand. The language can also to some degree help deal with hardware limitations, allowing the programmer to build on reliable programming primitives. However, there may be a problem of leaky abstractions where it can be hard for a programmer to discover hardware problems because the software that interfaces with the hardware is hidden from the programmer.

Another development is that reconfigurable robots increasingly get more and more powerful processors and communication hardware, a development which is primarily driven and made possible by the cell-phone industry. This development opens an opportunity for efficient programming and debugging of reconfigurable robots. The reason is that up until now reconfigurable robots have been resource constrained to the degree that it was not possible to run programs targeted at debugging in parallel to the executing program because either there was simply not enough available memory and processing energy or the debugging tool would interfere with the executing program to the degree that its behavior would be completely altered or simply not work at all. However, with the increase in processing and communication energy this problem may be reduced, and this will open the door to new forms of programming middleware that has been instrumental to the success of other areas of robotics such as Player/Stage [73.68] and robot operating system ROS [73.69].

In the broader context breakthroughs in programming and debugging of reconfigurable robots will be a significant contribution that can help us develop solutions to complex tasks that are currently beyond our reach.

## 73.6 Perspective

This concludes the overview of reconfigurable robots. The question is where does this leave us? What does the future of reconfigurable robots and reconfigurable robot research look like?

First of all, the field of reconfigurable robots has matured significantly over the last decade, leading to the first applications of modular robot technology: Cubelets [73.4], a construction kit teaching children

about emergent behavior in complex systems. Another example is LocoKit that has been developed to efficiently explore morphology related questions in the context of robot locomotion [73.5, 70]. The community, in general, is very engaged in understanding how reconfigurable robots can be adapted to this specific application, which in time is likely to lead to more applications.

From a research point of view, the vision of an autonomously distributed reconfigurable robot still remains to be realized. This requires advances in all areas covered in this chapter. Like other fields of robotics, reconfigurable robotics is nurtured by the progressive development of rapid prototyping technology and smartphone technology, including wireless charging, which may open the path to novel mechatronic designs. Also, the emerging field of soft robotics may hold potential for radical new designs of reconfigurable robots. Overall, there seems to be a growing opportunity to exploit these advances to design a new generation of reconfigurable robots.

In the area of distributed control, which is probably the best understood area of reconfigurable robots, there

is a clear understanding of how the modules of a reconfigurable robot can be coordinated internally. However, there is still a significant open challenge in making reconfigurable robots adapt to and interact with unknown environments through sensors. Also, a more engineering oriented area of programmability and debugging is crucial for the field if we are to handle the complexity of reconfigurable robots more efficiently.

The potential of autonomously distributed reconfigurable robots is as exciting as ever, and their realization today appears much more realistic than when the idea was conceived 25 years ago, thanks to the hard work of the community. However, there are still important discoveries to be made before the potential of autonomously distributed reconfigurable robots is realized.

## 73.7 Further Reading

This chapter has provided a high-level overview of the field of reconfigurable robots. Those readers interested in a complementary introduction should con-

sider reading [73.71] and those needing a more detailed introduction are referred to the books [73.72, 73].

# 74. Probabilistic Modeling of Swarming Systems

Nikolaus Correll, Heiko Hamann

This chapter provides an overview on probabilistic modeling of swarming systems. We first show how population dynamics models can be derived from the master equation in physics. We then present models with increasing complexity and with varying degrees of spatial dynamics. We will first introduce a model for collaboration and show how macroscopic models can be used to derive optimal policies for the individual robot analytically. We then introduce two models for collective decisions; first modeling spatiality implicitly by tracking the number of robots at specific sites and then explicitly using a Fokker–Planck equation. The chapter is concluded with open challenges in

combining non-spatial with spatial probabilistic modeling techniques.

## 74.1 From Biological to Artificial Swarms

The swarming behavior of ants, wasps, and bees demonstrates the emergence of stupendously complex spatio-temporal patterns ranging from a swarm finding the shortest paths to the assembly of three-dimensional structures with intricate architecture and well-regulated thermodynamics [74.1, 2]. In the bigger scheme of things, these systems represent just the tip of the iceberg; their behavior is considerably less complex than that of the brain, cities, or galaxies, all of which are essentially swarming systems (and all of which can be reduced to first principles and interactions on atomic scale). Yet, social insects make the world of self-organization accessible to us as they are comparably easy to observe. Studying these systems is interesting from an engineering perspective as they demonstrate how collectives can transcend the abilities of the individual member and let the organism as a whole exhibit cognitive behavior.

*Cognition* is derived from the Latin word *cognoscere* and means *to know, to recognize*, and also to *conceptualize*. In the human brain, cognition emerges – to the best of our knowledge – from the complex in-

teractions of highly connected, large-scale distributed neural activity. We argue that *cognition* can manifest itself at multiple different levels of complexity, ranging from conceptualizing collective decisions such as assuming a certain shape or deciding between different abstract choices in social insects to reasoning on complex problems and expressing emotions in humans, the combination of the latter two often framed as the *Turing test* in artificial intelligence. This chapter aims at developing formal models to capture the characteristic properties of the most simple cognitive primitives in swarming systems. In particular, we wish to understand the relationship between the activities of the individual member of the swarm and the dynamics that arise at collective level. The resulting models can be matched to data recorded from physical systems, be used to predict the outcome of a robot’s individual behavior on a larger swarm, and used in an optimization framework to determine the best parameters that help improve a certain metric [74.3].

This chapter reviews probabilistic models of three swarming primitives that are examples of conceptu-

alizations that are exclusively represented at the collective level: collaboration, collective decision making, and collective optimization. Guided by examples from social insects, we present models that generalize to arbitrary agent systems and can serve as building blocks for more complex systems. The probabilistic component of the models arises from:

1. The agent's motion, which often has a random component
2. Explicit random decisions made by individual agents
3. Random encounters between agents.

Randomness in an agent's motion can be introduced, for example, by physical properties such as slip, by deficits in robot hardware, or by explicitly explorative behavior, e.g., based on random turns. It is, therefore, reasonable to model at least the single-agent behavior with probabilistic methods. Yet, it is possible to model the expected swarm-level behavior using deterministic models. In such a swarm-level model the

underlying stochastic motion of agents is summarized in macroscopic properties, which are averages such as the expected swarm fraction in a certain state or at a certain position [74.4–7].

Such probabilistic models are in contrast with deterministic models of swarming systems, which explicitly model the positions of individual robots. Representative examples include controllers for flocking [74.8], consensus [74.9], and optimal sensor distribution for sampling a given probability density function [74.10]. While the robots' spatial distribution is explicitly modeled, those models have difficulties dealing with randomness or robot populations in which robots can be in different states at the same time.

After providing a brief background on phenomenological probabilistic models based on the master equation, this chapter will first review population dynamic models that ignore the spatial distribution of the individual robots and the swarm and then present models that explicitly model the spatial distribution of the robot swarm using time-dependent, spatial probability density functions.

## 74.2 The Master Equation

Let a robot be in a discrete set of states with probability  $p_i \in \mathbf{P}$ , with  $\mathbf{P}$  a vector maintaining the probabilities of all possible states and  $\sum \mathbf{P} = 1$ . These states model internal states of the robot, determined by its program, or external states, determined by the state of the robot within its environment. Actions of the robot and environmental effects will change these probabilities. This is captured by a phenomenological set of first-order differential equations, also known as the master equation [74.11],

$$\frac{d\mathbf{P}}{dt} = \mathbf{A}(t)\mathbf{P}, \quad (74.1)$$

where  $\mathbf{A}(t)$  is the transition matrix consisting of entries  $p_{ij}(t)$  that correspond to the probability of a transition from state  $i$  to state  $j$  at time  $t$ . Multiplying both sides with the total number of robots  $N_0$  allows us to calculate the average number of robots in each state. For brevity, we write

$$N_i(t) = N_0 p_i(t).$$

Similarly, when expanding the master equation for a continuous space variable, one finds the Fokker–Planck equation, also known as the Kolmogorov forward equation or the Smoluchowski equation [74.12, 13].

## 74.3 Non-Spatial Probabilistic Models

We will first consider two models that assume the spatial distribution of the agents in the environment to be uniform: collaboration and collective decision.

### 74.3.1 Collaboration

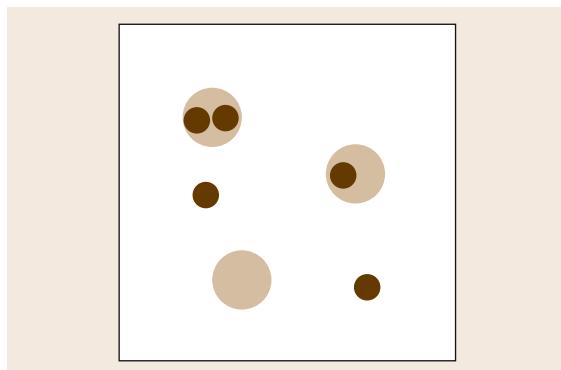

An important swarming primitive is *collaboration*, which requires a number of agents ( $n$ ) to get together at

a site. Collaboration is different from the more general *task allocation* problem, in which the number of agents is not explicitly specified. In swarm robotics, a *site* can have spatial meaning, but can also be understood in an abstract way as means to form teams. Although there are many different algorithms for team formation, we focus on a collaboration mechanism that was introduced in the *stick-pulling experiment* [74.14] and turned

out to be a recurrent primitive in swarm robotic systems, e.g., in swarm robotic inspection, where robots can serve as temporary markers in the environment [74.15]. Here, collaboration happens when an inspecting robot encounters a marker, which informs it that this specific area has already been inspected. The collaboration model, therefore, finds application in studying trade-offs between serving as *memory* to the swarm and actively contributing to the swarming behavior's metric.

In the stick-pulling experiment  $N_0$  robots are concerned with pulling  $M_0$  sticks out of the ground in a bounded environment. This task requires exactly  $n = 2$  robots. Physically, this can be understood as a stick that is too long to be extracted from the ground by a single robot. Rather, every robot that grabs the stick can pull it out a little further and keeps it there until the next robot arrives. In this work, we abstract the classical stick-pulling experiment to a generic collaboration model in which robots are simply required to meet, see also Fig. 74.1. Intuitively, the amount of time spent waiting for collaboration to happen is a trade-off between (1) waiting at a site to find a collaborator and (2) having the chance to find a collaborator oneself by actively browsing the environment. Finding the collaboration rate, and the individual parameters that lead to it, that is *optimal* for a given environment, i.e., the number of collaboration sites and the number of agents, illustrates how probabilistic models can be employed to design this process and find optimal collaboration policies.

The following model is loosely based on the development in [74.16], which applies discrete time

**Fig. 74.1** A collaboration example.  $N_0 = 5$  robots (black) in a bounded environment with  $M_0 = 3$  collaboration sites, each requiring  $n = 2$  robots to be present simultaneously for collaboration to happen

difference equations. For simplicity, we assume that collaboration happens instantaneously and focus on a continuous-time representation and stochastic waiting times. The reader is referred to [74.16] for an extensive treatment of deterministic waiting times and [74.17] for an extension to  $n > 2$  agents. Variables used in the equations that follow are summarized in Table 74.1.

Let  $n_s(t)$  with  $n_s(0) = N_0$  be the number of searching agents at time  $t \in \mathbb{R}^+$  and  $N_0$  the total number of agents. Let  $n_w(t) = N_0 - n_s(t)$  be the number of waiting agents at time  $t$ . With  $p$  the probability to encounter or match a waiting agent and  $T_r$  the average time an agent will wait for collaboration, we can write

$$\dot{n}_s(t) = -p(M_0 - n_w(t))n_s(t) \quad (74.2)$$

$$\begin{aligned} &+ \frac{1}{T_r}n_w(t) \\ &+ pn_s(t)n_w(t). \end{aligned} \quad (74.3)$$

Thus,  $n_s(t)$  decreases by the rate at which searching agents encounter empty collaboration sites (of which there exist  $M_0 - n_w(t)$  at time  $t$ ), and it increases by those agents that return either from unsuccessful (at rate  $1/T_r$ ) or successful collaboration, i.e., find any of the  $n_w(t)$  waiting agents.

In order to maximize the collaboration rate in the system we are interested in maximizing the rate at which robots return from successful collaboration, i.e.,  $c(t) = pn_s(t)n_w(t)$ .

Solving for  $\dot{n}_s(t) = 0$  and substituting  $n_w(t) = N_0 - n_s(t)$  allows us to calculate the number of robots at steady-state  $n_s^*$

$$n_s^* = \frac{\left[ (2N_0 - M_0)pT_r - 1 + \sqrt{8N_0pT_r(1 + (M_0 - 2N_0)pT_r)^2} \right]}{4pT_r}. \quad (74.4)$$

As  $n_w^* = N_0 - n_s^*$  by definition, we can write

$$c^* = p \left( n_s^* N_0 - n_s^{*2} \right). \quad (74.5)$$

**Table 74.1** Notation used in the collaboration model

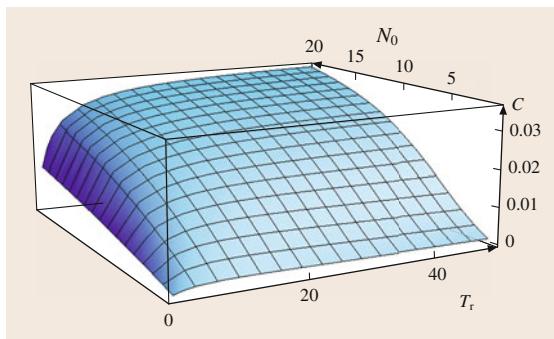

|          |                                            |
|----------|--------------------------------------------|
| $n_s(t)$ | Average number of searching agents         |
| $n_w(t)$ | Average number of waiting agents           |
| $p$      | Probab. to encounter/match a waiting agent |
| $c(t)$   | Average rate of collaboration matches      |
| $N_0$    | Total number of agents                     |
| $M_0$    | Total number of collaboration sites        |
| $T_w$    | Waiting time                               |

The collaboration rate as a function of  $T_r$  and  $N_0$  is shown in Fig. 74.2. By solving  $dc^*/dn_s^* = 0$ , we can calculate  $n_{s, \text{opt}}^* = \frac{1}{2}N_0$  that maximizes  $c^*$ . Substituting  $n_{s, \text{opt}}^*$  into (74.4) and solving for  $T_r$ , we can calculate the optimal waiting time  $T_{r, \text{opt}}$  as

$$T_{r, \text{opt}} = \frac{1}{(M_0 - N_0)p}. \quad (74.6)$$

As  $T_{r, \text{opt}}$  cannot be negative, an optimal waiting time can only exist if  $M_0 > N_0$ . This intuitively makes sense, because if there are less agents than collaboration sites, waiting too long might consume all agents in waiting states. We can also see that the more collaboration sites there are, the less an agent should wait. There are two interesting special cases: first,  $N_0 = M_0$ . In this case  $T_{r, \text{opt}}$  is undefined. Considering that collaboration sites exceed agents by exactly one,  $T_{r, \text{opt}}$  is fully defined by  $1/p$ . Thus, the higher the likelihood is that agents find a collaboration site, the lower the waiting time should be. In this case, it makes sense to release searching agents from wait states to find another agent to collaborate. If this likelihood is low, however, agents are better off waiting to serve as collaborators for few searching agents.

With  $T_{r, \text{opt}}$  given by (74.6) we can derive the following guidelines for agent behavior. First, an optimal wait time exists only if there are less agents than collaboration sites. Otherwise, longer waits improve the chance of collaboration. Second, if the number of agents, the number of collaboration sites, and the likelihood to encounter a collaboration site are known to each agent at all times, e.g., due to global communication or shared memory, agents could cal-

**Fig. 74.2** The collaboration rate as a function of  $T_r$  and  $N_0$  for  $M_0 = 10$  collaboration sites. There exists an optimal  $T_r$  for  $N_0 < M_0$ , whereas the collaboration rate increases steadily otherwise for increasing values of  $T_r$

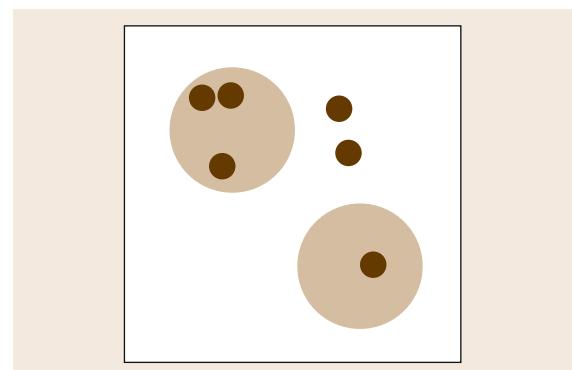

**Table 74.2** Notation used in the collective decision model

|          |                                                  |
|----------|--------------------------------------------------|
| $n_s(t)$ | Average number of searching agents               |
| $n_i(t)$ | Average number of agents committed to choice $i$ |
| $p_i$    | Unbiased probability to select choice $i$        |
| $T_i$    | Unbiased time to stay with choice $i$            |
| $N_0$    | Total number of agents                           |
| $M_0$    | Total number of choices                          |
| $T_w$    | Waiting time                                     |

culate  $T_{r, \text{opt}}$  at all time. If these quantities are not known, however, agents can estimate these quantities based on their interactions in the environment by observing the rates at which they encounter collaboration and empty sites. Individual agent learning algorithms that accomplish this goal are discussed in detail in [74.18].

### 74.3.2 Collective Decisions

Another collective intelligent swarming primitive is *collective decisions*. These can be observed in the path selection of ants [74.19] or shelter selection of cockroaches [74.20] or robots [74.21], but can also have non-spatial meaning, for example when a consensus on  $M_0$  different discrete values is needed. An example of such a situation is shown in Fig. 74.3. While the above references provide models that are specific to their application, this chapter provides a generalized model for collective decisions that rely on different ways of social amplification, i.e., a change of the behavior based on the activities of other swarm members, or the absence thereof.

**Fig. 74.3** Collective decision example.  $N_0 = 6$  robots decide between  $M_0 = 2$  choices. Three plus one robot have already made decisions, two robots remain undecided

Model parameters for the collective decision model are summarized in Tab. 74.2. Let  $n_s(t)$  with  $n_s(0) = N_0$  be the number of searching/undecided agents at time  $t \in \mathbb{R}_+$  and  $N_0$  the total number of agents. Let  $p_i$ ,  $0 < i \leq M_0$ , be the unbiased probability for an agent to select value  $i$  from  $M_0$  different values. This probability is unbiased as it does not depend on social amplification. We can then write the following differential equations for the number of agents  $n_i(t)$  that have the selected value  $i$

$$\dot{n}_i(t) = n_s(t)p_iR_i(t) - \frac{1}{T_i}n_i(t)Q_i(t), \quad n_i(0) = 0, \quad (74.7)$$

$$n_s(t) = N_0 - \sum_{i=1}^{M_0} n_i(t), \quad (74.8)$$

where  $T_i$  is the average time spent on solution  $i$  before resuming search, and  $R_i(t), Q_i(t) : n_i(t), n_s(t) \rightarrow \mathbb{R}_+$  are functions that might or might not depend on the number of agents in other states, and therefore making the differential equation for  $n_i(t)$  linear or non-linear, respectively. There are four interesting cases: both  $R_i(t)$  and  $Q_i(t)$  being constant, both being functions of one or more states of the system, e.g.,  $n_i(t)$  or  $n_s(t)$ , and combinations thereof.

If both  $R_i(t)$  and  $Q_i(t)$  are constants, one can show that the number of agents selecting choice  $i$  at steady-state  $n_i^*$  is given by

$$n_i^* = \frac{R_i}{Q_i} n_s^*, \quad (74.9)$$

with  $n_s^*$  the number of agents that remain undecided at steady-state. (This results from agents discarding choices at rate  $1/T_i$ .) For example, for a two-choice system, using  $n_s^* = N_0 - n_1^* - n_2^*$  yields the steady states

$$n_1^* = \frac{Q_2 R_1}{Q_1 Q_2 + Q_2 R_1 + Q_1 R_2}, \quad (74.10)$$

$$n_2^* = \frac{Q_1 R_2}{Q_1 Q_2 + Q_2 R_1 + Q_1 R_2}. \quad (74.11)$$

A solution for  $R_1 = 0.01$ ,  $R_2 = 0.04$ , and  $Q_1 = Q_2 = 1/10$  is depicted in Fig. 74.4 and leads to  $\approx 7$  and  $\approx 27\%$  of agents in states one and two, respectively, while most agents remain undecided. In this system, the speed at which the steady-state is reached depends on the values of  $R_i$ , with higher values of  $R_i$  leading

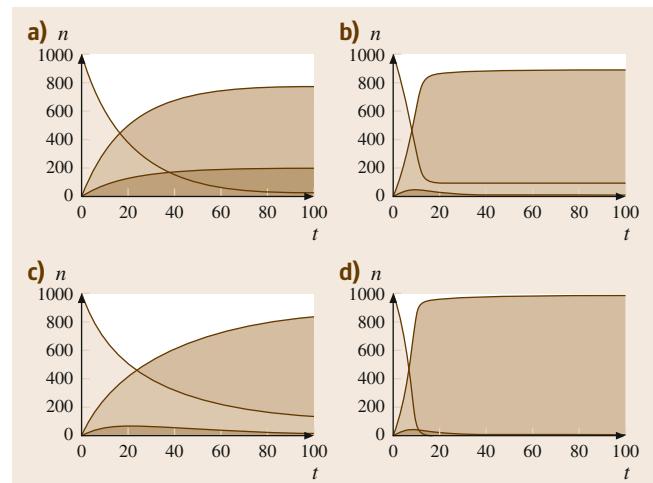

to faster decisions, whereas the steady-state of undecided agents is determined by  $Q_i$ , with lower values of  $Q_i$  corresponding to lower values of  $n_s^*$ . In particular, values for  $Q_i = 1/100$  or  $Q_i = 1/1000$  will drastically increase convergence, in this example to 67 and 78% for the majority choice, respectively.

If  $Q_i(t)$  is constant, but  $R_i(t)$  is a non-linear function of the form  $R_i(t) = f[n_i(t)]^\alpha_i$  with  $\alpha_i > 1$  a constant, we observe  $n_i(t)$  to grow faster due to *social amplification* of attraction; the larger  $n_i(t)$ , the larger the positive influx into  $\dot{n}_i(t)$ . Systems with this property usually converge much faster than linear systems. For example, a system with

$$R_i(t) = \left(1 + \frac{n_i(t)}{N_0}\right)^{\alpha_i} \quad (74.12)$$

shows faster convergence than a linear system for  $\alpha_i \geq 1$ . Here, normalizing social attraction with  $N_0$  provides independence of the dynamics of the number of agents. An example with  $\alpha_i = 5$  is shown in Fig. 74.4b.

Similarly, if  $R_i(t)$  is constant, but  $Q_i(t)$  is a non-linear function of the form  $Q_i(t) = f[n_i(t)]^\beta_i$  with  $\beta < 0$

**Fig. 74.4a-d** Time evolution of a collective decision where solution two is picked four times as likely as solution one, and both solutions are re-evaluated after an average of 100 s, for different non-linear dynamics. Graphs show the fraction of agents picking solutions one and two. (a) Linear system achieving steady-states of  $\approx 20\%$  and  $\approx 80\%$ , matching analytical results. (b) Time evolution of a system with social amplification of attraction using  $R_i$  given by (74.12) and  $\alpha_i = 5$  for both choices. (c) Social amplification of rest using (74.13) and  $\beta_i = 5$ . (d) Social amplification of both attraction and rest with  $\alpha_i = \beta_i = 5$

a constant, we observe  $n_i(t)$  to grow faster due to social amplification of rest; the larger  $n_i(t)$ , the smaller the out-flux from  $\dot{n}_i(t)$ . For example, a system with

$$Q_i(t) = \left(1 + \frac{n_i(t)}{N_0}\right)^{\beta_i} \quad (74.13)$$

also shows faster convergence than a linear system. Notice that we do not consider positive exponents for  $\beta_i$ , as this will drive agents away from decisions exponentially fast and will simply increase  $n_s(t)$ , i.e., the number of undecided agents. Results for a two-choice system with  $\alpha_i = \beta_i = 5$  are shown in Fig. 74.4c.

Finally, systems that rely both on social amplification of attraction *and* rest exhibit the best convergence, when compared with a purely linear system as well as systems that rely only on either social amplification mechanism. Results for a two-choice system with  $\alpha_i = \beta_i = 5$  are shown in Fig. 74.4d.

Similar models, i.e., models that rely on non-linear amplification of either attraction, rest, or both have been proposed for a series of social insect experiments. For example, in [74.19] an ant colony is presented with a binary choice to select the shortest of two branches of a bridge that connect their nest to a food source. Here, a model with social amplification of attraction – by means of an exponentially higher likelihood to choose a branch with higher pheromone concentration – is chosen and successfully models the dynamics observed experimentally. In [74.20] a model that uses social amplification of rest is chosen to model the behavior of a swarm of cockroaches deciding between two shelters of equal size but different brightness. The preference

of cockroaches for darker shelters is expressed with a higher  $p_i$  for this shelter. Convergence to the dark shelter is then achieved by social amplification of rest, increasing the time cockroaches remain in a shelter exponentially with the number of individuals that are already in the shelter. Here, all cockroaches converge to a single shelter, even though the model proposed in [74.20] employs negative social amplification of attraction by introducing a notion of shelter capacity, which cancels the positive term in  $\dot{n}_i(t)$  when the shelter reaches a constant carrying capacity. Finally, [74.22] presents a model for cockroach aggregation in which the likelihood to join an aggregate of cockroaches increases with the size of the aggregate, whereas the likelihood to leave a cluster exponentially decreases with its size.

The examples from the social insect domain are trade-offs between the expressiveness of the model and its complexity. As the true parameter values of  $\alpha_i$  and  $\beta_i$  are unknown, the same experimental data can be accurately matched by models with different dynamics. For example, social amplification of attraction as observed on larvae of German cockroaches in [74.22] was deemed to have negligible influence on mature American cockroaches selecting shelters with limiting carrying capacity in [74.20].

With respect to artificial agent and robotic systems, the models presented can instead provide design guidelines for achieving a desired convergence rate. At the same time, the models are able to support decisions on sensing and communication sub-systems that are required to implement one or the other social amplification mechanism.

## 74.4 Spatial Models: Collective Optimization

The concept of optimization in collective systems is difficult to separate from the concept of collective decisions. Rather, there seems to be a continuous transition. Collective decisions are made between several distinct alternatives, implying a discrete world of options (e.g., left and right branches in path selection, two shelters, etc.). Typically, one refers to the term *optimization* in collective systems in the case of tasks that allow for a vast (possibly even infinite) number of alternatives implying a continuous world of options.

For this optimization scenario we apply the probabilistic model reported in [74.4, 5, 23–25]. It is based

on a stochastic differential equation (**SDE**, the Langevin equation) and a partial differential equation (**PDE**, the Fokker–Planck equation), which can be derived from the former. While the Langevin equation is a stochastic description of the trajectory in space over time of a single robot, the Fokker–Planck equation describes the temporal evolution of the probability density in space for these trajectories. Hence, it can be interpreted as the average over many samples of robot trajectories (i.e., ensembles of trajectories). Even a second, more daring interpretation arises. We can interpret this probability density directly as a swarm density, that is, the expected fraction of the robot swarm for a given area and time.

The deterministic PDE describes the mean swarm fraction in space and time. Interactions between robots can be modeled via dependence on the swarm density itself [74.4].

We introduce our formalism (see Table 74.3 for a summary of all variables used). The Langevin equation that gives the position of a robot  $\mathbf{R}$  at time  $t$  is

$$\dot{\mathbf{R}}(t) = -\mathbf{A}(\mathbf{R}(t), t) + \mathbf{B}(\mathbf{R}(t), t)\mathbf{F}(t), \quad (74.14)$$

where  $\mathbf{A}$  defines directed motion via drift depending on the current position  $\mathbf{R}$  and  $\mathbf{B}(\mathbf{R}(t), t)\mathbf{F}$  defines random motion based on  $\mathbf{F}$ , which is a stochastic process (e.g., white noise). Based on the Langevin equation the Fokker–Planck equation can be derived [74.4, 11, 12, 26]

$$\begin{aligned} \frac{\partial \rho(\mathbf{r}, t)}{\partial t} &= -\nabla(\mathbf{A}(\mathbf{r}, t)\rho(\mathbf{r}, t)) \\ &\quad + \frac{1}{2}Q\nabla^2(B^2(\mathbf{r}, t)\rho(\mathbf{r}, t)), \end{aligned} \quad (74.15)$$

for a swarm density  $\rho(\mathbf{r}, t)$  (according to the above interpretation) at position  $\mathbf{r}$  and time  $t$ , a drift term ( $-\nabla(\mathbf{A}(\mathbf{r}, t)\rho(\mathbf{r}, t))$ ) due to directed motion and a diffusion term ( $\frac{1}{2}Q\nabla^2(B^2(\mathbf{r}, t)\rho(\mathbf{r}, t))$ ) due to random motion, whereas typically we set  $Q = 2$  for simplicity. According to our general approach [74.4] we introduce a Fokker–Planck equation for each robot state and manage the transitions between states by rates similar to the rate equation approach of the above sections.

The optimization scenario considered here was inspired by the behavior of young honeybees. The algorithm, which defines the robots' behavior, is derived from a behavioral model of honeybees [74.27, 28]. Honeybees of an age of less than 24 h stay in the hive, cannot yet fly, navigate towards spots of a preferred warmth of 36 °C, and stay mostly inactive. An interesting example of swarm intelligent behavior is how they

search and find the right temperature that their bodies need. It turns out that they do not seem to do a gradient ascent in the temperature field but rather a correlated random walk with inactive periods triggered by social interaction. Both the above-mentioned behavioral model and the robot controller – called BEECLUST – are defined by the following:

1. Each robot moves straight until it perceives an obstacle  $\Omega$  within sensor range.
2. If  $\Omega$  is a wall the robot turns away and continues with step 1.
3. If  $\Omega$  is another robot, the robot measures the local temperature. The higher the temperature is the longer the robot stays stopped. When the waiting elapses, the robot turns away from the other robot and continues with step 1.

The temperature field that we investigate in the scenario here has one global optimum (36 °C) at the right end of the arena and one local optimum (32 °C) at the left end of the arena. In analogy to the behavior observed in young honeybees, the swarm is desired to aggregate fully at the global optimum but, at the same time, should also stay flexible within a possibly dynamic environment. The latter is implemented by robots (bees) that leave the cluster from time to time and explore the remaining arena. If a more preferable spot were to emerge elsewhere they would start to aggregate there, and the former cluster might shrink in size and finally vanish fully.

Now we apply the above modeling approach to this scenario. We have two states: *moving* and *stopped*. It turns out that in the *moving* state we do not have any directed motion, hence, we will turn off the bias in the Langevin equation (74.14,  $\mathbf{A} = 0$ ). Without any directed motion in BEECLUST (no gradient ascent, actually movement fully independent from the temperature field) the Fokker–Planck equation can be reduced to a mere diffusion equation in order to model the moving robots

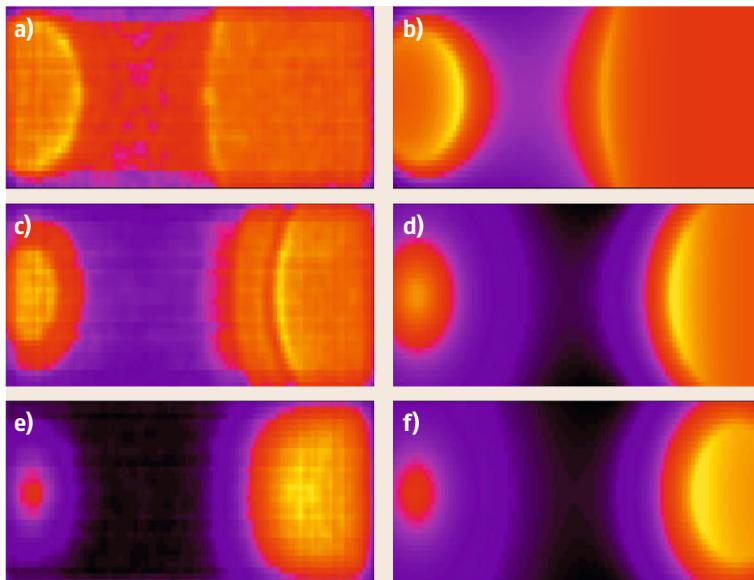

$$\frac{\partial \rho(\mathbf{r}, t)}{\partial t} = \nabla^2(B^2(\mathbf{r}, t)\rho(\mathbf{r}, t)). \quad (74.16)$$

This equation is our approach for state *moving* yet without addressing state transition rates.

The state *stopped* is even easier to model as it naturally lacks motion. That way it can be viewed as a reduction to a mere rate equation defined in each position  $\mathbf{r}$ . The state transition rates are defined by a stopping rate  $\varphi$ , which can be determined, for exam-

**Table 74.3** Notation used in the optimization model

|              |                                                    |
|--------------|----------------------------------------------------|
| $\mathbf{R}$ | Robot position                                     |
| $\mathbf{A}$ | Direction and intensity of robots' directed motion |
| $B$          | Intensity of robots' random motion                 |
| $\mathbf{F}$ | Stochastic process (fluctuating directions)        |
| $\mathbf{r}$ | Point in space                                     |
| $Q$          | Theoretic term describing intensity of collisions  |
| $\rho_s$     | Expected density of robots in state <i>stopped</i> |
| $\rho_m$     | Expected density of robots in state <i>moving</i>  |
| $w$          | Waiting time                                       |
| $\varphi$    | Rate of stopping robots                            |

**Fig. 74.5a-f** Comparison of histograms of swarm density obtained by an agent-based simulation and the corresponding model based on (74.18) for different times and an initial state with equal distribution of robots. An optimal temperature peak of  $36^{\circ}\text{C}$  is at the *right end* of the arena, at the *left end* there is a suboptimal peak in temperature of  $32^{\circ}\text{C}$ , the *middle part* is cooler. We observe that on average at first clusters form at *both ends* of the arena, but later those on the *left* vanish. Swarm size is  $N = 25$ . The histograms obtained by simulation are based on  $10^6$  samples. (a) Simulation,  $t = 30$ ; (b) model,  $t = 30$ ; (c) simulation,  $t = 130$ ; (d) model,  $t = 130$ ; (e) simulation,  $t = 200$ ; (f) model,  $t = 200$

ple, empirically or by geometrical investigations (e.g., calculation of collision probabilities) [74.4]. For the *stopped* state we obtain

$$\frac{\partial \rho_s(\mathbf{r}, t)}{\partial t} = \rho_m(\mathbf{r}, t)\varphi - \rho_m(\mathbf{r}, t - w(\mathbf{r}))\varphi, \quad (74.17)$$

for a stopping swarm fraction  $\rho_s(\mathbf{r}, t)\varphi$  at spot  $\mathbf{r}$  and time  $t$ , and an awakening swarm fraction  $\rho_s(\mathbf{r}, t - w(\mathbf{r}))\varphi$ . The robots stop and wait for a time period  $w(\mathbf{r})$ , which depends on the temperature at spot  $\mathbf{r}$ .

Here, we choose to approximate the robots' correlated random walk as mere diffusion in a rough estimation. The function  $B$  in (74.16) is reduced to a diffusion constant  $D$ . We add the rates of stopping/awakening and obtain the equation for state *moving*

$$\begin{aligned} \frac{\partial \rho_m(\mathbf{r}, t)}{\partial t} &= D\nabla^2 \rho_m(\mathbf{r}, t) - \rho_m(\mathbf{r}, t)\varphi \\ &\quad + \rho_m(\mathbf{r}, t - w(\mathbf{r}))\varphi. \end{aligned} \quad (74.18)$$

If we ignore diffusion and focus on one point in space we would have a mere rate equation similar to the above sections (except for the time delay)

$$\dot{\rho}_m(t) = -\rho_m(t)\varphi + \rho_m(t - w(\mathbf{r}))\varphi. \quad (74.19)$$

Using (74.18) ((74.17) is mathematically not necessary) we can model the BEECLUST behavior. For a provided initial distribution of the robots we end up with an initial value problem for a PDE that we can solve numerically.

The solution of this initial value problem is the temporal evolution of the swarm density. In Fig. 74.5 we compare the model to the results obtained by a simple agent-based simulation of BEECLUST. This comparison is meant to be qualitative only. The model catches most of the qualitative features that occur in simulation, although we approximate the robots' motion in a rough estimation by diffusion.

Our approach shows how borders between the fields of engineering and biology vanish in swarm robotics. The BEECLUST algorithm is at the same time a controller for robots but also a behavioral model of an animal. The same Fokker–Planck model is used to model the macroscopic behavior of honeybees and robot swarms.

The Fokker–Planck model gives good estimates for expected swarm densities in space, the transient/asymptotic behavior of the swarm, and density flows. Modeling space explicitly allows for specific investigations such as objective areas and obstacles of certain shapes. Other case studies included an emergent taxis task which relies on one group of robots that is *pushing* another group by collision avoidance [74.4], a collective perception task in which robots have to discriminate aggregation areas of different sizes [74.29], and a foraging task [74.30]. This model is mostly relevant to scenarios with spatially inhomogeneous swarm densities, that is, swarms forming particular spatial structures that cannot be averaged over several runs.

## 74.5 Conclusion

We presented mathematical models for three distributed swarming behaviors: collaboration, deciding between different choices, and optimization. Each of these processes are collective decisions of increasing complexity.

While the behaviors and trajectories of individual robots might be erratic and probabilistic, the average swarm behavior might be considered deterministic. This holds for both the models and the observed reality in robotic and biological experiments. An analogy is the distinction between the complex, microscopic dynamics of multi-particle systems and the much simpler properties of the corresponding ensembles of such systems in thermodynamics. This insight is important as it allows us to design the individual behavior so

that the expected value of collective performance is maximized.

Although we presented models with increasing level of spatiality – from collaboration sites in the environment to modeling the distribution of robots over continuous space – modeling swarming systems with heterogeneous spatial and state distributions using closed form expressions is still a major challenge. A better understanding of swarming systems with non-uniform spatial distributions will help us to better understand the impact of environmental patterns such as terrain, winds, or currents, thereby enabling swarm engineering for a series of real-world applications that swarming systems have yet to tackle.

# 75. A Robust Evolving Cloud-Based Controller

# A Robust Evolving Cloud-Based Controller

Plamen P. Angelov, Igor Škrjanc, Sašo Blažič

In this chapter a novel online self-evolving cloud-based controller, called Robust Evolving Cloud-based Controller (**RECCo**) is introduced. This type of controller has a parameter-free antecedent (IF) part, a locally valid **PID** consequent part, and a center-of-gravity based defuzzification. A first-order learning method is applied to consequent parameters and reference model adaptive control is used locally in the **ANYA** type fuzzy rule-based system. An illustrative example is provided mainly for a proof of concept. The proposed controller can start with no pre-defined fuzzy rules and does not need to pre-define the range of the output, number of rules, membership functions, or connectives such as AND, OR. This **RECCo** controller learns autonomously from its own actions while controlling the plant. It does not use any off-line pre-training or explicit models (e.g. in the form of differential equations) of the plant. It has been demonstrated that it is possible to fully autonomously and in an unsupervised manner (based only on the data density and selecting representative prototypes/focal points from the control hypersurface acting as a data space) generate and self-tune/learn a non-linear controller structure and evolve it in online mode. Moreover,

the results demonstrate that this autonomous controller has no parameters in the antecedent part and surpasses both traditional **PID** controllers being a non-linear, fuzzy combination of locally valid **PID** controllers, as well as traditional fuzzy (Mamdani and Takagi–Sugeno) type controllers by their lean structure and higher performance, lack of membership functions, antecedent parameters, and because they do not need off-line tuning.

## 75.1 Overview of Some Adaptive and Evolving Control Approaches

Fuzzy logic controllers were proposed some four decades ago by *Mamdani* and *Assilian* [75.1]. Their main advantage is that they do not require the model of the plant to be known and their linguistic form is closer to the way human reasoning is expressed and formalized. It is difficult to identify all possible events or the frequency of their occurrences while modeling a system. The lack of this knowledge requires use of an approximate model of a system.

Due to the fact that a fuzzy logic algorithm has the characteristic of a universal approximator, it is possible to model systems containing unknown nonlinearities using a set of IF-THEN fuzzy rules.

The main challenges in designing conventional fuzzy controllers are that they are sometimes designed to work in certain modeling conditions [75.2]. Moreover, fuzzy controllers include at least two parameters per fuzzy set, which are usually predefined in advance

and tuned off-line [75.3]. Many techniques have been presented for auto-tuning of the parameters of controllers in batch mode [75.4], mostly using genetic algorithms [75.5, 6] or neural networks [75.7, 8] off-line. From a practical point of view, however, there is no guarantee that pre-training parameters have satisfactory performance in online applications when the environment or the object of the controller changes. To tackle this problem several approaches have been proposed for online adaptation of fuzzy parameters [75.9–15].

Nevertheless, only a few approaches have been introduced for online adaptation of fuzzy controller structures when no prior knowledge of the system is available. Evolving fuzzy rule-based controllers were introduced in 2001 by Angelov et al. [75.16]. They allow the controller structure (fuzzy rules, fuzzy sets, membership functions, etc.) to be created based on data collected online. This is based on a combination of inverse plant dynamic modeling [75.17] using self-evolving fuzzy rule-based systems [75.18]. The proposed approach is applied to autonomously learning controllers that are self-designed online.

The advantage of this method is that there is no need for pre-tuning of the control parameters. Moreover, the proposed method can start with an empty topology, and the structure of the controller is modified online based on the data obtained during the operation of the closed loop system. Two main phases were introduced for parameter learning of the controller's consequents and modifying the structure of the controller. The proposed approach was successfully applied to a nonlinear servo system consisting of a DC motor and showed satisfactory performance [75.19], as well as to control of mobile robots [75.20]. The drawback of this approach is that the addition of new membership functions increases the number of rules exponentially, and each membership requires at least two parameters in the antecedent part to be specified, plus connectives such as AND, OR, NOT. Many of these problems have been overcome with the latest version of the approach [75.21], which combines the Angelov–Yager (ANYA) type fuzzy rule-based system (FRB) [75.22] with the inverse plant dynamics model. ANYA can be seen as the next form of FRB system types after the two well-known Mamdani and Takagi–Sugeno type FRBs. It does not require the membership functions to be defined for the antecedent part, nor the connectives such as AND, OR, NOR. It still has a linguistic form and is non-linear. It is fuzzy in terms of the defuzzification. In order to clarify what that means let us

recall that all three types of FRB: Mamdani, Takagi–Sugeno, and ANYA can be represented as a set of fuzzy rules of the form IF (antecedent) and THEN (consequent). While in the Mamdani type FRB both antecedent and consequent parts are fuzzy, in the so-called Takagi–Sugeno type FRB the consequent part is a functional,  $f(x)$  (most often linear) with the antecedent part being fuzzy. In both types of FRB the defuzzification can be either of so-called center-of-gravity (COG) or winner takes all (WTA) type. There are variations such as few winners take all, etc., but usually COG is applied unless a classification problem is considered, where WTA performs better. In ANYA type FRBs the antecedent part is defined using an alternative, density-based representation which is parameter-free and reduces the problems of definition and tuning of membership functions (one of the stumbling blocks in the application of the fuzzy set theory overall). The consequent part of the ANYA type FRB can still be same as in Takagi–Sugeno type FRBs. For more detail, the reader is referred to [75.21, 22]. The so-called SPARC self-evolving controller, however, has poorer performance in the first moments when applied *from scratch* (with no pre-trained model and no rules). In this chapter, model reference control and gradient-based learning of the consequents of the individual locally valid rules. In the proposed method the antecedent part is determined using focal points/prototypes (selected descriptive actual data points) instead of pre-defining the membership functions in an explicit manner. The fuzzy rules are formed around selected representative points from the control surface; thus, there is no need to define the membership functions per variable. It has a much simplified antecedent part which is formed using so-called data clouds. Fuzzy data clouds are fuzzy sets of data samples which have no specific shape, parameters, or boundaries. With ANYA type FRBs the relative density is used to define the relative membership to a particular cloud. It takes into account the distance to all previous data samples and can be calculated recursively.

In order to show the effective performance of the proposed controller, it is applied to a simulated problem of temperature control in a water bath [75.21].

The remainder of this chapter is organized as follows. In Sect. 75.2 the new simplified FRB system is introduced, including rule representation and the associated inference process. The evolving methodology used for the online learning of both the structure and the parameters of RECCo is described in Sect. 75.3. First, we present the mechanism for the

online adaptation of the consequents in Sect. 75.3.1 and then, we illustrate the structure evolution process in Sect. 75.3.2. In Sect. 75.4, the simulation exam-

ple is presented as a proof of concept for the proposed methodology. Finally, conclusions are drawn in Sect. 75.5.

## 75.2 Structure of the Cloud-Based Controller

**ANYA** [75.22] is a recently proposed type of **FRB** system characterized by the use of non-parametric antecedents. Unlike traditional Mamdani and Takagi-Sugeno **FRB** systems, **ANYA** does not require an explicit definition of fuzzy sets (and their corresponding membership functions) for each input variable. On the contrary, **ANYA** applies the concepts of fuzzy data clouds and relative data density to define antecedents that represent exactly the real data density and distribution and that can be obtained recursively from the streaming data online.

Data clouds are subsets of previous data samples with common properties (closeness in the data space). Contrary to traditional membership functions, they represent directly and exactly all the previous data samples. Some given data can belong to all the data clouds with a different degree  $\gamma \in [0, 1]$ , thus the fuzziness in the model is preserved and used in the defuzzification, as will be shown later. It is important to stress that clouds are different from traditional clusters in that they do not have specific shapes and, thereby, do not require the definition of boundaries.

First it was proposed to use **ANYA** to design fuzzy controllers for the situations in which the lack of knowledge about the plant makes it difficult to define the rule antecedents in [75.21]. SPARC autonomous controllers have a rule base with  $N$  rules of the following form

$$R^i : \text{IF } (\mathbf{x} \sim X^i) \text{ THEN } (u^i), \quad (75.1)$$

where  $\sim$  denotes the fuzzy membership expressed linguistically as *is associated with*,  $X^i \in \mathcal{R}^n$  is the  $i$ -th data cloud defined in the input space,  $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$  is the controller's input vector, and  $u^i$  is the control action defined by the  $i$ -th rule.

It is to be noted that no aggregation operator is required to combine premises of the form  $\text{IF } x_j \text{ is } X_j^k$ , as in traditional fuzzy systems. All the remaining components of the **FRB** system (e.g., the consequents and the defuzzification method) can be selected as in any of the traditional fuzzy systems.

A rule base of the form (75.1) can describe complex, generally non-linear, non-stationary, non-deterministic

systems that can be only observed through their inputs and outputs. Hence, autonomous controllers based on **ANYA** type **FRB** systems are suitable to describe dependence of the type *IF X THEN U* based on the history of pairs of data observations of the form  $z_j = [\mathbf{x}_j^T; u_j]^T$  (with  $j = 1, \dots, k-1$  and  $z \in \mathbb{R}^{n+1}$ ), and the current  $k$ -th input  $\mathbf{x}_k^T$ .

The degree of membership of the data sample  $\mathbf{x}_k$  to the cloud  $X^i$  is measured by the normalized relative density as follows

$$\lambda_k^i = \frac{\gamma_k^i}{\sum_{j=1}^N \gamma_k^j}, \quad i = 1, \dots, N, \quad (75.2)$$

where  $\gamma_k^i$  is the local density of the  $i$ -th cloud for that data sample.

This local density is defined by a suitable kernel over the distance between  $\mathbf{x}_k$  and all the other samples in the cloud, i.e.,

$$\gamma_k^i = K \left( \sum_{j=1}^{M^i} d_{kj}^i \right), \quad i = 1, \dots, N, \quad (75.3)$$

where  $d_{kj}^i$  denotes the distance between the data samples  $\mathbf{x}_k$  and  $\mathbf{x}_j$ , and  $M^i$  is the number of input data samples associated with the cloud  $X^i$ .

In a similar manner, we consider that a sample is associated with the cloud with the highest local density. In addition, we use the Euclidean distance, i.e.,  $d_{kj}^i = \|\mathbf{x}_k - \mathbf{x}_j\|^2$ . Nonetheless, any other type of distance could also be used [75.22].

In this study we used a Cauchy kernel. Thereby, (75.3) can be recursively determined as follows [75.23]

$$\gamma_k^i = \frac{1}{1 + \|\mathbf{x}_k - \mu_k\|^2 + \Sigma_k - \|\mu_k\|^2}, \quad (75.4)$$

where  $\gamma_k^i$  denotes the relative density to the  $i$ -th data cloud calculated in the  $k$ -th time instant, and  $\Sigma_k$  denotes the scalar product of the data  $\mathbf{x}_k$

$$\Sigma_k = \frac{k-1}{k} \Sigma_{k-1} + \frac{1}{k} \|\mathbf{x}_k\|^2, \quad (75.5)$$

with starting condition  $\Sigma_1 = ||x_1||^2$ . The update of the mean value,  $\mu$  is straightforward

$$\mu_k = \frac{k-1}{k} \mu_{k-1} + \frac{1}{k} x_k, \quad (75.6)$$

with the starting condition  $\mu_1 = x_1$ .

As for the defuzzification, it is to be noted that ANYA can work with both Mamdani and Takagi–Sugeno–Kang (TSK) consequents. In this case, we use the latter type, as is usual in control applications [75.19, 24–26]. Hence, if we consider the weighted average for the defuzzification, the output of the ANYA controller is

$$u_k = \sum_{i=1}^N \lambda_k^i u^i = \frac{\sum_{i=1}^N \gamma_k^i u^i}{\sum_{i=1}^N \gamma_k^i}, \quad (75.7)$$

where  $u^i$  denotes the  $i$ -th rule consequent.

From a *local* point of view, the goal of the controller is to bring the plant's output from its current value to the desired reference value as soon as possible, i. e., ideally  $y_{k+1} = r_k$ , where  $k$  and  $k+1$  represent consecutive control steps. It is well known that it is not possible to do this immediately due to several limitations in the system (most notably – the actuator ones). A useful practice is to introduce a reference model that represents the desired closed-loop dynamics of the controlled systems [75.27]. The simplest choice is to use a linear reference model of the first order. Then the prediction of the reference output  $y^r$  can be obtained using the following equations

$$y_{k+1}^r = a_r y_k^r + (1 - a_r) r_k, \quad 0 < a_r < 1, \quad (75.8)$$

where  $a_r$  is the pole of the first-order filter.

It can be tuned according to the desired speed of the closed-loop system. Comparing the output of the plant  $y_k$  to the output of the reference model  $y_k^r$ , the tracking error  $\varepsilon$  is obtained

$$\varepsilon_k = y_k - y_k^r. \quad (75.9)$$

The goal of the controller in terms of the tracking error,  $\varepsilon_k$  is to keep it as low as possible. Since the reference model output  $y_k^r$  is a filtered version of the reference

signal  $r_k$ , this means that the tracking error has no step changes due to reference signal changes. It also has to be noted that tracking error is used as a driving error during parameter adaptation, as we shall see in Sect. 75.3.1.

As noted above, the proposed approach is compatible with a wide spectrum of control laws in rule consequents. Here, the PID-based rule consequents are proposed

$$u_k^i = P_k^i \varepsilon_k + I_k^i \Sigma_k + D_k^i \Delta_k, \quad i = 1, \dots, N, \quad (75.10)$$

where  $\Sigma_k$  and  $\Delta_k$  denote the discrete-time integral and derivative of the tracking error, respectively,

$$\begin{aligned} \Sigma_k &= \sum_{\kappa=1}^{k-1} \varepsilon_\kappa, \\ \Delta_k &= \varepsilon_k - \varepsilon_{k-1}, \end{aligned} \quad (75.11)$$

while  $P_k^i$ ,  $I_k^i$ , and  $D_k^i$  are parameters that will be tuned by means of adaptation of rule consequents.

The approach offers the possibility of implementing several subsets of PID-based controllers such as P, PI, PD, etc. For simplicity, only proportional controllers will be used in the rule consequent for the rest of this chapter

$$u_k^i = P_k^i \varepsilon_k, \quad i = 1, \dots, N. \quad (75.12)$$

It has to be kept in mind that most real-life controllers are limited in their operation and can only provide control actions within a specific range, namely, the actuator's interval  $[u_{\min}, u_{\max}]$ . If the computed control signal  $u_k$  is outside the actuator's interval, it can simply be projected onto the interval if P or PD type controllers are used. If integral controllers are used as well, some classical approaches to avoid integral windup should be implemented. When the violations of the actuator's constraints are more drastic, because of the chosen dynamics of the reference model and a narrow actuator interval, then also the interruption of the control parameters adaptation can be employed to make the adaptation more robust. This modification will also be explained in detail later.

## 75.3 Evolving Methodology for RECCo

In this section, we present the methodology applied for evolving the structure and parameters of the consequents of RECCo online. Initially, the controller is empty, so it has to be initialized from the first data sample received. After this, the same steps are repeated for all incoming data. First, the consequents of the current rules are updated according to the error at the plant output. Then, a new control action is generated by applying the inference process described in Sect. 75.2. Finally, the structure of the controller is updated. If the appropriate conditions are satisfied, a new cloud (and hence, a rule) is created; otherwise, the new sample is used to update the information about the data density and the consequent parameters of the current configuration of the controller.

In the following sections, the entire process is described in more detail. Section 75.3.1 is devoted to the mechanism for online adaptation of the rule consequents. In Sect. 75.3.2 the process of adding new clouds is described.

### 75.3.1 Online Adaptation of the Rule Consequents

Assuming that the plant is monotonic with respect to the control signal, the partial derivative of the plant's output with respect to the control signal has a definite constant sign  $G_{\text{sign}} = \pm 1$ , which has to be known in advance. Therefore, the combination of the error at the plant's output and the sign of the monotonicity of the plant with respect to the control signal provides information about the right direction in which to move the rule consequents to achieve the local control objective [75.10].

As is already known, the parameters of the rule consequents are obtained by means of adaptation. In normal circumstances the parameter changes are calculated as follows

$$\Delta P_k^i = \gamma_p G_{\text{sign}} \lambda_k^i(x) \varepsilon_k, \quad i = 1, \dots, N, \quad (75.13)$$

where  $\gamma_p$  is an adaptive gain for the proportional controller gains.

Equation (75.13) is obtained by using gradient descent and having the square of the tracking error as a cost function. The controller gains are obtained by summing up the terms obtained in (75.13)

$$P_k^i = P_{k-1}^i + \Delta P_k^i, \quad i = 1, \dots, N. \quad (75.14)$$

Note that parameters keep changing until the tracking error is driven towards 0. Note also that only parameters corresponding to the active clouds are adapted, while the others are kept constant.

Systems with parameter adaptation are subjected to parameter drift, which can lead to performance degradation and, eventually, to system instability [75.28]. There exist many known approaches to make adaptive laws more robust [75.29–31]. We will employ parameter projection, parameter leakage, introduce dead zone into adaptive laws, and employ the saturation of the adaptive parameters when the actuator is in saturation.

#### Dead Zone in the Adaptive Law

As already has already been said, adaptation of the parameters in the closed loop always presents potential danger to the system's stability. The adaptation is driven by an error signal that is always composed of the useful component and the harmful one. The latter is due to disturbances and parasitic dynamics, and is usually bounded. Large errors are usually mostly composed of useful components, while small tracking error is very often due to harmful signals. Having the adaptation active during the time that the error is small results in a false adaptation. The idea behind the dead zone in the adaptive law is that the adaptation is simply switched off if the absolute value of the error that governs the adaptation is small [75.32]

$$\Delta P_k^i = \begin{cases} \gamma_p G_{\text{sign}} \lambda_k^i(x) \varepsilon_k & |\varepsilon_k| \geq d_{\text{dead}} \\ 0 & |\varepsilon_k| < d_{\text{dead}} \end{cases}, \quad i = 1, \dots, N. \quad (75.15)$$

#### Parameter Projection

Parameter projection is a natural way to prevent parameter drift. The idea is to project the parameters onto a compact set [75.27]. In our case, each individual parameter is projected on a certain interval or a ray. When projecting the parameters some prior knowledge must always be available. Since in our case proportional controller gains are adapted, their sign is always known and is equal to  $G_{\text{sign}}$ . In the case of positive plant gain all the consequent parameters should be bounded by 0 from below, while an upper bound may or may not (if not enough prior knowledge is available) be provided. The adaptive law given by (75.14) is generalized as

follows if the controller gains are projected onto the interval  $[\underline{P}, \bar{P}]$

$$P_k^i = \begin{cases} P_{k-1}^i + \Delta P_k^i & \underline{P} \leq P_{k-1}^i + \Delta P_k^i \leq \bar{P} \\ \underline{P} & P_{k-1}^i + \Delta P_k^i < \underline{P} \\ \bar{P} & P_{k-1}^i + \Delta P_k^i > \bar{P} \end{cases}, \quad i = 1, \dots, N, \quad (75.16)$$

where  $\underline{P}$  and  $\bar{P}$  are two design parameters. In our approach  $\underline{P} = 0$  and  $\bar{P} = \infty$  will be used.

### Leakage in the Adaptive Law

The idea of leakage is that the discrete integration in the adaptive law in (75.14) presents a potential danger to the adaptive system, and the pole due to the integrator should be pushed inside the unit disc [75.33], which results in the adaptive law

$$P_k^i = (1 - \sigma_P)P_{k-1}^i + \Delta P_k^i, \quad i = 1, \dots, N, \quad (75.17)$$

where  $\sigma_P$  defines the extent of the leakage. The introduction of the leakage results in adaptive parameter boundedness. This is why leakage is sometimes referred to as soft projection.

### Interruption of Adaptation

When the chosen dynamics and the actuator constraints are in conflict, such that tracking of the reference model cannot be achieved in a sufficiently small interval, then drift of the control parameters often occurs, because the adaptive law is driven with a tracking error  $\varepsilon_k$ , which cannot be reduced, due to the control signal constraints. The interruption of the adaptation results in the following modification

$$\Delta P_k^i = \begin{cases} \gamma_P G_{\text{sign}} \lambda_k^i(\mathbf{x}) \varepsilon_k, & u_{\min} \leq u_k \leq u_{\max} \\ 0, & \text{else} \end{cases}, \quad i = 1, \dots, N. \quad (75.18)$$

### 75.3.2 Evolution of the Structure: Adding New Clouds

The adaptation of the parameters of the consequents is performed online in a closed loop manner (while the controller operates over the real plant). The control is applied from the first moment (no a-priori information or controller structure is needed). Adaptive systems

traditionally [75.34] concern tuning parameters of the controllers for which the structure has been pre-selected by the designer. Self-evolving controllers [75.16, 24] offer the possibility of evolving the structure of the controller as well as adapting parameters. This helps design *on the fly* controllers, which are non-linear and with no pre-defined structure or knowledge about the plant model. This requires us to define a mechanism for the online evolution of the controller's structure, i. e., for adding new antecedents and fuzzy rules.

We already defined the local density earlier. Now, the global density  $\Gamma$ , will be defined. Its definition is analogous to the one given for the local density, except that it takes into account the distance to all the previously observed samples  $z_j$  ( $j = 1, \dots, k-1$ ). It has to be noted that the global density is computed for the points  $z_k = [\mathbf{x}_k^T; u_k]^T$ , whilst the local density is defined only for the input vectors  $\mathbf{x}_k$ . Using again the Cauchy kernel, this density can be defined as

$$\Gamma_k = \frac{1}{1 + \frac{\sum_{j=1}^{k-1} (d_{kj})^2}{k-1}}, \quad (75.19)$$

and can be computed recursively by [75.23]

$$\Gamma_k = \frac{1}{1 + ||z_k - \mu_k||^2 + \Sigma_k^G - ||\mu_k^G||^2}, \quad (75.20)$$

where  $\Gamma_k$  denotes the global density to all the data calculated in the  $k$ -th time instant, and  $\Sigma_k^G$  denotes the scalar product of the data  $z_k$

$$\Sigma_k^G = \frac{k-1}{k} \Sigma_{k-1}^G + \frac{1}{k} ||z_k||^2, \quad (75.21)$$

with starting condition  $\Sigma_1^G = ||z_1||^2$ . The update of the mean value  $\mu_k^G$  is straightforward

$$\mu_k = \frac{k-1}{k} \mu_{k-1} + \frac{1}{k} z_k, \quad (75.22)$$

with starting condition  $\mu_1^G = z_1$ .

Since this measure considers all existing samples, it provides an indication of how representative a given point  $z_k$  is with respect to the entire data distribution.

Additionally, and only for learning purposes, a focal point  $X_f^i$  and a radius  $r_{jk}^i$  are defined for each cloud. The focal point is a real data sample that has highly

representative qualities. The fact that the focal point is always a real sample is important, as it avoids problems that may appear when only a descriptive measure is used instead (as in the case of the average of the points in the cloud). In order to follow the philosophy of the proposed methodology (i.e., avoiding the need to pre-define the parameters of the rules), the focal point is updated online. Thus, for each new sample  $z_k$ , the following process is applied:

1. Find the associated cloud  $C^i$ , according to

$$C^i = \arg \max_i (\gamma_k^i) . \quad (75.23)$$

2. Check the representative qualities of the new data point using the following conditions,

$$\gamma_k^i > \gamma_f^i , \quad (75.24a)$$

$$\Gamma_k > \Gamma_f^i , \quad (75.24b)$$

where  $\gamma_f^i$  and  $\Gamma_f^i$  represent the local and global density of the current focal point, respectively.

3. If both conditions are satisfied, then replace the focal point by applying  $X_f^C \leftarrow x_k$ .

The radius provides an idea of the spread of the cloud. Since the cloud does not have a definite shape or boundary, the radius represents only an approximation of the spread of the data in the different dimensions. It is also recursively updated as follows [75.35]

$$r_{jk}^i = \rho \cdot r_{j(k-1)}^i + (1 - \rho) \sigma_{jk}^i ; \quad r_{j1}^i = 1 , \quad (75.25)$$

where  $\rho$  is a constant that regulates the compatibility of the new information with the old one and is usually set to  $\rho = 0.5$  [75.35]. The value  $\sigma_{jk}^i$  denotes the cloud's local scatter over the input data space and is given by

$$\sigma_{jk}^i = \sqrt{\frac{1}{M^i} \sum_{l=1}^{M^i} \|X_f^i - x_l\|_j^2} ; \quad \sigma_{j0}^i = 1 . \quad (75.26)$$

It is important to note that the radii and focal points are only used to provide an idea of the location and distribution of the data in the clouds during the structure evolution process. However, they are not actually used to represent the clouds or the fuzzy rules and do not affect the inference process at any point.

The structure-learning mechanism applied for the proposed RECCo is based on the following principles [75.36, 37]:

- a) Good generalization and summarization are achieved by forming new clouds from data samples with high global density  $\Gamma$ .
- b) Excessive overlap between clouds is avoided by controlling the minimum distance between them.

Hence, the evolution of the structure is based on the addition of new clouds and the associated rules. First, RECCo is initialized by creating a cloud  $C^1$  from the first data sample  $z_1 = [x_1^T; u_1]^T$ . The antecedent of the first rule is then defined by this cloud and its consequent equals the value  $u_1$ . Next, for all the further incoming data samples  $z_k$ , the following steps are applied:

1. The sample  $z_k = [x_k^T; u_k]^T$  is considered to have good generalization and summarization capabilities if its global density is higher than the global density of all the existing clouds. Thus, the following condition is defined

$$\Gamma_k > \Gamma_f^i , \quad \forall i = 1, \dots, N . \quad (75.27)$$

Note that this is a very restrictive condition that requires that the inequality is satisfied for all the existing clouds, which is not very often for real data.

2. Check if the existing clouds are sufficiently far from  $z_k$  with the following condition

$$d_{ki} > \frac{r_{jk}^i}{2} , \quad \forall i = 1, \dots, N , \quad (75.28)$$

where  $d_{ki}$  represents the distance from the current sample to the focal point of the associated cloud,  $X_f^i$ .

3. According to the result of the previous steps, take one of the following actions:

- a) If conditions (75.27) and (75.28) are both satisfied, then create a new cloud  $C^{N+1}$ . The focal point of the new cloud is  $X_f^{N+1} = x_k$ . Its local scatter is initialized based on the average of the local scatters of the existing clouds [75.35]

$$\sigma_{jk}^{N+1} = \frac{1}{N} \sum_{l=1}^N \sigma_{jk}^l , \quad j = 1, \dots, n . \quad (75.29)$$

Additionally, the corresponding rule has to be added to the rule base. The antecedent of the new rule is defined by the newly created cloud  $C^{N+1}$ . For the consequent, we provide an initial value that guarantees that the output of the new controller when the input vector is equal

to the focal point (i.e.,  $x = X_f^{N+1}$ ) equals the controller's output under its previous configuration for that same input [75.21]. The rationale behind this initialization is to provide a smooth transition from the old configuration of the controller to the new one. This avoids sudden changes in the output surface that could damage the controller's performance in the first time instants after the rule has been added (and before the consequents are adapted) [75.25].

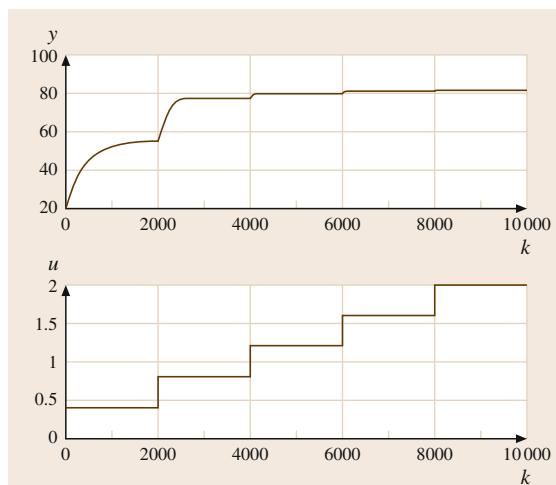

- b) If the conditions are not satisfied, update the parameters of the cloud  $C^i$  associated with  $z_k$ , as previously explained.

It is important to stress that the methodology presented for the evolution of the controller's structure starts from an empty controller. However, if an initial set of rules is known beforehand (e.g., provided by an expert or obtained from any other training method), it can be used for the initial controller. In this case, the algorithm's initialization step can be omitted.

## 75.4 Simulation Study

A simulation study of the proposed self-organizing controller is presented in this section. The main attention is given to the study of different modifications of self-organizing controllers to make the adaptive laws more robust. In the study, we show the implementation of parameter projection, parameter leakage, and the introduction of dead zone into the adaptive laws. The study was carried out with the assumption of no prior knowledge about the plant dynamics. The mathematical model was only used to simulate the plant dynamics.

The plant for the simulation study is the thermal process of a water bath. The main goal is the control of the temperature in the water bath. The plant is described with the following mathematical model in a discrete

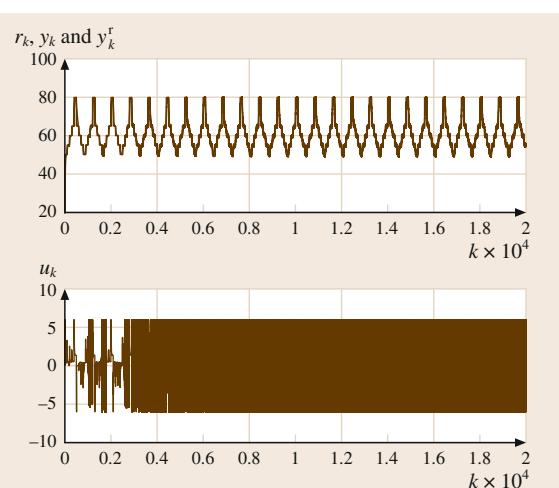

**Fig. 75.1** Open-loop response of the plant: output temperature and input variable

form

$$y(k+1) = ay(k) + bu(k) + (1-a)y_o, \quad (75.30)$$

where  $a = e^{-\alpha T_s}$  and  $b = \frac{\beta(1-e^{-\alpha T_s})}{\alpha}$ . The parameters of the plant are estimated as  $\alpha = 10^{-4}$ ,  $\beta = 8.7 \times 10^{-3}$ ,  $y_o = 20^\circ\text{C}$ . The sampling period,  $T_s$ , is equal to 25 s.

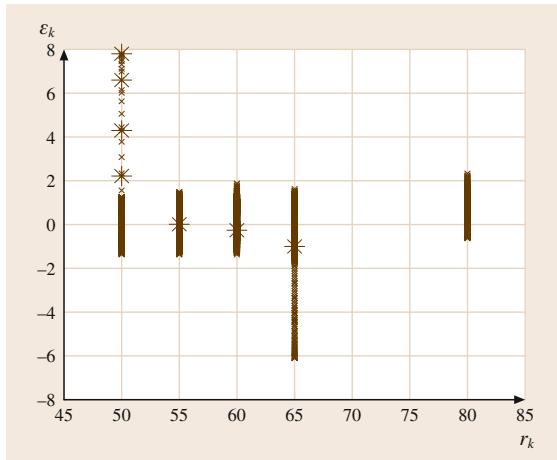

The open loop response of the plant is shown in Fig. 75.1. It is shown that the behavior of the plant exhibits a huge nonlinearity in the static gain of the process. The reference signal is chosen to show the ability of self-learning and dealing with nonlinearity, which is the main advantage of the proposed algorithm. The

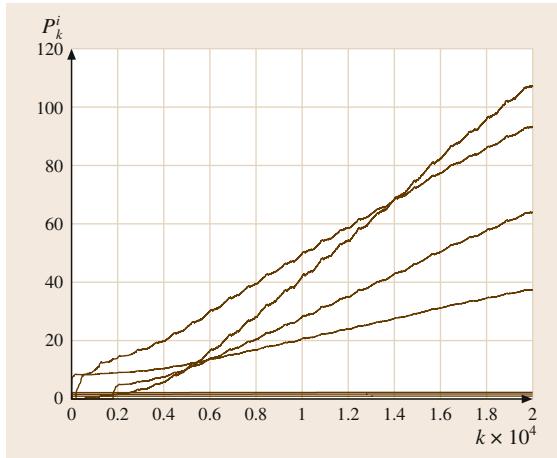

**Fig. 75.2** Reference, model reference, output signal tracking, and control signal in the case of no robust adaptive laws

clouds are defined in a way so as to enable dealing with nonlinearity, and for that reason the input variables for the controller are the reference value  $r_k$  and the tracking error  $\varepsilon_k$ .

All the simulations started from zero fuzzy rules and membership functions, and new rules were generated during the process. The first simulation was done for the case without any robust adaptive laws. The parameters of the control law do not converge and drift, which leads to performance degradation and, after some time, also to instability. In this example, the actuator interval was given as  $[-6, 6]$ , the reference model parameter was defined as  $a_r = 0.925$ , and the adaptive gain  $\gamma_P = 0.1$ . The upper plot of Fig. 75.2 shows the reference  $r$ , the

**Fig. 75.3** Clouds in the case of no robust adaptive laws

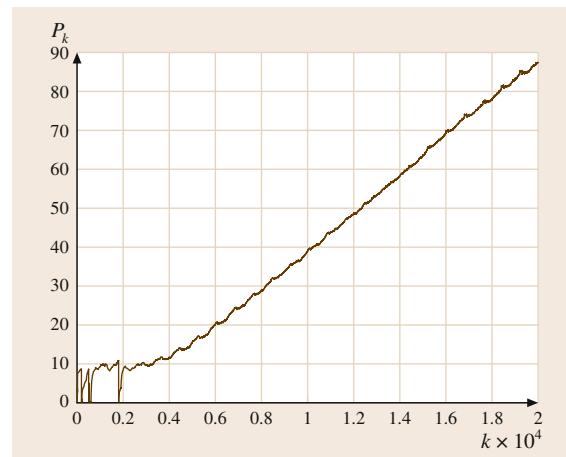

**Fig. 75.4** Adaptive parameters  $P_k^i$  in the case of no robust laws

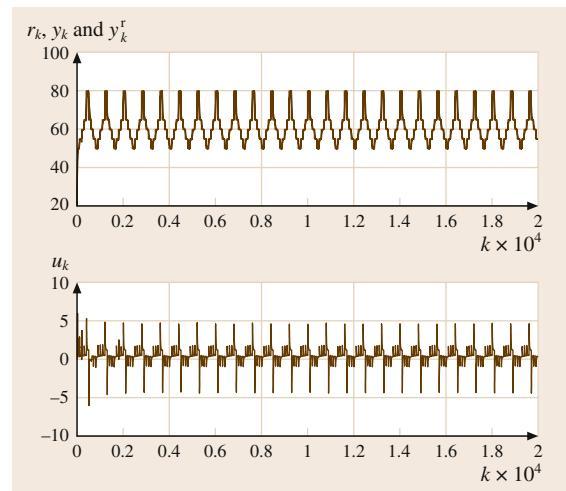

model reference  $y_r$ , the output signal  $y$ , and the lower plot shows the control signal. The seven clouds generated during the self-learning procedure are given in Fig. 75.3.

The drifts of the adaptive parameters  $P_k^i$  are shown in Fig. 75.4, where the parameters for all clouds are shown, and in Fig. 75.5, where the adaptive parameter  $P_k$  is shown.

The second simulation is done with dead zone modification to make the adaptation robust. The dead zone was chosen as  $d_{\text{dead}} = 2$ . All the other parameters of the algorithm were the same as in the first simulation:

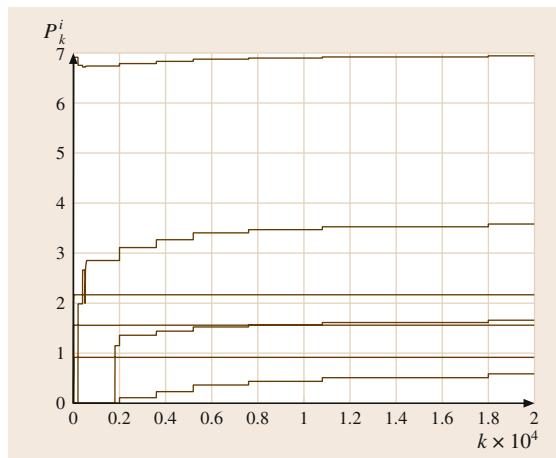

**Fig. 75.5** Drift of the adaptive parameter  $P_k$  in the case of no robust laws

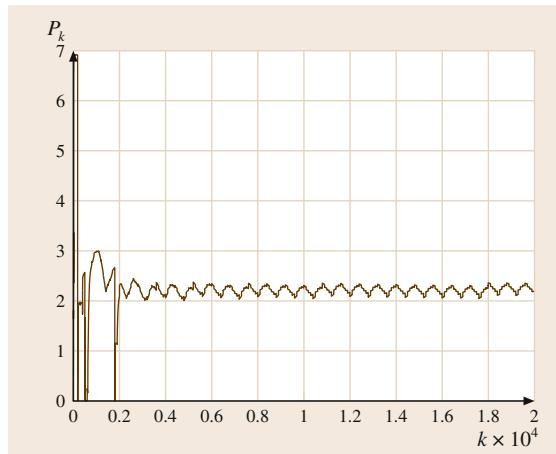

**Fig. 75.6** Reference, model reference, output signal tracking, and control signal in the case of a dead zone

the actuator's interval was given as  $[-6, 6]$ , the reference model parameter was defined as  $a_r = 0.925$ , and the adaptive gain  $\gamma_P = 0.1$ . In the upper plot, Fig. 75.6 shows the reference, the model reference, and the output signal, and in the lower part the control signal. The model reference tracking is suitable and the parameters of the control law converge and enable a reasonable performance.

The clouds generated during the self-learning procedure are the same as those obtained in the first example in Fig. 75.3. During the procedure seven clouds were generated again. The adaptive parameters  $P_k^i$  are shown in Fig. 75.7, where the parameters for all clouds

**Fig. 75.7** Adaptive parameters  $P_k^i$  in the case of a dead zone

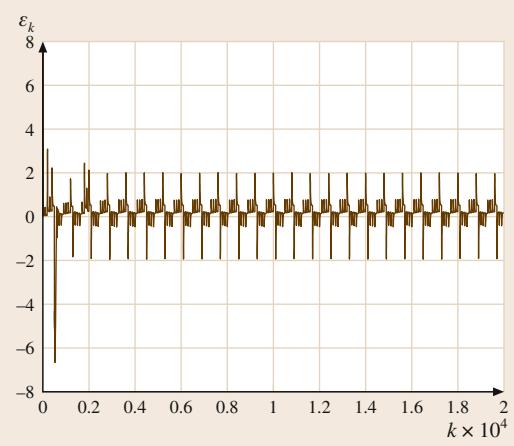

**Fig. 75.8** Drift of the adaptive parameter  $P_k$  in the case of dead zone

are shown, and in Fig. 75.8, where the adaptive parameter  $P_k$  is shown.

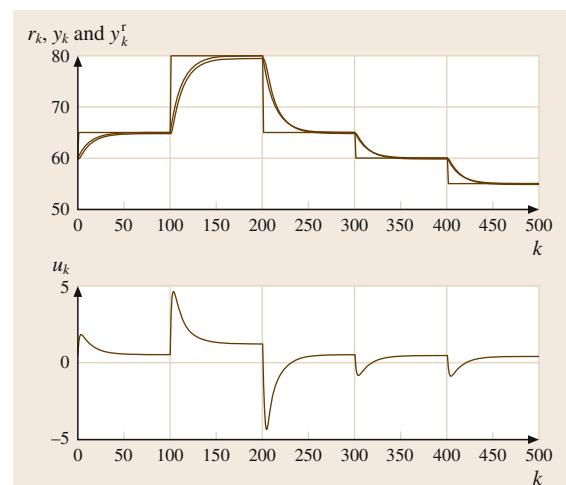

The tracking error  $e_k$  in the case of dead zone modification is shown in Fig. 75.9.

The results of the last 500 samples are shown in detail in Fig. 75.10. It can be seen that the tracking using the proposed modification of the adaptive laws has a very good control performance.

The relatively big dead zone stops the adaptation of the control parameters and results in a bigger tracking error. On the other hand, a smaller dead zone would result in longer settling of the adaptive parameters and

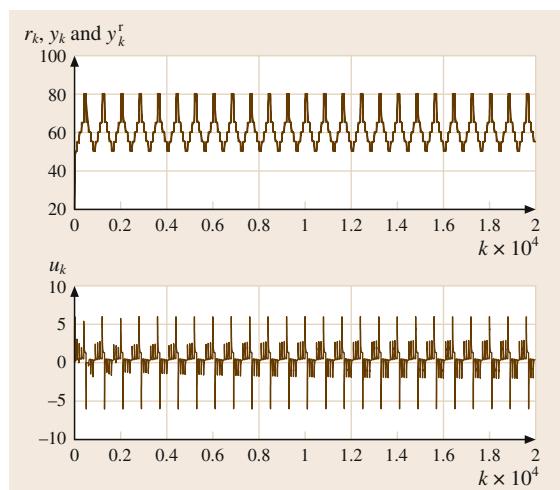

**Fig. 75.9** Tracking error

**Fig. 75.10** Reference, model reference, output signal tracking, and control signal in the case of a dead zone, in detail

also in possible drifting. This way, the combination of a dead zone and a leakage adaptive law is proposed in the third simulation, where the rest of the parameters are the same as in the previous simulation, except the dead zone, which is now chosen to be  $d_{\text{dead}} = 0.25$ , and the leakage term which is defined as  $\sigma_P = 10^{-5}$ .

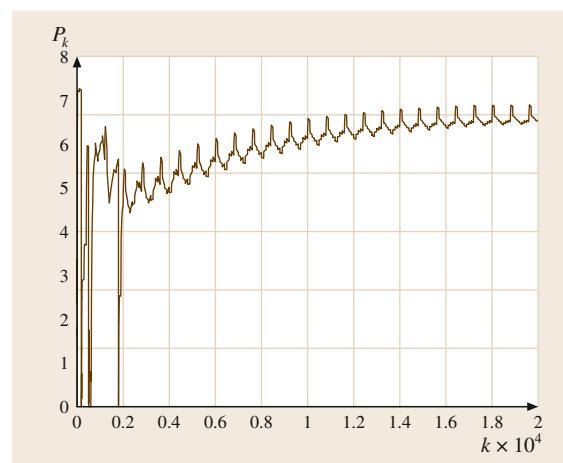

Figure 75.11 shows the reference, the model reference, the output signal, and the control signal. The model reference tracking is satisfactory and the parameters of the control law converge and enable a reasonable performance.

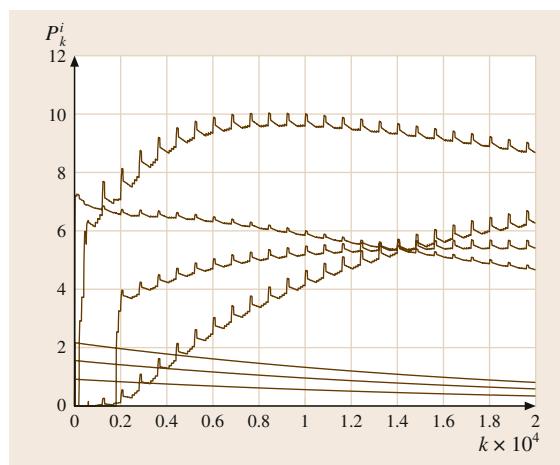

**Fig. 75.11** Reference, model reference, output signal tracking, and control signal in the case of leakage in the adaptive law

The clouds generated during the self-learning procedure with leakage in adaptive law are the same as those obtained in the previous two examples, and are given in Fig. 75.3. The positions of the clouds remain the same in all three approaches using different robust modifications of the adaptive laws. The adaptive parameters  $P_k^i$  are shown in Fig. 75.12, where the parameters for all clouds are shown, and in Fig. 75.13 where the adaptive parameter  $P_k$  is shown.

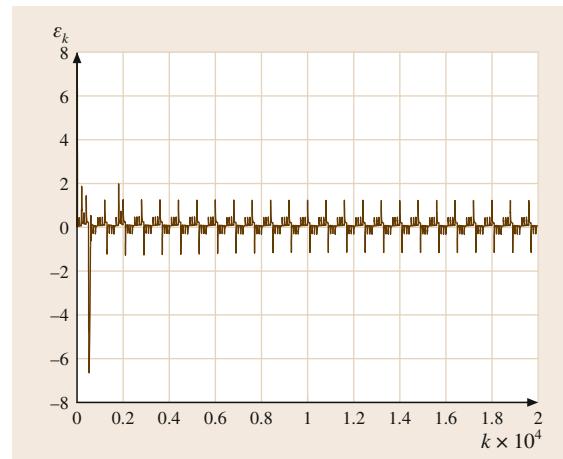

The tracking error  $e_k$  in the case of leakage in the adaptive law is shown in Fig. 75.14. Due to the use of a smaller dead zone and leakage in the adaptive law, the tracking is better and also the parameter convergence is good.

**Fig. 75.13** Drift of the adaptive parameter  $P_k$  in the case of leakage in the adaptive law

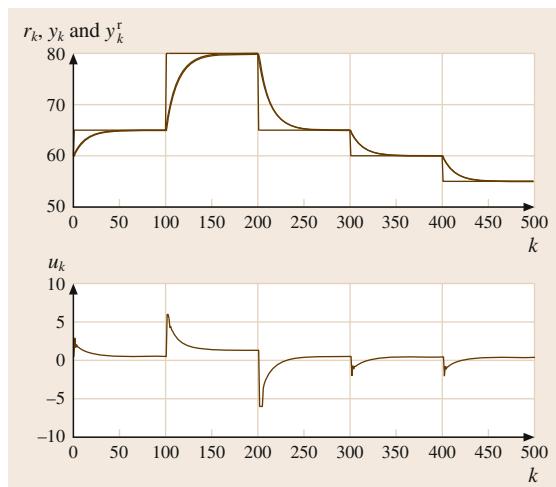

**Fig. 75.12** Adaptive parameters  $P_k^i$  in the case of leakage in the adaptive law

**Fig. 75.14** Tracking error

The results of the last 500 samples are shown in detail in Fig. 75.15. It is shown that the tracking using the proposed leakage in the modification of the adaptive laws has a high control performance.

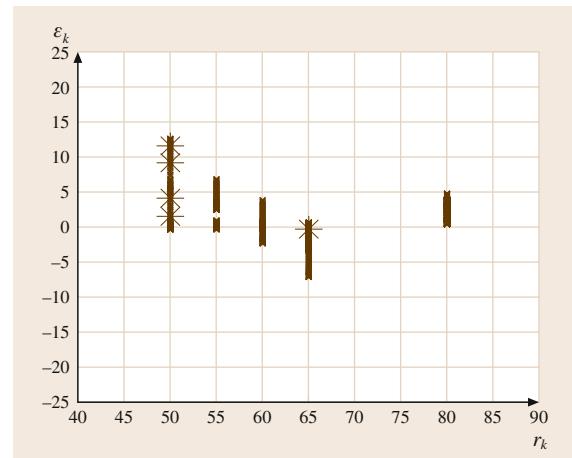

In the fourth simulation study we would like to show an example of drastic constraints in the process actuator. In this case, the actuator constraints are given by the interval  $[-1, 2]$ . The dead zone is now chosen

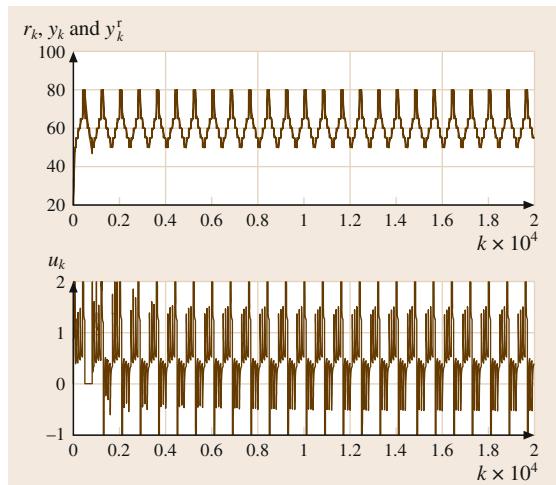

**Fig. 75.15** Reference, model reference, output signal tracking, and control signal in the case of leakage in the adaptive law, in detail

to be  $d_{\text{dead}} = 0.5$ . Figure 75.16 shows the reference, the model reference, the output signal, and the control signal in the case of adaptation interruption. The model reference tracking is satisfactory and the parameters of the control law converge and enable a reasonable performance.

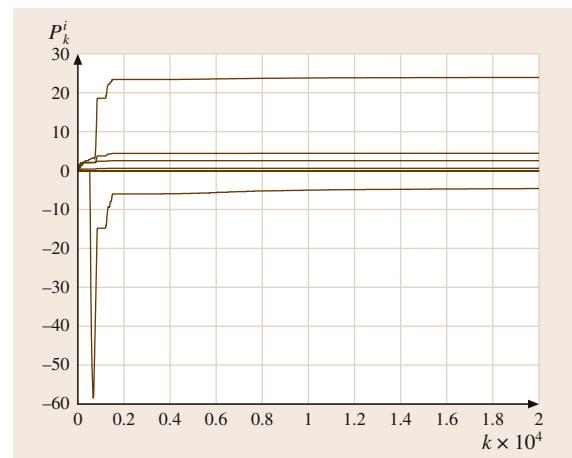

The clouds generated during the self-learning procedure are shown in Fig. 75.17. The positions of the clouds is now different because of the constraints and

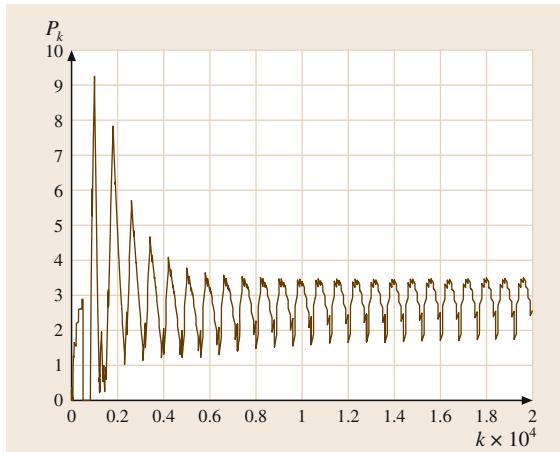

**Fig. 75.17** Clouds in the case of adaptation interruption

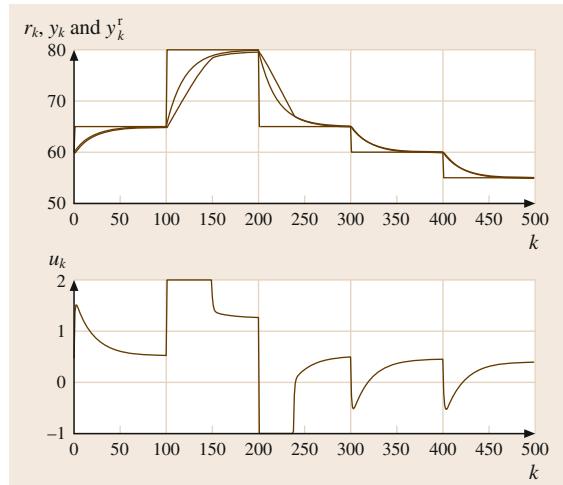

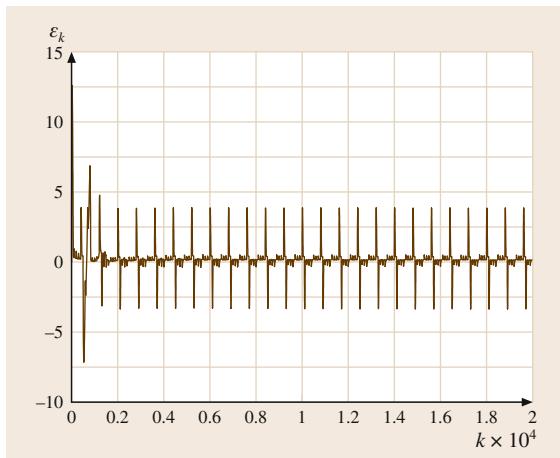

**Fig. 75.16** Reference, model reference, output signal tracking, and control signal in the case of adaptation interruption

**Fig. 75.18** The adaptive parameters  $P_i^k$  in the case of adaptation interruption

**Fig. 75.19** The drift of the adaptive parameter  $P_k$  in the case adaptation interruption

**Fig. 75.21** Reference, model reference, output signal tracking, and control signal in the case of adaptation interruption

different tracking errors. The adaptive parameters  $P_k^t$  are shown in Fig. 75.18, where the parameters for all clouds are shown, and in Fig. 75.19, where the adaptive parameter  $P_k$  is shown.

The tracking error  $\varepsilon_k$  in the case of adaptation interruption is shown in Fig. 75.20.

The results of the last 500 samples are shown in detail in Fig. 75.21. It is shown that perfect tracking in the case of a highly constrained control signal can be achieved by using the proposed modification based on adaptation interruption.

**Fig. 75.20** Tracking error ◀

## 75.5 Conclusions

In this chapter, a new approach for an online self-evolving cloud-based fuzzy rule-based controller (**RECCo**), which has no antecedent parameters, was proposed. One illustrative example was provided to support the concept. It has been shown that the proposed controller can start with no a-priori knowledge. All the fuzzy rules are defined during the self-evolving phase. The controller performs the self-evolving algorithm simultaneously with the control of the plant. The advantage of the proposed controller is the self-evolving procedure,

which enables a working algorithm that starts from no a-priori knowledge; it can cope perfectly with nonlinearity because of the use of fuzzy data clouds, which actually divide the input space and enable the use of different control parameters in each cloud, and also enables adaptation to changes of the process parameters during the control. No explicit membership function is needed, no pre-training or any explicit model in any form. The proposed algorithm combines the well-known concept of model-reference adaptive control al-

gorithms with the concepts of evolving fuzzy systems of ANYA type (no antecedent parameters and density-based fuzzy aggregation of the linguistic rules). In this work, we analyzed problems related to the adaptive approach.

Different modifications of adaptive laws were studied. Those modifications make the adaptive laws more robust to parameter drift which often leads to performance degradation and instability.

# 76. Evolving Embedded Fuzzy Controllers

# Evolving Emb

Oscar H. Montiel Ross, Roberto Sepúlveda Cruz

The interest in research and implementations of type-2 fuzzy controllers (**T2FCs**) is increasing. It has been demonstrated that these controllers provide more advantages in handling uncertainties than type-1 FCs (**T1FCs**). This characteristic is very appealing because real-world problems are full of inaccurate information from diverse sources. Nowadays, it is no problem to implement an intelligent controller (**IC**) for microcomputers since they offer powerful operating systems, high-level languages, microprocessors with several cores, and co-processing capacities on graphic processing units (**GPUs**), which are interesting characteristics for the implementation of fast type-2 ICs (**T2ICs**). However, the above benefits are not directly available for the design of embedded ICs for consumer electronics that need to be implemented in devices such as an application-specific integrated circuit (**ASIC**), a field-programmable gate array (**FPGAs**), etc. Fortunately, for **T1FCs** there are platforms that generate code in **VHSIC** hardware description language (**VHDL**; **VHSIC**: very high speed integrated circuit), C++, and Java. This is not true for the design of **T2ICs**, since there are no specialized tools to develop the inference system as well as to optimize it.

The aim of this chapter is to present different ways of achieving high-performance computing for evolving **T1** and **T2** ICs embedded into **FPGAs**. Therefore, we provide a compiled introduction to **T1** and **T2** FCs, with emphasis on the well-known bottle neck of the interval **T2FC** (**IT2FC**), and software and hardware proposals to minimize its effect regarding computational cost. An overview of learning systems and hosting technology for their implementation is given. We explain different ways to achieve such implementations: at the circuit level using a hardware description lan-

guage, using a multiprocessor system and a high-level language, and combining both methods. We explain how to use the **IT2FC** developed in **VHDL** as a standalone system, and as a coprocessor for the **FPGA** Fusion of Actel, Spartan 6, and Virtex 5. We present the methodology and two new proposals to achieve evolution of the **IT2FC** for **FPGA**, one for the static region of the **FPGA**, and the other one for the reconfigurable region using the dynamic partial reconfiguration methodology.

## 76.1 Overview

An intelligent system and evolution are intrinsically related since it is difficult to conceive intelligence without evolution because intelligence cannot be static. Human beings create, adapt, and replace their own rules throughout their whole lives. The idea to apply evolution to a fuzzy system is an attempt to construct a mathematical assembly that can approximate human-like reasoning and learning mechanisms [76.1]. A mathematical tool that has been successfully applied to better represent different forms of knowledge is fuzzy logic (**FL**); also if-then rules are a good way to express human knowledge, so the application of **FL** to a rule-based system leads to a Fuzzy Rule-Based System (**FRBS**). Unfortunately, an **FRBS** is not able to learn by itself, the knowledge needs to be derived from the expert or generated automatically with an evolutionary algorithm (**EA**) such as a genetic algorithm (**GA**) [76.2].

The use of **GAs** to design machine learning systems constitutes the soft computing paradigm known as the genetic fuzzy system where the goal is to incorporate learning to the system or tuning different components of the **FRBS**. Other proposals in the same line of work are: genetic fuzzy neural networks, genetic fuzzy clustering, and fuzzy decision trees. A system with the capacity to evolve can be defined as a self-developing, self-learning, fuzzy rule-based or neuro-fuzzy system with the ability to self-adapt its parameters and structure online [76.3].

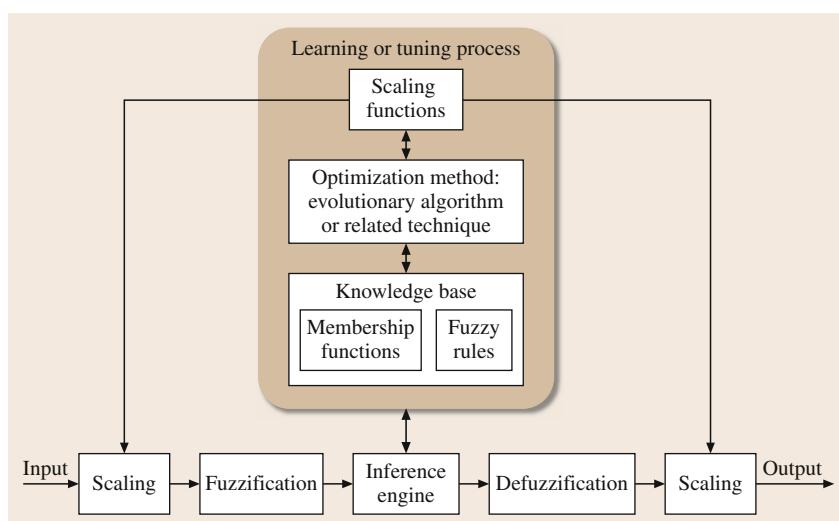

Figure 76.1 shows the general structure of an evolutionary **FRBS** (**EFRBS**) that can be used for tuning

or learning purposes. Although, it is difficult to make a clear distinction between tuning and learning, the particular aspect of each process can be summarized as follows. The tuning process is assumed to work on a predefined rule base having the target to find the optimal set of parameters for the membership functions and/or scaling functions. On the other hand, the learning process requires that a more elaborated search in the space of possible rule bases, or in the whole knowledge base be achieved, as well as for the scaling functions. Since the learning approach does not depend on a predefined set of rules and knowledge, the system can change its fundamental structure with the aim of improving its performance according to some criteria. The idea of using scaling functions for input and output variables is to normalize the universe of discourse in which membership functions were defined.

According to De Jong [76.4]:

*the common denominator in most learning systems is their capability of making structural changes to themselves over time with the intent of improving performance on tasks defined by the environment, discovering and subsequently exploiting interesting concepts, or improving the consistency and generality of internal knowledge structures.*

Hence, it is important to have a clear understanding of the strengths and limitations of a particular learning system, to achieve a precise characterization of all the

**Fig. 76.1** General structure of an evolutionary fuzzy rule-based system

permitted structural changes and how they are going to be made.

*De Jong* sets three different levels of complexity where the **GA** can perform legal structural changes in following a goal, these are [76.4]:

1. By changing critical parameters' values
2. By changing key data structures
3. By changing the program itself with the idea of achieving effective behavioral changes in a task subsystem where a prominent representative of this branch is the *learning production-systems program*.

A good reason behind the success of production systems in machine learning is due to the fact that they have a representation of knowledge that can simultaneously support two kinds of activities: (1) the knowledge can be treated as data that can be manipulated according to some criteria; (2) for a particular task, the knowledge can be used as an executable entity.

The two classical approaches for working with evolutionary **FRBS** (**EFRBS**) for a learning system are the Pittsburgh and Michigan approaches. Historically, in 1975 *Holland* [76.5] affirmed that a natural way to represent an entire rule set is to use a string, i.e., an individual; so, the population is formed by candidate rule sets, and to achieve evolution it is necessary to use selection and genetic operators to produce new generations of rule sets. This was the approach taken by *De Jong* at the University of Pittsburgh, hence the name of *Pittsburgh approach*. During the same period, *Holland* developed a model of cognition in which the members of population are individual rules, and the entire population is conformed with the rule set; this quickly became the *Michigan approach* [76.6, 7].

There are extensive pioneering and recent work about tuning and learning using **FRBS** most of them fall in some way in the Michigan or in the Pittsburgh approaches, for example, the supervised inductive algorithm [76.8, 9], the iterative rule learning approach [76.10], coverage-based genetic induction (**COGIN**) [76.11, 12], the relational genetic algorithm learner (**REGAL**) system [76.13], the compact fuzzy classification system [76.14], with applications to fuzzy control [76.15, 16], and about tuning type-2 fuzzy controllers [76.17–20].

The focus of this chapter is on evolving embedded fuzzy controllers; this subclassification reduces the number of related works; however, they are still a big quantity, since by an embedding system (**ES**), we can understand a combination of computer hardware (**HW**)

and software (**SW**) devoted to a specific control function within a larger system. Typically, the **HW** of an **ES** can be a dedicated computer system, a microcontroller, a digital signal processor, or a **FPGA**-based system. If the **SW** of the **ES** is fixed, it is called firmware; because there are no strict boundaries between firmware and software, and the **ES** has the capability of being reprogrammed, the firmware can be low level and high level. Low-level firmware tells the hardware how to work and typically resides in a read only memory (**ROM**) or in a programmable logic array (**PLA**); high-level firmware can be updated, hence is usually set in a flash memory, and it is often considered software.

In the literature, there is extensive work on successful applications of type-1 and type-2 fuzzy systems; with regards to evolving embedded fuzzy systems, they were applied in a control mechanism for autonomous mobile robot navigation in real environments in [76.21]. For the sake of limiting more the content of this chapter, we have focused on **EFRBS**s to be implemented in an **FPGA HW** platform, with special emphasis on type-2 **FRBS**s. In this last category, with respect to type-1 **FRBS** took our attention to the following proposals: The development of an **FPGA**-based proportional-differential (**PD**) fuzzy look-up table controller [76.22], **FPGA** implementation of embedded fuzzy controllers for robotic applications [76.23], a non-fixed structure fuzzy logic controller is presented in [76.24], a flexible architecture to implement a fuzzy controller into an **FPGA** [76.25], a very simple method for tuning the input membership function (**MF**) for modifying the implemented **FPGA** controller response [76.26]; how to test and simulate the different stages of a **FRBS** for future implementation into an **FPGA** are explained in [76.27–29]. On type-1 **EFRBS** there are some works like: A reconfigurable hardware platform for evolving a fuzzy system by using a cooperative coevolutionary methodology [76.30], the tuning of input **MFs** for an incremental fuzzy **PD** controller using a **GA** [76.31]. In the type-2 **FRBS** category, the amount of reported work is less; representative work can be listed as follows: an architectural proposal of hardware-based interval type-2 fuzzy inference engine for **FPGA** is presented in [76.32], the use of parallel **HW** implementation using bespoke coprocessors handled by a soft-core processor of an interval type-2 fuzzy logic controller is explored in [76.33], a high-performance interval type-2 fuzzy inference system (**IT2-FIS**) that can achieve the four stages fuzzification, inference, **KM**-type reduction, and defuzzification in four clock cycles is shown in [76.34]; the same

system is suitable for implementation in pipelines providing the complete **IT2-FIS** process in just one clock cycle.

This work deals with the development of evolving embedded type-1 and type-2 fuzzy controllers. In the chapter, a broad exploration of several ways to implement evolving embedded fuzzy controllers are presented. We choose to work with the Mamdani fuzzy

controller proposal since it provides a highly flexible means to formulate knowledge.

The organization of this chapter is as follows. In Sect. 76.2 we present the basis of **T1** and **T2 FL** to explain how to achieve the **HW** implementation of an **FRBS**. In Sect. 76.3 a brief description of the state of the art in hosting technology for high-performance embedded systems is given.

## 76.2 Type-1 and Type-2 Fuzzy Controllers

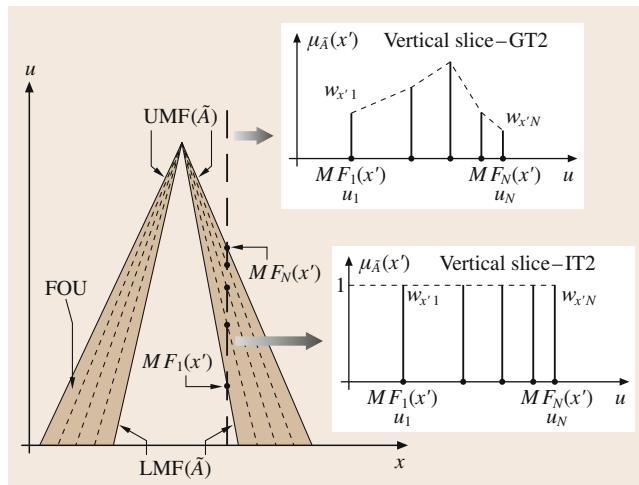

The type-2 fuzzy sets (**T2FS**) were developed with the aim of handling uncertainty in a better way than **T1 FS** does, since a **T1FS** has crisp grades of membership, whereas a **T2FS** has fuzzy grades of membership. An important point to note is that if all uncertainty disappears, a **T2 FS** can be reduced to a **TIFS**. A type-2 membership function (**T2MF**) is an **FS** that has primary and secondary membership values; the primary **MF** is a representation of an **FS**, and serves to create a linguistic representation of some concept with linguistic and random uncertainties with limited capabilities; the secondary **MF** allows capturing more about linguistic uncertainty than a **T1MF**.

There are two common ways to use a **T2FS**, the generalized **T2FS** (**GT2**), and the interval **T2FS** (**IT2FS**). The former has secondary membership grades of dif-

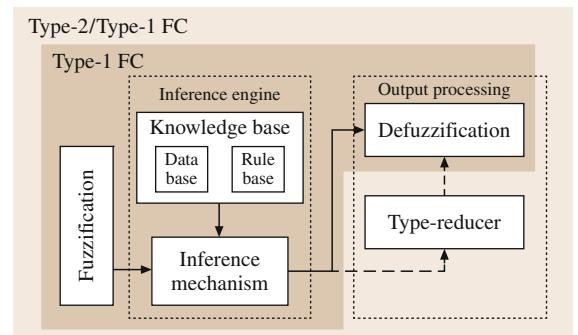

ferent values to represent more accurately the existing uncertainty; on the other hand, in an **IT2FS** the secondary membership value always takes the value of 1. Unfortunately, to date for **GT2** no one knows yet how to choose their best secondary **MFs**; moreover, this method introduces a lot of computations, making it inappropriate for current application in real-time (**RT**) systems, even those with small time constraints; in contrast, the calculations are easy to perform in an **IT2FS**.

A **T2MF** can be represented using a 3-D figure that is not as easy to sketch as a **T1MF**. A more common way to visualize a **T2MF** is to sketch its footprint of uncertainty (**FOU**) on the 2-D domain of the **T2FS**. We illustrate this concept in Fig. 76.2, where we show a vertical slice sketch of the **FOU** at the primary **MF** value  $x'$ ; in the case of a **GT2**, in the right upper part of the figure, the secondary **MF** shows different height values of the **GT2**; in the case of an **IT2F2**, just below is the secondary **MF** with uniform values for the **IT2FS**. Note that the secondary values sit on top of its **FOU**.

Figure 76.3 shows the main components of a fuzzy logic system showing the differences between the **T1** and **T2 FC**. For **T1** systems, there are three components: fuzzifier, inference engine, and the defuzzifier which is

**Fig. 76.2** Type-2 membership function. For the triangular **MF** the **FOU** is shown. The **FOU** is bounded by the upper part  $UMF(\tilde{A})$  and the lower part  $LMF(\tilde{A})$ . A vertical slice at  $x'$  is illustrated. Right, top: secondary **MF** values for a generalized **T2MF**; bottom: secondary **MF** values of an **IT2MF**

**Fig. 76.3** Type-1 and type-2 FC. The **T2FC** at the output processing has the type reducer block

the only output processing unit; whereas for a **T2** system there are four components, since the output processing has interconnected the type reducer (**TR**) block and the defuzzifier to form the output processing unit.

Ordinary fuzzy sets were developed by *Zadeh* in 1965 [76.35]; they are an extension of classical set theory where the concept of membership was extended to have various grades of membership on the real continuous interval  $[0, 1]$ . The original idea was to use a fuzzy set (**FS**); i.e., a linguistic term to model a word; however, after almost 10 years, *Zadeh* introduced the concept of type-n **FS** as an extension of an ordinary **FS** (**T1FS**) with the idea of blurring the degrees of membership values [76.36].

**T1FSs** have been demonstrated to work efficiently in many applications; most of them use the mathematics of fuzzy sets but lose the focus on words that are mainly used in the context to represent a function which is more mathematical than linguistic [76.37].

A **T1FS** is a set of ordered pairs represented by (76.1) [76.38],

$$A = \{(x, \mu_A(x)) \mid x \in X\}, \quad (76.1)$$

where each element is mapped to  $[0, 1]$  by its **MF**  $\mu_A$ , where  $[0, 1]$  means real numbers between 0 and 1, including the values 0 and 1,

$$\mu_A(x) : X \rightarrow [0, 1]. \quad (76.2)$$

A pointwise definition of a **T2FS** is given as follows.  $\widetilde{A}$  is characterized by a **T2MF**  $\mu_{\widetilde{A}}(x, u)$ , where  $x \in X$  and  $u \in J_x \subseteq [0, 1]$ , i.e. [76.39],

$$\widetilde{A} = \{(x, u), \mu_{\widetilde{A}}(x, u) \mid \forall x \in X, \forall u \in J_x \subseteq [0, 1]\}, \quad (76.3)$$

where  $0 \leq \mu_{\widetilde{A}}(x, u) \leq 1$ .

Another way to express  $\widetilde{A}$  is

$$\widetilde{A} = \int_{x \in X} \int_{u \in J_x} \mu_{\widetilde{A}}(x, u) / (x, u) \quad J_x \subseteq [0, 1], \quad (76.4)$$

where  $\int \int$  denote the union over all admissible input variables  $x'$  and  $u'$ . For discrete universes of discourse  $\int$  is replaced by  $\sum$  [76.39]. In fact,  $J_x \subseteq [0, 1]$  represents the primary membership of  $x \in X$  and  $\mu_{\widetilde{A}}(x', u)$  is a **T1FS** known as the secondary set. Hence, a **T2MF** can be any subset in  $[0, 1]$ , the primary membership, and corresponding to each primary membership, there is a secondary membership (which can also be in  $[0, 1]$ ) that defines the uncertainty for the primary membership.

When  $\mu_{\widetilde{A}}(x, u) = 1$ , where  $x \in X$  and  $u \in J_x \subseteq [0, 1]$ , we have the **IT2MF** shown in Fig. 76.2. The uniform shading for the **FOU** represents the entire **IT2FS** and it can be described in terms of an upper membership function and a lower membership function

$$\bar{\mu}_{\widetilde{A}}(x) = \overline{\text{FOU}(\widetilde{A})} \quad \forall x \in X, \quad (76.5)$$

$$\underline{\mu}_{\widetilde{A}}(x) = \underline{\text{FOU}(\widetilde{A})} \quad \forall x \in X. \quad (76.6)$$

Figure 76.2 shows an **IT2MF**, the shadow region is the **FOU**. At the points  $x_1$  and  $x_2$  are the primary **MFs**  $J_{x_1}$  and  $J_{x_2}$ , and the corresponding secondary **MFs**  $\mu_{\widetilde{A}}(x_1)$  and  $\mu_{\widetilde{A}}(x_2)$  are also shown.

The basics and principles of fuzzy logic do not change from **T1FSs** to **T2FSs** [76.37, 40, 41], they are independent of the nature of the membership functions, and in general, will not change for any type- $n$ . When a **FIS** uses at least one type-2 fuzzy set, it is a type-2 **FIS**.

In this chapter we based our study on **IT2FSs**, so the **IT2 FIS** can be seen as a mapping from the inputs to the output and it can be interpreted quantitatively as  $Y = f(X)$ , where  $X = \{x_1, x_2, \dots, x_n\}$  are the inputs to the **IT2 FIS**  $f$ , and  $Y = \{y_1, y_2, \dots, y_n\}$  are the defuzzified outputs. These concepts can be represented by rules of the form

$$\text{If } x_1 \text{ is } \widetilde{F}_1 \text{ and } \dots \text{ and } x_p \text{ is } \widetilde{F}_p, \text{ then } y \text{ is } \widetilde{G}. \quad (76.7)$$

In a **T1FC**, where the output sets are **T1FS**, the defuzzification produces a number, which is in some sense a crisp representation of the combined output sets. In the **T2** case, the output sets are **T2**, so the extended defuzzification operation is necessary to get **T1FS** at the output. Since this operation converts **T2** output sets to a **T1FS**, it is called type reduction, and the **T1FS** is called a type-reduced set, which may then be defuzzified to obtain a single crisp number.

The **TR** stage is the most computationally expensive stage of the **T2FC**; therefore, several proposals to improve this stage have been developed. One of the first proposals was the iterative procedure known as the Karnik–Mendel (**KM**) algorithm.

In general, all the proposals can be classified into two big groups. Group I embraces all the algorithmic improvements and Group II all the hardware improvements, as follows [76.42]:

1. Improvements to software algorithms, where the dominant idea is to reduce computational cost of **IT2-FIS** based on algorithmic improvements. This group can be subdivided into three subgroups.

- (a) Enhancements to the **KM TR** algorithm. As the classification's name claims, the aim is to improve the original **KM TR** algorithm directly, to speed it up. The best known algorithms in this classification are:
- Enhanced **KM (EKM)** algorithms. They have three improvements over the original **KM** algorithm. First, a better initialization is used to reduce the number of iterations. Second, the termination condition of the iterations is changed to remove unnecessary iterations (one). Finally, a subtle computing technique is used to reduce the computational cost of each iteration.
  - The enhanced Karnik–Mendel algorithm with new initialization (**EKMANI**) [76.43]. It computes the generalized centroid of general **T2FS**. It is based on the observation that for two alpha-planes close to each other, the centroids of the two resulting **IT2FS**s are also closed to each other. So, it may be advantageous to use the switch points obtained from the previous alpha-plane to initialize the switch points in the current alpha-plane. Although **EKMANI** was primarily intended for computing the generalized centroid, it may also be used in the **TR** of **IT2-FIS**, because usually the output of an **IT2-FIS** changes only a small amount at each step.
  - The iterative algorithm with stop condition (**IASC**). This was proposed by *Melgarejo et al.* [76.44] and is based on the analysis of behavior of the firing strengths.
  - The enhanced **IASC** [76.45] is an improvement of the **IASC**.
  - Enhanced opposite directions searching (**EODS**), which is a proposal to speed up **KM** algorithms. The aim is to search in both directions simultaneously, and in each iteration the points *L* and *R* are the switching points.
- (b) Alternative **TR** algorithms. Unlike iterative **KM** algorithms, most alternative **TR** algorithms have a closed-form representation. Usually, they are faster than **KM** algorithms. Two representative examples are:
- The Gorzalczany method. A polygon using the firing strengths  $[f^n, \bar{f}^n]$  and  $[(y^1, y^n)]$ , which can be viewed as an **IT2FS**. It computes an approximate membership value for each point. Here,  $\underline{y}^n = \bar{y}^n = y^n$ ,

for  $n = 1, 2, 3, \dots, N$ .

$$\mu(y) = \frac{\bar{f} - f}{2} \cdot [1 - (\bar{f} - f)] , \quad (76.8)$$

where  $\bar{f} - f$  is called the bandwidth. Then the defuzzified output can be computed as

$$y_G = \arg \max_y \mu(y) . \quad (76.9)$$

- ii. The Wu–Tan (**WT**) method. It searches an equivalent **T1FS**. The centroid method is applied to obtain the defuzzification. This is the faster method in this category.

2. Hardware implementation. The main idea is to take advantage of the intrinsic parallelism of the hardware and/or combinations of hardware and parallel programming. Here, we divided this group into four main approaches that embrace the existing proposals of reducing the computational time of the type reduction stage by the use of parallelism at different levels.

- (a) The use of multiprocessor systems, including multicore systems that enable the same benefits at a reduced cost. In this category are personal and industrial computers with processors such as the Intel Pentium Core Processor family, which includes the Intel Core i3, i5 and i7; the AMD Quad-Core Opteron, the AMD Phenom X4 Quad-Core processors, multicore microcontrollers such as the Propeller P8X32A from Parallax, or the F28M35Hx of the Concerto Microcontrollers family of Texas Instruments. Multicore processors also can be implemented into **FPGAs**.

- (b) The use of a general-purpose **GPU (GPGPU)**, and compute unified device architecture (**CUDA**). In general, **GPU** provides a new way to perform high performance computing on hardware. In particular **IT2FCs** can take the most advantage of this technology because their complexity. Traditionally, before the development of the **CUDA** technology, the programming was achieved by translating a computational procedure into a graphic format with the idea to execute it using the standard graphic pipeline; a process known as encoding data into a texture format. The **CUDA** technology of NVIDIA offers a parallel programming model for **GPUs** that does not require the use of a graphic application programming interface (**API**), such as OpenGL [76.46].

- (c) The use of **FPGAs**. This approach offers the best processing speed and flexibility. One of the main advantages is that the developer can determine the desired parallelism grade by a trade-off analysis. Moreover, this technology allows us to use the strength of all platforms in tight integration to provide the large performance available at the present time. It is possible to have a standalone **T1/T2FC**, or to integrate the same **T1/T2FC** as a coprocessor as part of a high performance computing system.
- (d) The use of **ASICs**. The **T1/T2FC** is factory integrated using complementary metal-oxide-semiconductor (**CMOS**) technology. The main

advantages are that they are cheaper than **FPGAs**. Differently to **FPGA** technology, **ASIC** solutions are not field reprogrammable.

A system based on an **FPGA** platform allows us to program all the Group I algorithms since modern **FPGAs** have embedded hard and/or soft processors; this kind of system can be programmed using high-level languages such as C/C++ and also they can incorporate operating systems such as Linux. On the other hand, **T1/T2 FC** hardware implementations have the advantage of providing competitive faster systems in comparison to **ASIC** systems and the in field reconfigurability.

## 76.3 Host Technology

Until the beginnings of this century, general-purpose computers with a single-core processor were the systems of choice for high-performance computing (**HPC**) for many applications; they replaced existing big and expensive computer architectures [76.47]. In 2001, IBM introduced a reduced instruction set computer (**RISC**) microarchitecture named POEWER4 (performance optimization with enhanced **RISC**) [76.48]. This was the first dual core processor embedded into a single die, and subsequently other companies introduced different multicore microprocessor architectures to the market, such as the Arm Cortex A9 [76.49], Sparc64 [76.50], Intel and AMD Quad Core processors, Intel i7 processors, and others [76.51]. These developments, together with the rapid development of **GPUs** that offer massively parallel architectures to develop high-performance software, are an attractive choice for professionals, scientists, and researchers interested in speeding up applications. Undoubtedly, the use of a generic computer with **GPU** technology has many advantages for implementing an embedded learning fuzzy system [76.46], and disadvantages are mainly related to size and power consumption. A solution to the aforementioned problems is the use of application specific integrated circuits (**ASICs**) fuzzy processors [76.52–54], or reprogrammable hardware based on microcontrollers and/or **FPGAs**.

The orientation of this paper is towards tuning and learning using **FRBS** for embedded applications; for now, we are going to focus on **FPGAs** and **ASIC** technology [76.55], since they provide the best level of parallelization. Both families of devices provide characteristics for **HPC** that the other options cannot. Each

technology has its own advantages and disadvantages, which are narrowing down due to recent developments. In general, **ASICs** are integrated circuits that are designed to implement a single application directly in fixed hardware; therefore, they are very specialized for solving a particular problem. The costs of **ASIC** implementations are reduced for high volumes; they are faster and consume less power; it is possible to implement analog circuitry, as well as mixed signal design, but the time to market can take a year or more. There are several design issues that need to be carried out that do not need to be achieved using **FPGAs**, the tools for development are very expensive. On the other hand, **FPGAs** can be introduced to the market very fast since the user only needs a personal computer and low-cost hardware to burn the **HDL** (**HDL**) code to the **FPGA** before it is ready to work. They can be remotely updated with new software since they are field reprogrammable. They have specific dedicated hardware such as blocks of random access memory (**RAM**); they also provide high-speed programmable I/O, hardware multipliers for digital signal processing (**DSP**), intellectual property (**IP**) cores, microprocessors in the form of hard cores (factory implemented) such as PowerPC and ARM for Xilinx, or Microblaze and Nios softcore (user implemented) for Xilinx and Altera, respectively. They can have built-in analog digital converters (**ADCs**). The synthesis process is easier. A significant point is that the **HDL** tested code developed for **FPGAs** may be used in the design process of an **ASIC**.

There are three main disadvantages of the **FPGAs** versus **ASICs**, they are: **FPGA** devices consume more

power than **ASICs**, it is necessary to use the resources available in the **FPGA** which can limit the design, and they are good for low-quantity production. To overcome these disadvantages it is very important to achieve optimized designs, which can only be attained by coding efficient algorithms.

During the last decade, there has been an increasing interest in evolving hardware by the use of evolutionary computations applied to an embedded digital system. Although different custom chips have been proposed for

this plan, the most popular device is the **FPGA** because its architecture is designed for general-purpose commercial applications. New FGAs allow modification of part of the programmed logic, or add new logic at the running time. This feature is known as dynamic or active reconfiguration, and because in an **FPGA** we can combine a multiprocessor system and coprocessors, **FPGAs** are very attractive for implementing evolvable hardware algorithms. Therefore, in the next sections, we shall put special emphasis on multiprocessor systems and **FPGAs**.

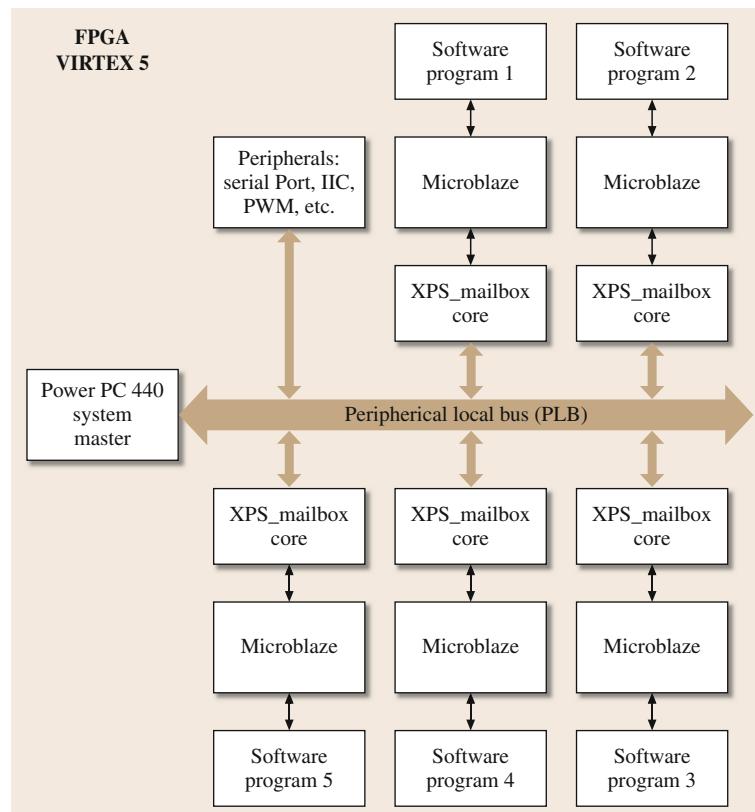

## 76.4 Hardware Implementation Approaches

In this section, an overview of the three main lines of attack to do a hardware implementation of an intelligent system is given.

### 76.4.1 Multiprocessor Systems

Multiprocessor systems consist of multiple processors residing within one system; they have been available

for many years. Multicore processors have equivalent benefits to multiprocessors at a lower cost; they are integrated in the same electronic component. At the present time, most modern computer systems have many processors that can be single core or multicore processors; therefore, we can have three different layouts for multiprocessing: a multicore system, a multiprocessor system, and a multiprocessor/multicore system.

**Fig. 76.4** Multicore system embedded into an **FPGA**. Embedded is a hard-processor PowerPC440 and five MicroBlaze soft-processors. In this system we can process an **EA** using the island model

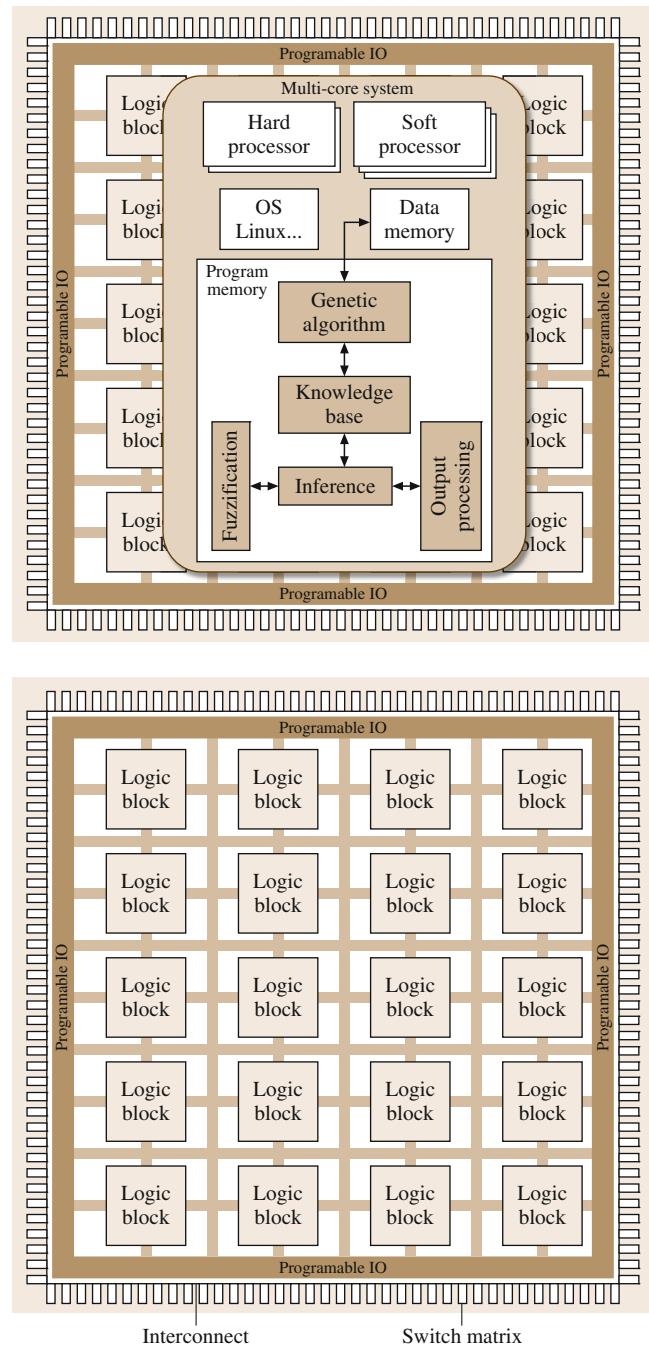

**Fig. 76.5** The whole embedded evolutionary IT2FC implemented in the program memory of the multiprocessor system, similarly as in a desktop computer ►

Figure 76.4 shows a multicore system embedded into a Virtex 5 **FPGA** XC5VFX70; it has the capacity to integrate a distributed multicore system with a hard-processor PowerPC 440 as the master, five Microblaze 32-bit soft-processor slaves, coprocessors, and peripherals. The **FPGA** capacity to integrate devices is, of course, limited by the size of the **FPGA**. Figure 76.5 shows the full implementation in the program memory of the multiprocessor system.

#### 76.4.2 Implementations into **FPGAs**

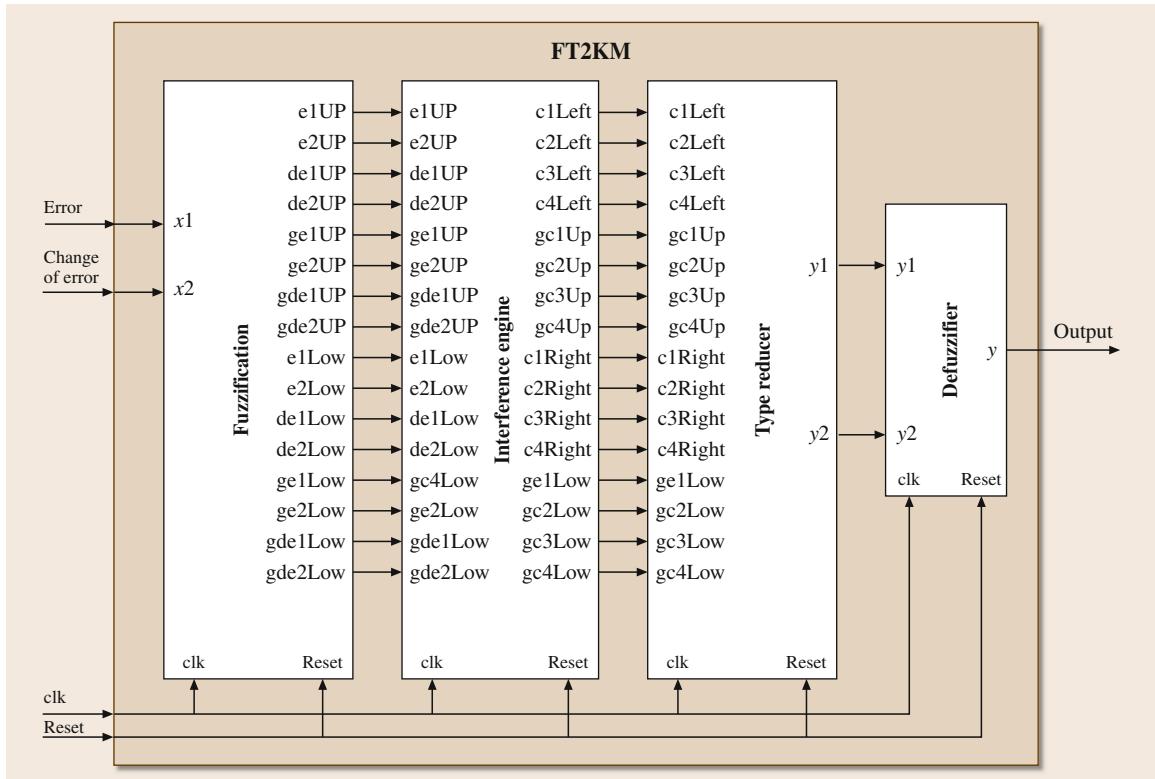

The architecture of **FPGAs** offers massive parallelism because they are composed of a large array of configurable logic blocks (**CLBs**), digital signal processing blocks (**DSPs**), block **RAM**, and input/output blocks (**IOBs**). Similarly, to a processor's arithmetic unit (**ALU**), **CLBs** and **DSPs** can be programmed to perform arithmetic and logic operations like compare, add/subtract, multiply, divide, etc. In a processor, **ALU** architectures are fixed because they have been designed in a general-purpose manner to execute various operations. **CLBs** can be programmed using just the operations that are needed by the application, which results in increased computation efficiency. Therefore, an **FPGA** consists of a set of programmable logic cells manufactured into the device according to a connection paradigm to build an array of computing resources; the resulting arrangement can be classified into four categories: symmetrical array, row-based, hierarchy-based, and sets of gates [76.56]. Figure 76.6 shows a symmetrical array-based **FPGA** that consists of a two-dimensional array of logic blocks immersed in a set of vertical and horizontal lines; examples of **FPGAs** in this category are Spartan and Virtex from Xilinx, and Atmel AT40K. In Fig. 76.6 three main parts can be identified: a set of programmable logic cells also called logic blocks (**LBS**) or configurable logic blocks (**CLBs**), a programmable interconnection network, and a set of input and output cells around the device.

Embedded programmable logic devices usually integrate one or several processor cores, programmable logic and memory on the same chip (an **FPGA**) [76.56]. Developments in the field of **FPGA** have been very amazing in the last two decades, and for this reason, **FPGAs** have moved from tiny devices with a few thousand gates that were used in small applications such as

**Fig. 76.6** Symmetric array-based **FPGA** architecture *island style*

finite state machines, glue-logic for complex devices, and very limited CPUs. In a 10-year period of time, a 200% growth rate in the capacity of Xilinx **FPGAs**

**Fig. 76.7** IT2FC design entity (FT2KM). This top-level module contains instances of the four fuzzy controller submodules

devices was observed, a 50% reduction rate in power consumption, and prices also show a significant decrease rate. Other **FPGA** vendors, such as ACTEL, and ALTERA show similar developments, and this trend still continues. These developments, together with the progress in development tools that include software and low-cost evaluation boards, have boosted the acceptance of **FPGAs** for different technological applications.

### Development Flow

The development flow of an **FPGA**-based system consists of the following major steps:

1. Write in **VHDL** the code that describes the systems' logic; usually a top-down and bottom-up methodology is used. For example, to design an **IT2FC**, we need to achieve the following procedure:
  - (a) Describe the design entity where the designer defines the input and output of the top **VHDL** module. The idea is to present the complex object in different hierarchical levels of abstrac-

tion. For our example, the top design entity is **FT2KM**.

- (b) Once the design entity has been defined, it is required to define its architecture, where the description of the design entity is given; in this step, we define its behavior, its structure, or a mixture of both. For the case of the **IT2 FLS**, we define the system's internal behavior, so we determined the necessity to achieve a logic design formed by four interconnected modules: fuzzification, inference engine, type reduction, and defuzzification. The **VHDL** circuits (sub-modules) are described using a register transfer logic (**RTL**) sequence, since we can divide the functionality in a sequence of steps. At each step, the circuit achieves a task consisting in data transference between registers and evaluation of some conditions in order to go to the next step; in other words, each **VHDL** module (design entity) can be divided into two areas: data and control. Each of the four modules needs

to be conceptualized, so we need to define its own design entity and, therefore, its particular architecture as well interconnections with internal modules. This process is achieved when we have reached the last system component.

- (c) Integrate the system. It is necessary to create a main design entity (top level) that integrates the submodules defining their interconnections. In Fig. 76.7 the integration of the four modules is shown.
- 2. Develop the test bench in **VHDL** and perform **RTL** simulations for each submodule of the main design entity. It is necessary to achieve timing and functional simulations to create reliable internal design entities.
- 3. Perform synthesis and implementation. In the synthesis process, the software transforms the **VHDL** constructs to generic gate-level components, such as simple logic gates and flip-flops. The implementation process is composed of three small subprocesses: translate, map, and place, and route. In the translate process the multiple design files of a project are merged into a single netlist. The map process maps the generic gates in the netlist to the **FPGA**'s logic cells and **IOBs**, this process is also known as technology mapping. In the place and route process, using the physical layout inside the **FPGA** chip, the process places the cells in physical locations and determines the routes to connect diverse signals. In the Xilinx flow, the static timing analysis performed at the end of the implantation process determines various timing parameters such as maximal clock frequency and maximal propagation delay [76.57].
- 4. Generate the programming file and download it to the **FPGA**. According to the final netlist a configuration file is generated, which is downloaded to the **FPGA** serially.
- 5. Test the design entity using a simulation program such as Simulink of Matlab and the Xilinx system generator (**XSG**) for Xilinx devices. The idea here is first to plot the surface control in order to analyze the general behavior of the design (a controller in

our example), and second to integrate the design entity as a block of the desired system to be controlled. Although, this fifth step, is not in the current literature of logic design for **FPGA** implementation, it is the authors's recommendation since we have experienced good results following this practice.

Using the design entity FT2KM.vhd, which was created and tested using the aforementioned development flow, we can integrate it an **FPGA** in two ways:

1. As a standalone system. Here, we mean an independent system that does not require the support of any microprocessor to work, the system itself is a specialized circuit that can produce the desired output. The **IT2FC** is implemented using the **FPGA** flow design; therefore, it is programmed using the complete development flow for a specific application.
2. As a coprocessor. The coprocessor performs specialized functions in such a way that the main system processor cannot perform as well and faster. For **IT2FCs**, given an input, the time to produce an output is big enough to achieve an adequate control of many plants when the **IT2FC** is programmed using high-level language, even we have used a parallel programming paradigm. Since a coprocessor is a dedicated circuit designed to offload the main processor, and the **FPGA** can offer parallelism on the circuit level, the designer of the **IT2FC** coprocessor can have control of the controller performance. The coprocessor can be physically separated, i. e., in a different **FPGA** circuit (or module), or it can be part of the system, in the same **FPGA** circuit. In this work, we show two methods to develop a system with an **IT2FC** as a coprocessor. In both methods, we consider that we have a tested **IT2FC** design entity. In the first case, we shall use the **FT2KM** design entity to incorporate the fuzzy controller as a coprocessor of an ARM processor into an **FPGA** Fusion. In the second case, we are going to create the **IT2FC** **IP** core using the Xilinx Platform Studio; the core will serve as a coprocessor of the MicroBlaze processor embedded into a Spartan 6 **FPGA**.

## 76.5 Development of a Standalone IT2FC

Figure 76.7 shows the top-level design entity (FT2KM) of the **IT2FC** and its components (submodules) for **FPGA** implementation. The entity codification of the top-level entity and its components are given in

Sect. 76.5.1. All stages include the clock (**clk**) and reset (**rst**) signals. In the defuzzifier, we have included these two signals to illustrate that a full process takes only four clock cycles, one for each stage. In prac-

tice, we did not add these two signals, since when we used it as a coprocessor, in order to incorporate it to the system, one 8-bit data latch is added at the output. For a detailed description of the **IT2FC** stages consult [76.34].

The fuzzification stage has two input variables,  $x_1$  and  $x_2$ . This module contains a fuzzifier for the upper MFs, and another for the lower MFs of the **IT2FC**. For the upper part, for the first input  $x_1$ , considering that a crisp value can be fuzzified by two MFs because it may have membership values in two contiguous T2MFs, the linguistic terms are assigned to the VHDL variables  $e_{1\text{up}}$  and  $e_{2\text{up}}$ , and their upper membership values are  $ge_{1\text{up}}$  and  $ge_{2\text{up}}$ . For the second input  $x_2$ , the linguistic terms are assigned to the VHDL variables  $de_{1\text{up}}$  and  $de_{2\text{up}}$ , and  $gde_{1\text{up}}$  and  $gde_{2\text{up}}$  are the upper membership values. The lower part of the fuzzifier is similar; for example, for the input variable  $x_1$  the VHDL assigned variables are  $e_{1\text{low}}$  and  $e_{2\text{low}}$ , and their lower MF values are  $ge_{1\text{low}}$  and  $ge_{2\text{low}}$ , etc. The fuzzification stage entity *only needs one clock cycle* to perform the fuzzification. These eight variables are the inputs of the inference engine stage [76.58].

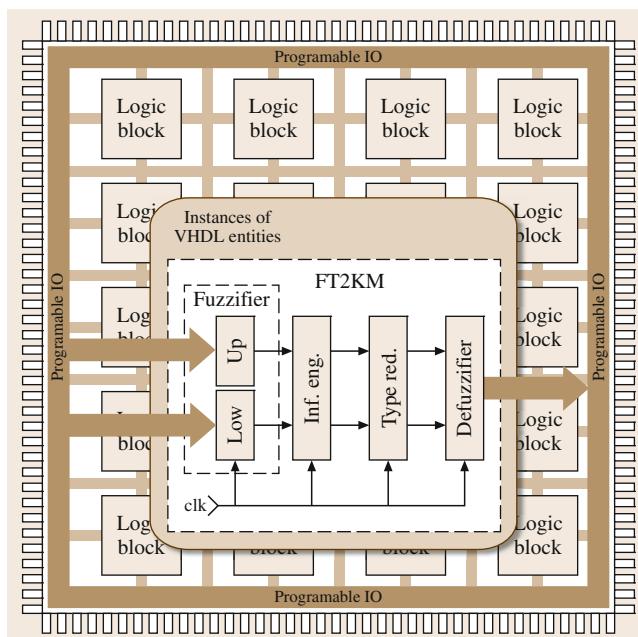

The inference engine is divided into two parallel inference engine entities IEEup is used to manage the upper bound of the **IT2FC**, and IEElow for the lower bound of the **IT2FC**s. Each entity has eight inputs from the corresponding fuzzifier stage, and eight outputs; four belong to the output linguistic terms, the rest correspond to their firing strengths. All the inputs enter into a parallel selection VHDL process, the circuits into the process are placed in parallel; the degree of parallelism can be tailored by an adequate codification style. In our case, all the rules are processed in parallel and the eight outputs of each inference engine section (upper bound and lower bound) are obtained at the same time because the *clk* signal synchronizes the process, hence *this stage needs only one clock cycle to perform a whole inference and provide the output to the next stage*. In the upper bound, the four antecedents are formed at the same time, for example, for the first rule, the antecedent is formed using the concatenation operator &, so it looks like  $\text{ante} := e1 \& de1$ . Each antecedent can address up to four rules and depending on the combination, one of the four rules is chosen; the upper inference engine output provides the active consequents and its firing strengths. The lower bound of the inference engine is treated in the same way [76.59].

At the input of the **TR**, we have the equivalent values of the pre-computed  $y_l^i$ , i.e., the linguistic terms of the active consequents ( $C_{1\text{left}}$ ,  $C_{2\text{left}}$ ,  $C_{3\text{left}}$ , and  $C_{4\text{left}}$ ), the upper firing strength ( $gc_{1\text{up}}$ ,  $gc_{2\text{up}}$ ,  $gc_{3\text{up}}$ , and  $gc_{4\text{up}}$ ), in addition to the equivalent values of the pre-computed  $y_r^i$  ( $C_{1\text{right}}$ ,  $C_{2\text{right}}$ ,  $C_{3\text{right}}$ , and  $C_{4\text{right}}$ ), the lower firing strength ( $gc_{1\text{low}}$ ,  $gc_{2\text{low}}$ ,  $gc_{3\text{low}}$ , and  $gc_{4\text{low}}$ ) [76.60]. All the above-mentioned signals go to a parallel selection process to perform the **KM** algorithm [76.39]. There are parallel blocks to obtain the average of the upper and lower firing strength for the active consequents, required to obtain the average of the  $y_r$  and  $y_l$ ; a block to obtain the different defuzzified values of  $y_r$  and  $y_l$ ; parallel comparator blocks to obtain the final result of  $y_r$  and  $y_l$  [76.61].

The final result of the **IT2FC** is obtained using the defuzzification block, which computes the average of the  $y_r$  and  $y_l$ , and produces the only output  $y$ .

### 76.5.1 Development of the **IT2** **FT2KM** Design Entity

Figure 76.8 shows the implementation of a static **IT2FC** that can work as a standalone system. By static, we mean that the only way to reconfigure (modify) the FC is to stop the application and uploading the whole

**Fig. 76.8** A standalone **IT2FC** is embedded into an **FPGA**. The fuzzifier reads the inputs directly from the **FPGA** terminals. The defuzzifier sends the crisp output to the **FPGA** terminals. The system may be embedded in the static region or in the reprogrammable region

configuration bit file (bitstream). In this system, the inputs of the fuzzifier and the defuzzifier output are connected directly to the **FPGA** terminals. The assignment of the terminals is achieved in accordance with the internal architecture of the chosen **FPGA**. Hence, it is necessary to provide to the Xilinx Integrated Synthesis Environment (**ISE**) program, special instructions (constraints) to carry through the synthesis process. They are generally placed in the user constraint file (**UCF**), although they may exist in the **HDL** code. In general, constraints are instructions that are given to the **FPGA** implementation tools with the purpose of directing the mapping, placement, timing, or other guidelines for the implementation tools to follow while processing an **FPGA** design. In Fig. 76.7 the overall entity of design of the **IT2FC** (FTK2M) was defined as follows,

```
entity FT2KM is
  Port(clk, reset : in std_logic;
       x1, x2 : in std_logic_vector(8 downto 1);
       y : out std_logic_vector (8 downto 1)
  );
end FT2KM;
```

The architecture of FT2KM has four components, and all of them have two common input ports: clock (**clk**), and reset (**rst**). All ports in an entity are signals by default. This is important since a signal serves to pass values in and out of the circuit; a signal represents circuit interconnects (wires). A component is a simple piece of customized code formed by entities as corresponding architectures, as well as library declarations. To allow a hierarchical design, each component must be declared before been used by another circuit, and to use a component it is neccesary to instantiate it first. In this approach the components are:

1. The component labeled as *fuzzyUpLw*. It is the **T2** fuzzifier that consists of one fuzzifier for the upper **MF** of the **FOU** and one for the lower **MF**. It has two input ports *x1* and *x2*; these are 16: *e1Up* to *de2Low*.

```
component fuzzyUpLw is
  port(clk, reset : in std_logic;
       x1, x2, ge1Up, ge2Up, gde1Up, gde2Up :
         in std_logic_vector(n downto 1);
       e1Up, e2Up, de1Up, de2Up, e1Low,
         e2Low, dellow,
       de2Low : out std_logic_vector(3 downto 1);
       ge1Up, ge2Up, gde1Up, gde2Up, ge1Low,
         ge2Low, gde1Low,
       gde2Low : out std_logic_vector(n downto 1);
  );
end component;
```

The instantiation of this component is achieved using nominal mapping and the name of this instance is *fuzt2*. Note that ports *clk*, *reset*, and *x1* and *x2* are mapped (connected) directly to the entity of design FT2KM, since as we explained before, all ports are signals by default, which represent wires. The piece of code that defines the instantiation of the *fuzzyUpLw* component is as follows,

```
fuzt2 : fuzzyUpLw port map(
    clk => clk, reset=> reset, x1 => x1, x2 => x2,
    e1Up => e1upsig, e2Up => e2upsig, de1Up => delupsig,
    de2Up => de2upsig, ge1Up => gelupsig, ge2Up => ge2upsig,
    gde1Up => gde1upsig, gde2Up => gde2upsig, e1Low => e1lowsig,
    e2Low => e2lowsig, de1Low => dellowsig, de2Low => de2lowsig,
    ge1Low => gelowsig, ge2Low => ge2lowsig, gde1Low => gdellowsig,
    gde2Low => gde2lowsig
);
```

2. The component *Infer\_type\_2* corresponds to the T2 inference the controller. It has 16 inputs that match to the 16 outputs of the fuzzification stage. This component has 16 outputs to be connected to the type reduction stage. The piece of code to include this component is:

```
component Infer_type_2 is
    port(rst, clk : in std_logic;
        e1, e2, de1, de2, e1_2, e2_2, de1_2, de2_2 : in STD_LOGIC_VECTOR (m downto 1);
        g_e1, g_e2, g_de1, g_de2, g_e1_2, g_e2_2,
        g_de1_2, g_de2_2 : in STD_LOGIC_VECTOR (n downto 1);
        c1, c2, c3, c4, c1_2, c2_2, c3_2, c4_2 : out STD_LOGIC_VECTOR (m downto 1);
        gc1_2, gc2_2, gc3_2, gc4_2, gc1, gc2, gc3, gc4 : out STD_LOGIC_VECTOR (n downto 1);
    );
end component;
```

This component is instantiated with the name *Infer\_type\_2* as follows,

```
inft2: Infer_type_2 port map(
    rst => reset, clk => clk, e1 => e1upsig, e2 => e2upsig, de1 => delupsig,
    de2 => de2upsig, g_e1 => gelupsig, g_e2 => ge2upsig, g_de1 => gde1upsig,
    g_de2 => gde2upsig, e1_2 => e1lowsig, e2_2 => e2lowsig, de1_2 => dellowsig,
    de2_2 => de2lowsig, g_e1_2 => gelowsig, g_e2_2 => ge2lowsig, g_de1_2 => gdellowsig,
    g_de2_2 => gde2lowsig, c1 => c1sig, c2 => c2sig, c3 => c3sig, c4 => c4sig,
    gc1 => gc1sig, gc2 => gc2sig, gc3 => gc3sig, gc4 => gc4sig, c1_2 => c12sig,
    c2_2 => c22sig, c3_2 => c32sig, c4_2 => c42sig, gc1_2 => gc12sig,
    gc2_2 => gc22sig, gc3_2 => gc32sig, gc4_2 => gc42sig
);
```

To connect the instances *fuzt2* and *Infer\_type\_2* it is necessary to define some signals (wires),

```
signal e1upsig, e2upsig, delupsig, de2upsig : std_logic_vector (m-1 downto 0);
signal gelupsig, ge2upsig, gde1upsig, gde2upsig :std_logic_vector (7 downto 0);
signal e1lowsig, e2lowsig, dellowsig, de2lowsig :std_logic_vector (m-1 downto 0);
signal gelowsig, ge2lowsig, gde1lowsig, gde2lowsig : std_logic_vector (7 downto 0);
```

3. The component *TypeRed* corresponds to the type reduction stage of the **T2FC**. It has 16 inputs that should connect the inference engine's outputs and it has two outputs *yr* and *yl* that should be connected to the defuzzifier through signals, once both have been instantiated. The piece of code to include this component is:

```
component TypeRed is
    Port (clk, rst : in std_logic;
          c1, c2, c3, c4, c1_2, c2_2, c3_2, c4_2 : in STD_LOGIC_VECTOR (3 downto 1);
          gc1, gc2, gc3, gc4, gc1_2, gc2_2, gc3_2, gc4_2 : in STD_LOGIC_VECTOR (7 downto 0);
          yl, yr : out std_logic_vector (8 downto 1));
end component;
```

This component is instantiated with the name *trkm* as follows,

```
inft2: Infer_type_2 port map(
    rst => reset, clk => clk, e1 => elupsig, e2 => e2upsig, de1 => delupsig,
    de2 => de2upsig, g_e1 => gelupsig, g_e2 => ge2upsig, g_de1 => gde1upsig,
    g_de2 => gde2upsig, e1_2 => e1lowsig, e2_2 => e2lowsig, de1_2 => dellowsig,
    de2_2 => de2lowsig, g_e1_2 => gellowsig, g_e2_2 => ge2lowsig, g_de1_2 => gde1lowsig,
    g_de2_2 => gde2lowsig, c1 => c1sig, c2 => c2sig, c3 => c3sig, c4 => c4sig,
    gc1 => gc1sig, gc2 => gc2sig, gc3 => gc3sig, gc4 => gc4sig, c1_2 => c12sig,
    c2_2 => c22sig, c3_2 => c32sig, c4_2 => c42sig, gc1_2 => gc12sig,
    gc2_2 => gc22sig, gc3_2 => gc32sig, gc4_2 => gc42sig
);
```

The signals that connect the instance *Infer\_type\_2* to the instance *trkm* are

```
signal c1sig, c2sig, c3sig, c4sig : std_logic_vector (m-1 downto 0);
signal gc1sig, gc2sig, gc3sig, gc4sig : std_logic_vector (7 downto 0);
signal c12sig, c22sig, c32sig, c42sig : std_logic_vector (m-1 downto 0);
signal gc12sig, gc22sig, gc32sig, gc42sig :std_logic_vector (7 downto 0);
```

4. The last component *defit2* corresponds to the defuzzifier stage of the T2FLC. It has two inputs and one output.

```
component defit2 is
    Port ( yl, yr : in std_logic_vector (n-1 downto 0);
           y : out std_logic_vector (n-1 downto 0));
end component;
```

This component is instantiated with the name *dfit2* as follows,

```
dfit2 : defit2 port map(yl => ylsig, yr => yrsig, y => y);
```

We did not define any signal for the port *y* since it can be connected directly to the entity of design *FT2KM*. The instances *trkm* and *dfit2* are connected using the following signals,

```
signal ylsig, yrsig : std_logic_vector (n-1 downto 0);
```

This approach of implementing an **IT2FC** provides the faster response. The whole process consisting of fuzzification, inference, type reduction, and defuzzification is achieved in four

clock cycles, which for a Spartan family implementation using a 50 MHz clock represents  $80 \times 10^{-9}$  s, and for a Virtex 5 **FPGA**-based system is  $40 \times 10^{-9}$  s.

## 76.6 Developing of **IT2FC** Coprocessors

The use of **IT2FC** embedded into an **FPGA** can certainly be the option that offers the best performance and flexibility. As we shall see, the best performance can be obtained when the embedded FC is used as standalone system. Unfortunately, this gain in performance can present some drawbacks; for example, for people who were not involved in the design process of the controller or who are not familiar with **VHDL** codification, or the code owners simply want to keep the codification secret. All these obstacles can be overcome by the use of **IP** cores. Next, we shall explain two methods of implementing **IT2FC** as coprocessors.

### 76.6.1 Integrating the **IT2FC** Through Internal Ports

In Fig. 76.9, we show a control system that integrates the FT2KM design entity embedded into the Actel Fusion **FPGA** [76.62] as a coprocessor of an ARM processor. This **FPGA** allows incorporating the soft processor ARM Cortex, as well as other **IP** cores to make a custom configuration. The embedded system contains the ARM processor, two memory blocks, timers, interrupt controller (**IC**), a Universal Asynchronous Receiver/Transmitter (**UART**) serial port, IIC, pulse width modulator/tachometer block, and a general-purpose input/output interface (**GPIO**) interfacing the FT2KM block. All the factory embedded components are soft **IP** cores. The FT2KM is a **VHDL** module that together with the **GPIO** form the Ft2km\_core soft coprocessor, handled as an **IP** core; however, in this case, it is necessary to have the **VHDL** code. In the system, the **IT2** coprocessor is composed of the **GPIO** and the FT2KM modules, forming the Ft2km\_core. In the system, moreover, are a DC motor with a high-resolution quadrature optical encoder, the system's power supply, an H-bridge for power direction, a personal computer, and a digital display.

The Ft2km\_core has six inputs and two outputs. The inputs are *error*, *c.error*, *ce*, *rst*, *w*, and *clk*. The 8-bit inputs *error* and *c.error* are the controller input for the error and change of error values. *ce* input is used to en-

able/disable the fuzzy controller, the input *rst* restores all the internal registers of the **IT2FC**, and the input *w* allows starting a fuzzy inference cycle. The outputs are *out*, and *IRQ/RDY*; the first one is the crisp output value, which is 8-bit wide. *IRQ/RDY* is produced when the output data corresponding to the respective input is ready to be read. *IRQ* is a pulse used to request an interrupt, whereas, *RDY* is a signal that can be programmed to be active in high or low binary logic level, indicating that valid output was produced; this last signal can be used in a polling mode. In Fig. 76.9 we used only 1 bit for the *IRQ/RDY* signal, at the moment of designing the system the designer will have to decide on one method. It is possible to use both, modifying the logic or separating the signal and adding an extra 1-bit output.

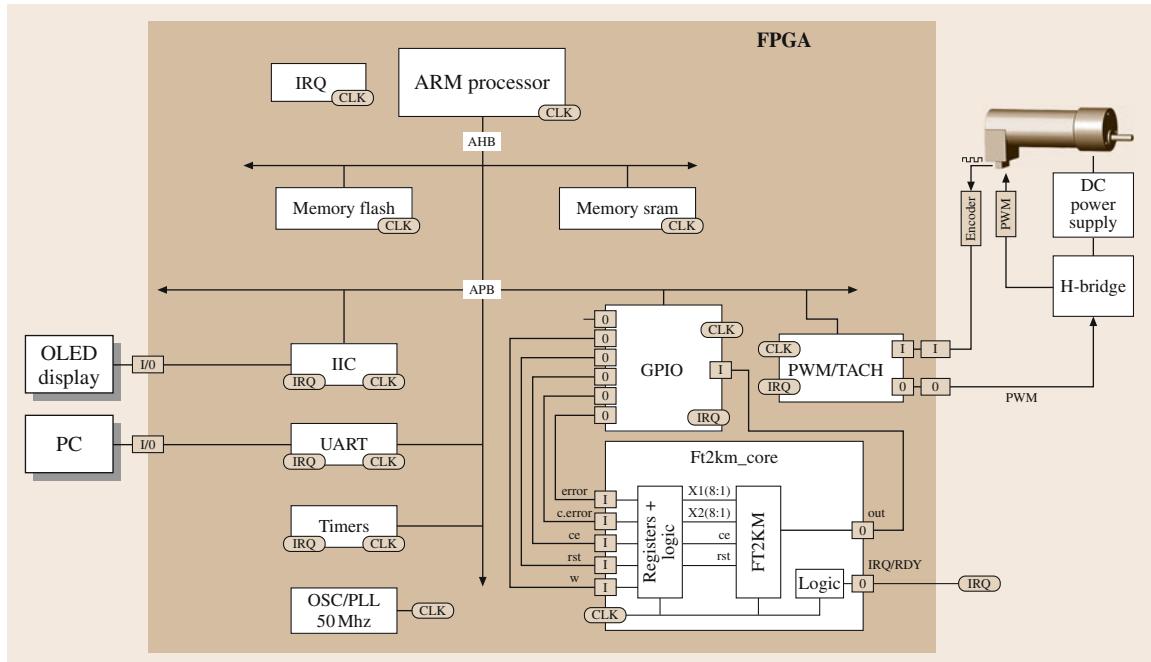

The **GPIO IP** has two 32 bit wide ports, one for input (reading bus) and one for output (write bus). The output bus connects the **GPIO IP** to the ARM cortex using the 32 bit bus APB. The input bus connects the **IT2FC IP** to the **GPIO IP**. The ARM cortex uses the Ft2km\_core as a coprocessor.

### 76.6.2 Development of **IP** Cores

In Sect. 76.6.1, we showed how to integrate the fuzzy coprocessor through an input/output port, i.e., the **IP GPIO**. We also commented on the existence of **IP** cores such as the **UART** and the timers that are connected directly to the system bus as in any microcontroller system with integrated peripherals. In this section, we shall show how to implement an **IT2FC** connected to the system bus to obtain an **IT2FC IP** core integrated to the system architecture. The procedure is basically the same for any **FPGA** of the Xilinx family. We worked with the Spartan 6 and Virtex 5, so the Xilinx **ISE** Design Suite was used.

The whole process to start an application that includes a microprocessor and a coprocessor can be broadly divided into three steps:

1. Design and implement the design entity that will be integrated as an **IP** core in further steps, then follows

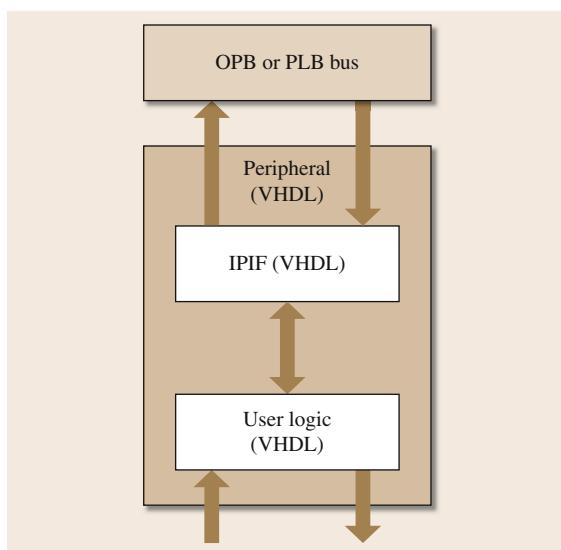

**Fig. 76.9** A coprocessor implemented into the Actel Fusion **FPGA**. The system has an ARM processor, the **IT2FC** coprocessor implemented through the general-purpose input/output port, and some peripherals

the development flow explained in Sect. 76.4.2. In our case, the design entity is **FT2KM**.

2. Create the basic embedded microcontroller system tailored for our application. We already know the kind and amount of memory that we will need, as

well as the peripherals. This step is achieved as follows: we create the microprocessor system using the base system builder (**BSB**) of the Xilinx Platform Studio (**XPS**) software. The system contains a Microblaze softcore, 16 KB of local memory, the data controller bus (**dlimb\_cntlr**), and the instruction controller bus (**ilmb\_cntlr**).

3. Create the **IP** core, which should contain the desired design entity, in our case the **FT2KM**. This step is achieved using the *Import Peripheral Wizard* found in the Hardware option in the **XPS**. The idea is to connect the FTKM design entity to the processor local bus (**PLB** V4.6) through three registers, one for each input (two registers) and one for the output. Upon the completion, this tool will create synthesizable **HDL** file (**ft2km\_core**) that implements the intellectual property interface (**IPIF**)

**Fig. 76.10** IP Core implementation of a user defined peripheral. The **IT2FC** coprocessor is implemented into the user logic module. This module achieves communication with the rest of the system through the **PLB** or the on-chip peripheral bus **OPB**. For a static coprocessor, use the **PLB**. For an implementation in the reconfigurable region, use the **OPB** ◀

services required and a stub *user\_logic\_module*. These two modules are shown in Fig. 76.10. The **IPIF** connects the user logic module to the system bus using the **OPB** or the **PLB** bus or to the on-chip peripheral bus (**OPB**). At this stage, we will need to use the **ISE Project Navigator (ISE)** software to integrate to the *user\_logic\_module* all the required files that implement the FT2KM design entity. Edit the *User.Logic.I.vhd* file to define the FT2KM component and signals. Open the *fik2\_core.vhd* file and create the *fik2\_core* entity and user logic. Synthesize the **HDL** code and exit

**ISE**. Return to the XSP and add the FTK2\_core IP to the embedded system, connect the new **IP** core to the *mb\_plb* bus system and generate address. Figure 76.10 shows the **IT2FC IP** core; the **IPIF** consists of the **PLB** V4.6 bus controller that provides the necessary signals to interface the **IP** core to the embedded soft core bus system.

4. Design the drivers (software) to handle this design entity as a peripheral.
5. Design the application software to use the design entity.

## 76.7 Implementing a GA in an FPGA

In essence, evolution is a two-step process of random variation and selection of a population of individuals that responds with a collection of behaviors to the environment. Selection tends to eliminate those individuals that do not demonstrate an appropriate behavior. The survivors reproduce and combine their features to obtain better offspring. In replication random mutation always occurs, which introduces novel behavioral characteristics. The evolution process optimizes behavior and this is a desirable characteristic for a learning system. Although the term *evolutionary computation* dates back to 1991, the field has decades of history, *genetic algorithms* being one avenue of investigation in simulated evolution [76.63]. **GAs** are family of computational models, which imitates the principles of natural evolution. For consistency they adopt biological terminology to describe operations. There are six main steps of a **GA**: population initialization, evaluation of candidates using a fitness function, selection, crossover, and termination judgment, as is shown in Algorithm 76.1. The first step is to decide how to code a solution to the problem that we want to optimize; hence, each individual is represented using a chromosome that contains the parameters. Common encoding of solutions are binary, integer, and real value. In binary encoding, every chromosome is a string of bits. In real-value encoding, every chromosome is a string than can contain one or several parameters encoded as real numbers. Algorithm 76.1 starts initializing a population with random solutions, and then each individual of the population is evaluated using a fitness function, which is selected according to the optimization goals. For example, for tuning a controller it may be enough to check if the actual output controller is minimizing errors between the target and

the reference. However, one or more complex fitness functions can be designed in order to carry out the control goal. In steps 3 to 5 the genetic operations are applied, i.e., selection, crossover (recombination), and mutation. In step 6, the termination criteria are checked, stopping the procedure if such criteria have been fulfilled.

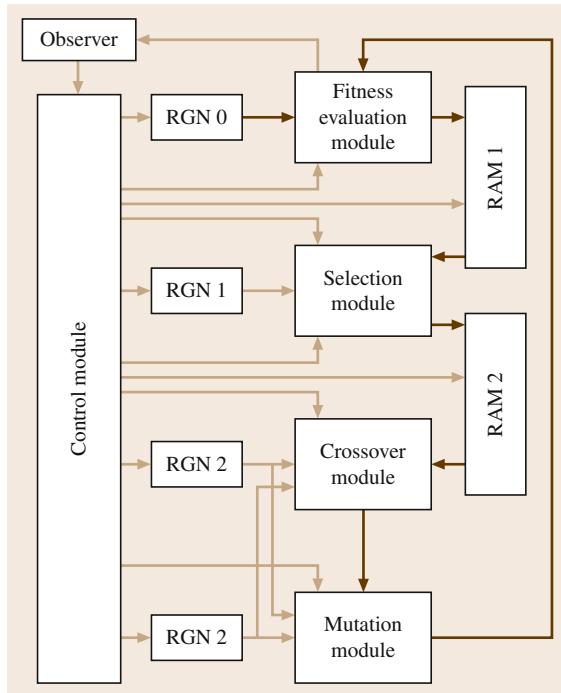

### Algorithm 76.1 General scheme of a GA

```

initialize population with random candidate solutions
evaluate each candidate
repeat
  select parents
  recombine pairs of parents
  mutate the resulting offspring
  evaluate new candidates
  select individuals for the next generation
until termination condition is satisfied

```

In this work, we have chosen work a **GA** to evolve the **IT2FC**. However, the ideas exposed here are valid for most evolutionary and natural computing methods. So, there are two methods to implement any evolutionary algorithm. One is based on executing software written using a computer language such as C/C++, similarly as with a desktop computer. The second method is based on designing specialized hardware using a **HDL**. Both have advantages and disadvantages; the first method is the easier method since there is much information about coding using a high level language for different **EAs**. However, this solution may have similar limitations for real-time systems since they are slower than hardware implementations by at least

**Fig. 76.11** High-level view of the structure of a **GA** for **FPGA** implementation

a factor of magnitude of five. On the other hand, state machine hardware-based designs are more complex to implement and use. In this section we shall present a small overview of both methods.

### 76.7.1 GA Software Based Implementations

It is well known that a **GA** can run in parallel, taking advantage of the two types of known parallelism: data and control parallelism. Data parallelism refers to executing one process over several instances of the **EA**, while control parallelism works with separate instances.

Coarse-grained parallelism and fine-grained parallelism are two methods often associated with the use of **EA** in parallel. The use of both methods is called a hybrid approach. Coarse-grained parallelism entails the **EA** cores to work in conjunction to solve a problem. The nodes swap individuals of their population with another node running the same problem. The cores

can exchange individuals with each other to improve diversity. The amount of information, frequency of exchange, direction, data pattern, etc., are factors that can affect the efficiency of this approach.

In fine-grained parallelism, the approach is to share mating partners instead of populations. The members of populations across the parallel cores select to mate their fittest members with the fittest found in a neighboring node's population. Then, the offspring of the selected individuals are distributed. The distribution of this next generation can go to one of the parents' populations, both parents' population, or all cores' populations, based on the means of distribution.

Figure 76.4 shows a six-core architecture design for the Virtex 5. Here, we can make fine or coarse-grained implementations of an **EA**. For example, for coarse-grained implementation, the island model with one processor per island can be used.

### 76.7.2 GA Hardware Implementations

Figure 76.11 shows a high-level view of the architecture of a **GA** for hardware implementation. The system has eight basic modules: selection module, crossover module, mutation module, fitness evaluation module, control module, observer module, four random generation number (**RGN**) modules, and two random access memory modules.

The control module is a Mealy state machine designed to feed all other modules with the necessary control signals to synchronize the algorithm execution. The selection module can have any existing method of selection, for example the Roulette Wheel Selection Algorithm. This method picks the genes of the parents of the current population, and the parents are processed to create new individuals. At the current generation, the crossover and genetic modules achieve the corresponding genetic operation on the selected parents. The fitness evaluation module computes the fitness of each offspring and applies elitism to the population. The observer module determines the stopping criterion and observes its fulfillment. RNGs are indispensable to provide the randomness that **EAs** require. Additionally, **RAM** 1 is necessary to store the current population and **RAM** 2 to store the selected parents of each generation.

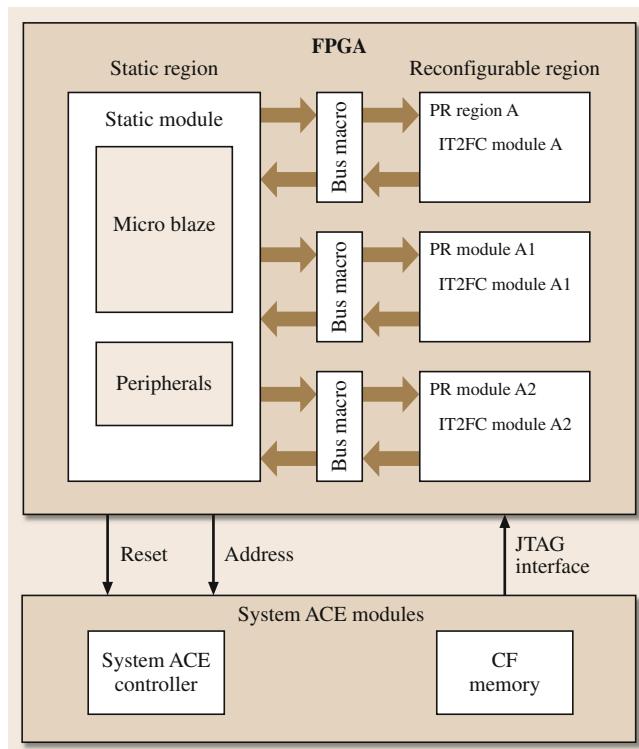

## 76.8 Evolving Fuzzy Controllers

In Sect. 76.1 the general structure of an **EFRBS** was presented. It was mentioned that the common denominator in most learning systems is their capability of making structural changes to themselves over time to improve their performance for defined tasks. It also was mentioned that the two classical approaches for fuzzy learning systems are the Michigan and Pittsburgh approaches, and there exist newer proposals with the same target. Although to program a learning system in a computer using high-level language, such as C/C++, requires some skill, system knowledge, and experimentation, there are no technical problems with achieving a system with such characteristics. This can be also true for hardware implementation, if the **EFRBS** was developed in C/C++ and executed by a hard or soft processor such as PowerPC or Microblaze, it is similarly as it is done in a computer. How to develop a coproces-

sor was explained in Sect. 76.6. The coprocessor was developed in the FPGA's static (base) region, which cannot be changed during a partial reconfiguration process. Therefore, such coprocessors cannot suffer any structural change. Achieving an **EFRBS** in hardware is quite different to achieving it using high-level language, because it is more difficult to change the circuitry than to modify programming lines.

**FPGAs** are reprogrammable devices that need a design methodology to be successfully used as reconfigurable devices. Since there are several vendors with different architectures, the methodology usually change from vendor to vendor and devices. For the Xilinx **FPGAs** the configuration memory is volatile, so, it needs to be configured every time that it is powered by uploading the configuration data known as *bitstream*. Configuring **FPGA** this way is not useful for many applications that need to change its behavior while they still working online. A solution to overcome such a limitation is to use partial reconfiguration, which splits the **FPGA** into two kinds of regions. The static (base) region is the portion of the design that does not change during partial reconfiguration, it may include logic that controls the partial reconfiguration process. In other words, partial reconfiguration (**PR**) is the ability to reconfigure select areas of an **FPGA** any time after its initial configuration [76.64]. It can be divided into two groups: dynamic partial reconfiguration (**DPR**) and static partial reconfiguration (**SPR**). **DPR** is also known as active partial reconfiguration. It allows changing a part of the device while the rest of the **FPGA** is still running. **DPR** is accomplished to allow the **FPGA** to adapt to changing algorithms and enhance performance, or for critical missions that cannot be disrupted while some subsystems are being defined. On the other hand, in **SPR** the static section of the **FPGA** needs to be stopped, so auto-reconfiguration is impossible (Fig. 76.12).

For Xilinx **FPGAs**, there are basically three ways to achieve **DPR** for devices that support this feature. The two basic styles are difference-based partial reconfiguration and module-based partial reconfiguration. The first one can be used to achieve small changes to the design, the partial bitstream only contains information about differences between the current design structure that resides in the **FPGA** and the new content of the **FPGA**. Since the bitstream differences are usually small, the changes can be made very quickly. Module-based partial reconfiguration is useful for reconfiguring large blocks of logic using modular design

**Fig. 76.12** The **FPGA** is divided into two regions: static and reconfigurable. The soft processor and peripherals are in the static region. Different fuzzy controller architectures are in the reconfigurable region. The bus macro are fixed data paths for signals going between a reconfigurable module and another module

concepts. The third style is also based on modular design but is more flexible and less restrictive. This new style was introduced by Xilinx in 2006 and it is known as early access partial reconfiguration (**EAPR**) [76.65, 66]. There are two key differences between the design flow **EAPR** and the module-based one. (1) In the **EAPR** flow the shape and size of partially reconfigurable regions (**PRRs**) can be defined by the user. Each **PRR** has at least one, and usually multiple, partially reconfigurable modules (**PRMs**) that can be loaded into the **PRR**. (2) For modules that communicate with each other, a special bus macro allows signals to cross over a partial reconfiguration boundary. This is an important consideration, since without this feature intermodule communication would not be feasible, as it is impossible to guarantee routing between modules. The bus macro provides a fixed *bus* of inter-design communication. Each time partial reconfiguration is performed, the bus macro is used to establish unchanging routing channels between modules, guaranteeing correct connections [76.65].

An important core that enables embedded microprocessors such as MicroBlaze and PowerPC to achieve reconfiguration at run time is **HWICAP** (hardware internal configuration access point) for the **OPB**. The **HWICAP** allows the processors to read and write the **FPGA** configuration memory through the **ICAP** (internal configuration access point). Basically it allows writing and reading the configurable logic block (**CLB**) look-up table (**LUT**) of the **FPGA**.

The process to achieve reconfigurable computing with application to **IT2FC** will be explained with more detail in Sect. 76.8.2. Moreover, how to evolve an **IT2FC** embedded into an **FPGA**, whether it resides in the static or in the reconfigurable region, will be also explained in therein.

### 76.8.1 EAPR Flow for Changing the Controller Structure

Figure 76.12 shows the basic idea of using **EAPR** flow for reconfigurable computing to change from one **IT2FC** structure to a different one. In this figure the Microblaze soft processor can evaluate each controller structure according to single or multiobjective criteria. The processor communicates with a **PR** region using the bus macro, which provides a means of locking the routing between the **PRM** and the base design. The system can achieve fast reconfiguration operations since partial bitstream are transferred between the **FPGA** and the compact flash memory (**CF**) where bitstreams are stored.

In general, the **EAPR** design flow is as follows [76.64, 67, 68]:

1. Hardware description language design and synthesis. The first steps in the **EAPR** design flow are very similar to the standard modular design flow. We can summarize this in three steps:
  - (a) Top-level design. In this step, the design description must only contain black-box instantiations of lower-level modules. Top-level design must contain: I/O instantiations, clock primitives instantiations, static module instantiations, **PR** module instantiations, signal declarations, and bus macro instantiations, since all non-global signals between the static design and the **PRMs** must pass through a bus macro.
  - (b) Base design. Here, the static modules of the system contain logic that will remain constant during reconfiguration. This step is very similar to the design flow explained in Sect. 76.4.2. However, the designer must consider input and output assignment rules for **PR**.
  - (c) **PRM** design. Similarly to static modules, **PR** modules must not include global clock signals either, but may use those from top-level modules. When designing multiple **PRMs** to take advantage of the same reconfigurable area, for each module, the component name and port configuration must match the reconfigurable module instantiation of the top-level module.
2. Set design constraints. In this step, we need to place constraints in the design for place and route (**PAR**). The constraints included are: area group, reconfiguration mode, timing constraint, and location constraints. The area group constraint specifies which modules in the top-level module are static and which are reconfigurable. Each module instantiated by the top-level module is assigned to a group. The reconfiguration mode constraint is only applied to the reconfigurable group, which specifies that the group is reconfigurable. Location constraints must be set for all pins, clocking primitives, and bus macros in top-level design. Bus macros must be located so that they straddle the boundary between the **PR** region and the base design.
3. Implement base design. Before the implementation of the static modules, the top level is translated to ensure that the constraints file has been created properly. The information generated by implementing the base design is used for the **PRM** implemen-

tation step. Base design implementation follows three steps: translate, map, and **PAR**.

4. Implement **PRMs**. Each of the **PRMs** must be implemented separately within its own directory, and follows base design implementation steps: i.e., translate, map and **PAR**.
5. Merge. The final step in the partial reconfiguration flow is to merge the top level, base, and **PRMs**. During the merge step, a complete design is built from the base design and each **PRM**. In this step, many partial bitstreams for each **PRM** and initial full bitstreams are created to configure the **FPGA**.

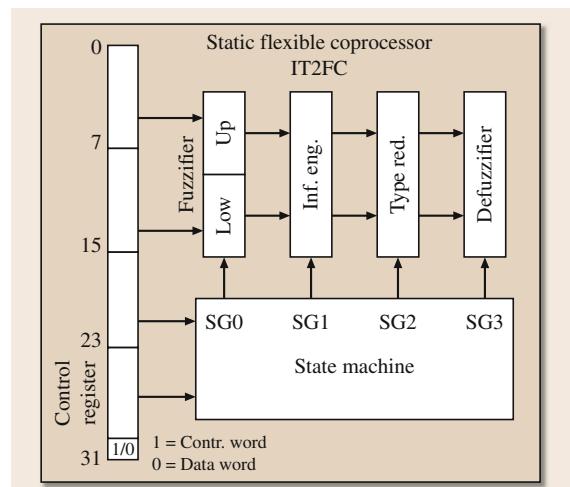

Partial dynamic reconfigurable computing allows us to achieve online reconfiguration. By selecting a certain bitstream is possible to change the full controller structure, or any of the stages (fuzzification, inference engine, type reduction, and defuzzification), as well as any individual section of each stage, for example, different membership functions for the fuzzification stage, etc. However, we need to have all the reconfigurable modules previously synthesized because they are loaded using partial bitstreams. Therefore, to have the capability to evolve reconfigurable modules we need to provide them with a control register (**CR**) to change the desired parameters.

Next, a flexible coprocessor (**FlexCo**) prototype of an **IT2FC** (**FlexCo IT2FC**) that can be implemented either in the static region as well as in the **PR** is presented.

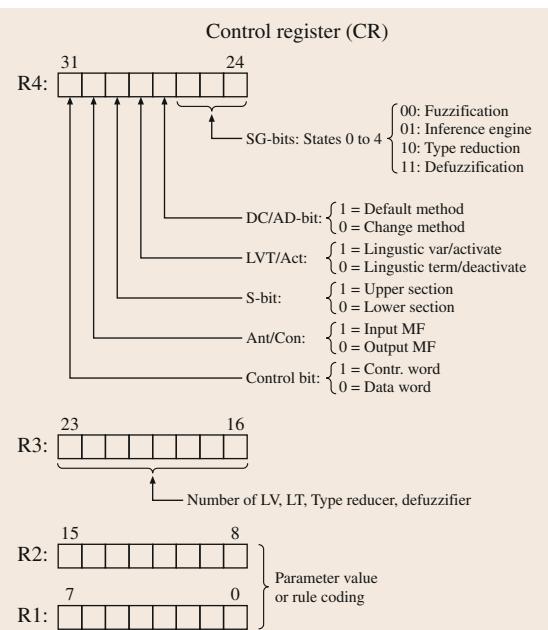

### 76.8.2 Flexible Coprocessor Prototype of an **IT2FC**

Figure 76.13 illustrates the **FlexCo IT2FC**, which contains the four stages (fuzzification, inference engine, type reduction, and defuzzification). They are connected depending on the target region, to the **PLB** or to the **OPB** through a 32 bits command register (**CR**), which is formed by four 8 bit registers named R1 to R4 (Fig. 76.14). The parameters of each stage can be changed by the programmer since they are not static as they were defined previously for the **FT2KM** (Sect. 76.5). Now, they are volatile registers connected through signals to save parameter values. The processor (MicroBlaze) can send through the **PLB** or the **OPB**, two kinds of commands to the **CR**: control words (**CWs**) and data words (**DWs**). The state machine of the **FlexCo IT2FC** interprets the command.

Figure 76.14 illustrates the **CR** coding for static and reconfigurable FC. This register is used to perform

**Fig. 76.13** Flexible coprocessor proposal of an **IT2FC** for the static region

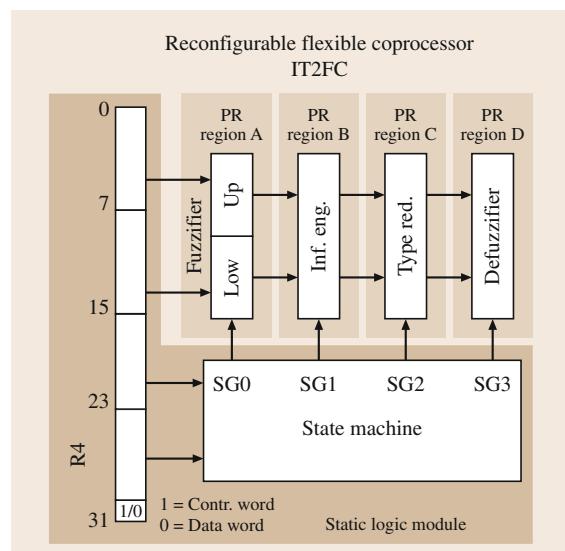

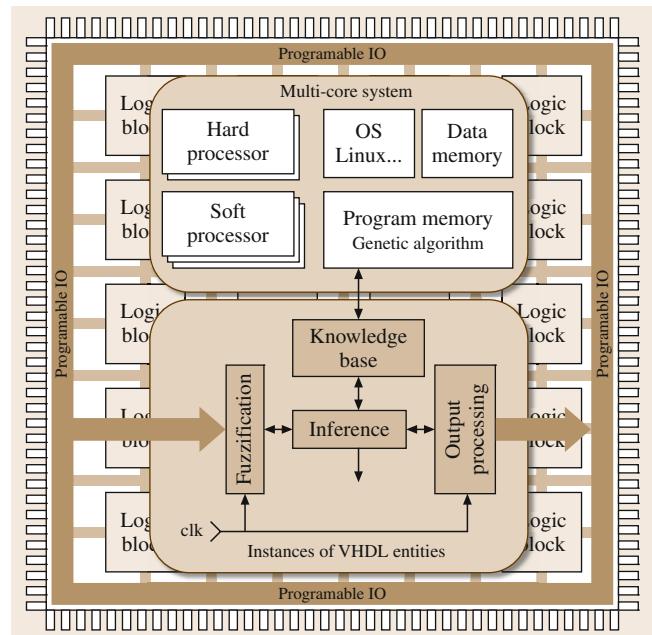

**Fig. 76.14** The control register is used for both styles of implementation, in the static region or in the reconfigurable region

parameter modification in both modes, static and reconfigurable. In general, bit 7 of R4 is used to differentiate between a **CW** or a **DW**, 1 means a **CW**, whereas 0 means a **DW**. The StaGe bits (SG-bits) serves to identify the **IT2FC** stage that is to be modified.

**Fig. 76.15** In the static region of the **FPGA** a multiprocessor system (**MPS**) with operating system. The **GA** resides in the program memory, it is executed by the **MPS**. The **IT2FC** may be implemented in the reconfigurable region, Fig. 76.16, or in the static region, Fig. 76.13 ►

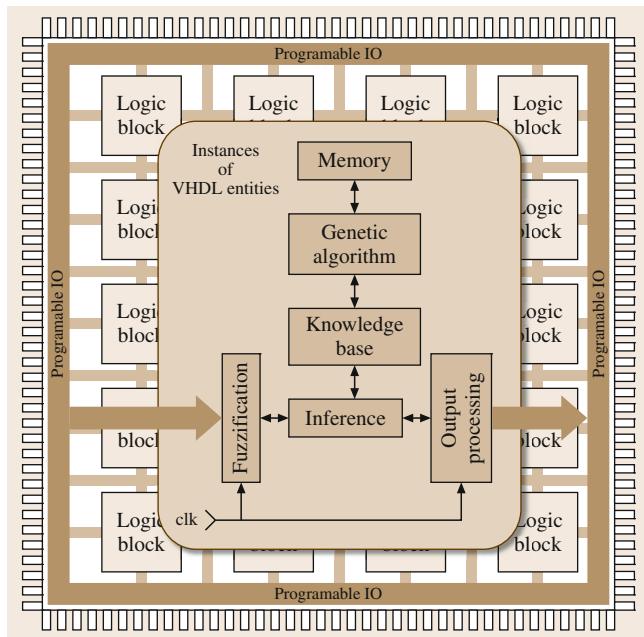

- **SG-bits = 00:** The fuzzification stage has been chosen, then it is necessary to set the bit Ant/Con to 1 to indicate that the antecedent **MFs** are going to be modified. With the section-bit (**S-bit**) we indicate which part of the **FOU** (upper or lower) will be modified. The bit linguistic-variable-term/active (**LVT/Active**) is to indicate whether we want to modify a linguistic variable (**LV**) or the linguistic term (**LT**), the **Act** option is for the inference engine (**IE**). In accordance to the **LV/LT** bit value, in the register R3 we set the number of the **LV** or the **LT** that will be changed. Finally, with registers R1 and R2, the parameter value of the **LV** or the **LT** is given, R1 is the least significant byte.
- **SG-bits = 01:** With this setting, the state machine identifies that the **IE** will be modified. It works in conjunction with Ant/Con, **S-bit**, and the registers R1, R2, and R3. Set a 0 value in the Ant/Con bit to change the consequent parameters of a Mamdani inference system, in **S-bit** choose the upper or lower **MF**, using R3 indicate the number of **MF**, and with R1 and R2 set the corresponding value or static implementation. It is possible to activate and deactivate rules using the bit **LVT/Active**. With bit dynamic change/activate-deactivate (**DC/AD**), it is possible to change the combination of antecedents and consequents of a specific rule provided that we have made this part flexible by using registers. For an implementation in the reconfigurable region, it is possible to add or remove rules. These two features need to work in conjunction with registers R1, R2, and R3.
- **SG-bits = 10:** This selection is to modify the type reduction stage. It is possible to have more than one type reducer. By setting the **DC/AD-bit** to 1, we indicate that we wish to change the method at running time without the necessity of achieving a reconfiguration process that implies uploading partial bitstreams. The methods can be selected using register R3. By using a **DC/AD-bit** equal to 0 and **LVT/Act** equal to 0, in combination with registers R1 to R3 we can indicate that we wish to change the preloaded values that the **KM**-algorithm needs to achieve the **TR**.

**Fig. 76.16** Flexible coprocessor proposal of an **IT2FC** for the reconfigurable region

- **SG-bits = 11:** Similarly to the type reduction stage, we can change the defuzzifier at running time.

With respect to the type reducer and defuzzification stages, we give the option to have more than one module, which has the advantage of making the process

**Fig. 76.17** This design may be implemented in both regions to have a dynamic reconfigurable system. For a static implementation, the system must have registers for all the variable parameters to make possible to change their values, Fig. 76.13

easier and possible for static designs, but the disadvantage is that the design will consume more macrocells, increasing the cost of the required **FPGAs**, boards, and power consumption. Next, we will explain the implementation of the **FlexCo IT2FC** for the static region and the reconfigurable region.

#### Implementing the **FlexCo IT2FC** on the Static Region

The **IT2FC** of is connected to the **PLB**. Although the controller structure is static, this system can be evolved for tuning and learning because it is possible to achieve parametric modifications to all the **IT2FC** stages. Figure 76.13 shows the architecture of this system and Fig. 76.15 a conceptual model of the possible implementation.

#### Implementing the **FlexCo IT2FC** on the PR

Figure 76.16 illustrates a more flexible architecture for **FlexCo IT2FC**. The **IT2FC** is implemented in the reconfigurable region, using a partially reconfigurable region (**PRR**) for each stage. This is convenient since each region can have multiple modules that can be swapped

in and out of the device on the fly. This is the most recommended method to achieve the evolving **IT2FC** since it is more flexible. One disadvantage is that at running time it is slower than the static implementation because more logic circuits are incorporated.

Figure 76.17 is an evolutive standalone system; as it was mentioned, the **IT2FC** and the **GA** can be in the static or in the reconfigurable region.

#### 76.8.3 Conclusion and Further Reading

**FPGAs** combine the best parts of **ASICs** and processor-based systems, since they do not require high volumes to justify making a custom design. Moreover, they also provide the flexibility of software, running on a processor-based system, without being limited by the number of cores available. They are one of the best options to parallelize a system since they are parallel in nature. In an **IT2FC**, a typical whole **T2**-inference, computed using an industrial computer equipped with a quad-core processor, lasts about  $18 \times 10^{-3}$  s. A whole **IT2FC** (fuzzification, inference, **KM**-type reducer, and defuzzification) lasts only four clock cycles, which for a Spartan implementation using a 50 MHz clock represents  $80 \times 10^{-9}$  s, and for a Virtex 5 **FPGA**-based system represents  $40 \times 10^{-9}$  s. For the Spartan family the typical implementation speedup is 225 000, whereas for the Virtex 5 it is 450 000. Using a pipeline architecture, the speedup of the whole **IT2** process can be obtained in just one clock cycle, so using the same criteria to compare, the speedup for Spartan is 90 000 and 2 400 000 for Virtex. Reported speedups of **GAs** implemented into an **FPGA**, are at least 5 times higher than in a computer system. For all these reasons, **FPGAs** are suitable devices for embedding evolving fuzzy logic controllers, especially the **IT2FC**, since they are computationally expensive. There are some drawbacks with the use of this technology, mostly with respect to the need to have a highly experienced development team because its implementation complexity. Achieving an evolving intelligent system using reconfigurable computing is not as direct as it is using a computer system. It requires the knowledge of **FPGA** architectures, **VHDL** coding, soft processor implementation, the development of coprocessors, high-level languages, and reconfigurable computing bases. Therefore, people interested in achieving such implementations require expertise in the above fields, and further reading must focus on these topics, **FPGA** vendor manuals and white papers, as well as papers and books on reconfigurable computing.

# 77. Multiobjective Genetic Fuzzy Systems

Hisao Ishibuchi, Yusuke Nojima

This chapter explains evolutionary multiobjective design of fuzzy rule-based systems in comparison with single-objective design. Evolutionary algorithms have been used in many studies on fuzzy system design for rule generation, rule selection, input selection, fuzzy partition, and membership function tuning. Those studies are referred to as genetic fuzzy systems because genetic algorithms have been mainly used as evolutionary algorithms. In many studies on genetic fuzzy systems, the accuracy of fuzzy rule-based systems is maximized. However, accuracy maximization often leads to the deterioration in the interpretability of fuzzy rule-based systems due to the increase in their complexity. Thus, multiobjective genetic algorithms were used in some studies to maximize not only the accuracy of fuzzy rule-based systems but also their interpretability. Those studies, which can be viewed as a subset of genetic fuzzy system studies, are referred to as multiobjective genetic fuzzy systems (**MoGFS**). A number of fuzzy rule-based systems with different complexities are obtained along the interpretability–accuracy tradeoff curve. One extreme of the tradeoff curve is a simple highly interpretable fuzzy rule-based system with low accuracy while the other extreme is a complicated highly accurate one with low interpretability. In **MoGFS**, multiple accuracy measures such as a true positive rate and a true negative rate can be simultaneously used as separate objectives. Multiple interpretability measures can also be simultaneously used in **MoGFS**.

## 77.1 Fuzzy System Design

A fuzzy rule-based system is a set of fuzzy rules, which has been successfully used as a nonlinear controller in various real-world applications. The basic structure of fuzzy rules for multi-input and single-output fuzzy con-

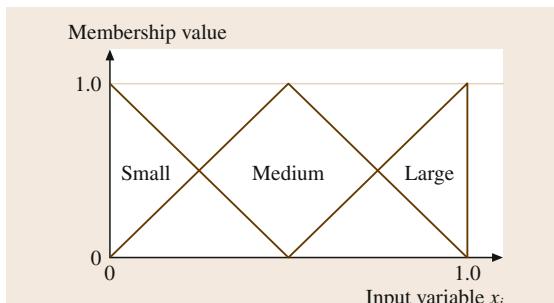

trol can be written as follows [77.1–3]

$$\text{Rule } R_q : \text{If } x_1 \text{ is } A_{q1} \text{ and } \dots \text{ and } x_n \text{ is } A_{qn} \quad (77.1) \\ \text{then } y \text{ is } B_q ,$$

where  $q$  is a rule index,  $R_q$  is the label of the  $q$ th rule,  $n$  is the number of input variables,  $x_i$  is the  $i$ th input variable ( $i = 1, 2, \dots, n$ ),  $A_{qi}$  is an antecedent fuzzy set for the  $i$ th input variable  $x_i$ ,  $y$  is an output variable, and  $B_q$  is a consequent fuzzy set for the output variable  $y$ . The antecedent and consequent fuzzy sets  $A_{qi}$  and  $B_q$  are specified by their membership functions  $\mu_{A_{qi}}(x_i)$  and  $\mu_{B_q}(y)$ , respectively. Examples of antecedent fuzzy sets are shown in Fig. 77.1 where the domain interval  $[0, 1]$  of the input variable  $x_i$  is partitioned into three fuzzy sets *small*, *medium*, and *large* with triangular membership functions.

Fuzzy rules of the form in (77.1) are based on the concept of linguistic variables by Zadeh [77.4–6]. According to Zadeh [77.4–6], a fuzzy set with a linguistic meaning such as *small* and *large* is referred to as a linguistic value while a variable with linguistic values is called a linguistic variable. For example, in Fig. 77.1, the three fuzzy sets are linguistic values while  $x_i$  is a linguistic variable. In our daily life, we almost always use linguistic variables and linguistic values. When we say *your car is fast but my car is slow*, the speed of cars is a linguistic variable while *fast* and *slow* are linguistic values. When we say *it is hot today*, the temperature is a linguistic variable while *hot* is a linguistic value. Of course, we use those linguistic values without explicitly specifying their meanings by membership functions. However, we have our own vague definitions of those linguistic values, which may be approximately represented by membership functions.

The main advantage of fuzzy rule-based systems over other nonlinear models such as multilayer feedforward neural networks is their linguistic interpretability. In Fig. 77.2, we show a two-input and single-output fuzzy rule-based system with the following nine fuzzy

**Fig. 77.1** Three antecedent fuzzy sets *small*, *medium*, and *large*

rules

Rule  $R_1$  : If  $x_1$  is *small* and  $x_2$  is *small*  
then  $y$  is *medium*,

Rule  $R_2$  : If  $x_1$  is *small* and  $x_2$  is *medium*  
then  $y$  is *small*,

Rule  $R_3$  : If  $x_1$  is *small* and  $x_2$  is *large*  
then  $y$  is *medium*,

Rule  $R_4$  : If  $x_1$  is *medium* and  $x_2$  is *small*  
then  $y$  is *small*,

Rule  $R_5$  : If  $x_1$  is *medium* and  $x_2$  is *medium*  
then  $y$  is *medium*,

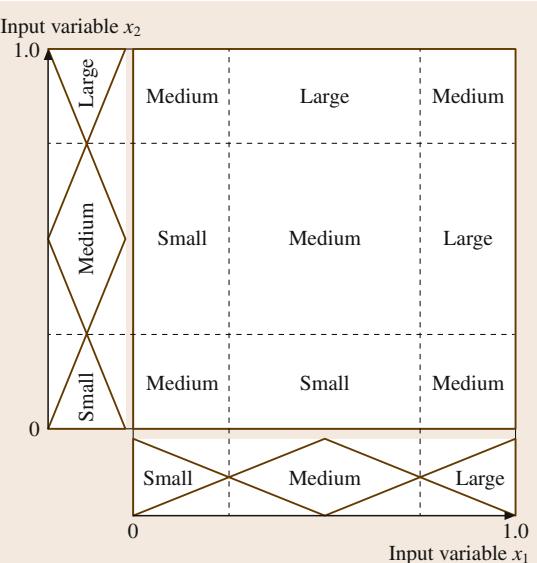

Rule  $R_6$  : If  $x_1$  is *medium* and  $x_2$  is *large*  
then  $y$  is *large*,

Rule  $R_7$  : If  $x_1$  is *large* and  $x_2$  is *small*  
then  $y$  is *medium*,

Rule  $R_8$  : If  $x_1$  is *large* and  $x_2$  is *medium*  
then  $y$  is *large*,

Rule  $R_9$  : If  $x_1$  is *large* and  $x_2$  is *large*  
then  $y$  is *medium*.

A linguistic value in each cell in Fig. 77.2 shows the consequent fuzzy set of the corresponding fuzzy rule.

**Fig. 77.2** A two-input and single-output fuzzy rule-based system with nine fuzzy rules

For example, *medium* in the bottom-right cell shows the consequent fuzzy set of the fuzzy rule  $R_7$  with the antecedent fuzzy set *large* for  $x_1$  and *small* for  $x_2$ . Let us assume that the consequent fuzzy sets in Fig. 77.2 are defined by the triangular membership functions in Fig. 77.1. Then, we can roughly understand the shape of the two-input and single-output nonlinear function represented by the fuzzy rule-based system in Fig. 77.2 (even when we do not know anything about fuzzy reasoning).

It is easy to linguistically understand the input-output relation of the fuzzy rule-based system in Fig. 77.2. That is, the fuzzy rule-based system in Fig. 77.2 has high interpretability. However, it is difficult to approximate a complicated highly nonlinear function by such a simple  $3 \times 3$  fuzzy rule-based system. More membership functions for the input and output variables may be needed for improving the accuracy of fuzzy rule-based systems. The tuning of each membership function may be also needed. Theoretically, fuzzy rule-based systems are universal approximators of nonlinear functions. This property has been shown for fuzzy rule-based systems [77.7–9] and multilayer feed-forward neural networks [77.10–12]. This means that fuzzy rule-based systems as well as neural networks have high approximation ability of nonlinear functions.

In Fig. 77.3, we show an example of a tuned  $7 \times 7$  fuzzy partition of the two-dimensional input space  $[0, 1] \times [0, 1]$ . We can design a much more ac-

curate fuzzy rule-based system by using such a tuned fuzzy partition than the simple  $3 \times 3$  fuzzy partition in Fig. 77.2. That is, we can say that Fig. 77.3 is a better fuzzy partition than Fig. 77.2 with respect to the accuracy of fuzzy rule-based systems. However, it is very difficult to linguistically interpret each antecedent fuzzy set in Fig. 77.3. In other words, it is very difficult to assign an appropriate linguistic value such as *small* and *large* to each antecedent fuzzy set in Fig. 77.3. Thus, we can say that the fuzzy partition in Fig. 77.3 does not have high linguistic interpretability. That is, Fig. 77.2 is a better fuzzy partition than Fig. 77.3 with respect to the linguistic interpretability of fuzzy rule-based systems. As shown by the comparison between the two fuzzy partitions in Figs. 77.2 and 77.3, accuracy maximization usually conflicts with interpretability maximization in the design of fuzzy rule-based systems.

Let us denote a fuzzy rule-based system by  $S$ . The fuzzy rule-based system  $S$  is a set of fuzzy rules. In fuzzy system design, the accuracy of  $S$  is maximized. The accuracy maximization of  $S$  is usually formulated as the following error minimization

$$\text{Minimize } f(S) = \text{Error}(S), \quad (77.2)$$

where  $f(S)$  is an objective function to be minimized, and  $\text{Error}(S)$  is an error measure.

As shown in Fig. 77.3, the accuracy maximization often leads to a complicated fuzzy rule-based system with low interpretability. Thus, a complexity measure is combined into the objective function in (77.2) as follows [77.13, 14]

$$\text{Minimize } f(S) = w_1 \text{Complexity}(S) + w_2 \text{Error}(S), \quad (77.3)$$

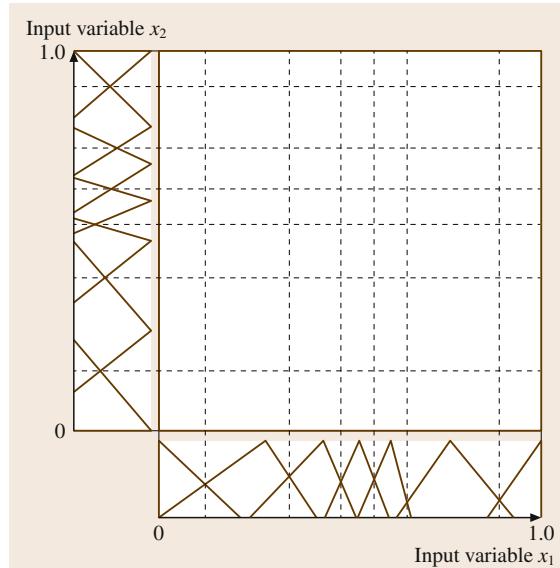

where  $w_1$  and  $w_2$  are nonnegative weights, and  $\text{Complexity}(S)$  is a complexity measure.

In the late 1990s, the idea of multiobjective fuzzy system design [77.15] was proposed where the accuracy maximization and the complexity minimization were handled as separate objectives

$$\begin{aligned} \text{Minimize } f_1(S) &= \text{Complexity}(S) \quad \text{and} \\ f_2(S) &= \text{Error}(S), \end{aligned} \quad (77.4)$$

where  $f_1(S)$  and  $f_2(S)$  are separate objectives to be minimized.

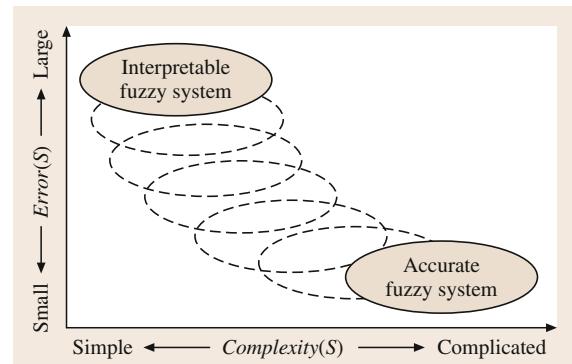

The two-objective optimization problem in (77.4) does not have a single optimal solution that simultaneously optimizes the two objectives  $f_1(S)$  and  $f_2(S)$ .

**Fig. 77.3** A tuned  $7 \times 7$  fuzzy partition

This is because the error minimization increases the complexity of fuzzy rule-based systems (i.e., the optimization of  $f_2(S)$  deteriorates  $f_1(S)$ ). That is, the two objectives  $f_1(S)$  and  $f_2(S)$  in (77.4) are conflicting with each other. In general, a multiobjective optimization problem has a number of nondominated solutions with different tradeoffs among the conflicting objectives. Those solutions are referred to as Pareto optimal solutions. The two-objective optimization problem in (77.4) has a number of nondominated fuzzy rule-based systems with different complexities (Figs. 77.2 and 77.3).

In Fig. 77.4, we illustrate the concept of complexity-accuracy tradeoff in the design of fuzzy rule-based systems. The horizontal axis of Fig. 77.4 shows the values of the complexity measure (i.e.,  $Complexity(S)$ ) while the vertical axis shows the values of the error measure (i.e.,  $Error(S)$ ). Around the top-left corner of Fig. 77.4, we have simple fuzzy rule-based systems with high interpretability and low accuracy (e.g., a simple  $3 \times 3$  fuzzy rule-based system in Fig. 77.2). The improvement in their accuracy increases their complexity. By minimizing the error measure  $Error(S)$ , we have complicated fuzzy rule-based systems with high accuracy and low interpretability around the bottom-right corner of Fig. 77.4 (e.g., a tuned  $7 \times 7$  fuzzy rule-based system in Fig. 77.3). In Fig. 77.4, we have many nondominated fuzzy rule-based systems along the complexity-accuracy tradeoff curve. It should be noted that there exist no fuzzy rule-based systems around the bottom-left corner (i.e., no ideal fuzzy rule-based sys-

**Fig. 77.4** Nondominated fuzzy rule-based systems with different complexity-accuracy tradeoffs

tems with high accuracy and high interpretability). This is because the two objectives in Fig. 77.4 are conflicting with each other.

Since the late 1990s, a number of multiobjective approaches have been proposed for fuzzy system design [77.16–19]. In this chapter, we explain the basic idea of multiobjective fuzzy system design using multi-objective evolutionary algorithms [77.20–22]. Whereas we started with fuzzy rules for fuzzy control in (77.1), our explanations in this chapter are mainly about multiobjective design of fuzzy rule-based systems for pattern classification. This is because early multiobjective approaches were mainly proposed for pattern classification problems.

## 77.2 Accuracy Maximization

In this section, we briefly explain various approaches proposed for improving the accuracy of fuzzy rule-based systems. Those approaches often deteriorate the interpretability.

### 77.2.1 Types of Fuzzy Rules

Fuzzy rules of the form in (77.1) have been successfully used in fuzzy controllers since Mamdani's pioneering work in 1970s [77.23, 24]. Those fuzzy rules have often been called Mamdani-type fuzzy rules or Mamdani fuzzy rules. A heuristic rule generation method of such a fuzzy rule from numerical data was proposed by Wang and Mendel [77.25], which has been used for function approximation.

A well-known idea for improving the approximation ability of fuzzy rules in (77.1) is the use of a linear function instead of a linguistic value in the consequent part

$$\begin{aligned} \text{Rule } R_q : & \text{If } x_1 \text{ is } A_{q1} \text{ and } \dots \text{ and } x_n \text{ is } A_{qn} \\ & \text{then } y = b_{q0} + b_{q1}x_1 + b_{q2}x_2 + \dots + b_{qn}x_n , \end{aligned} \quad (77.5)$$

where  $b_{qi}$  is a real number coefficient ( $i = 0, 1, \dots, n$ ). Fuzzy rules of this type were proposed by Takagi and Sugeno [77.26]. A fuzzy rule-based system with fuzzy rules in (7.5) is referred to as a Takagi–Sugeno model. The use of a linear function instead of a linguistic value

in the consequent part of fuzzy rules clearly increases the accuracy of fuzzy rule-based systems. However, it degrades their interpretability.

The following simplified version of fuzzy rules in Takagi–Sugeno models has been also used

$$\text{Rule } R_q : \text{If } x_1 \text{ is } A_{q1} \text{ and } \dots \text{ and } x_n \text{ is } A_{qn} \quad (77.6) \\ \text{then } y = b_q ,$$

where  $b_q$  is a consequent real number. It is easy to tune the consequent real number of each fuzzy rule. This is the main advantage of simplified fuzzy rules in (77.6). Thus, simplified fuzzy rules have often been used in trainable fuzzy rule-based systems called *neuro-fuzzy systems* [77.27–29]. In those studies, antecedent fuzzy sets as well as consequent real numbers are adjusted in the same manner as the learning of neural networks.

Due to their simple structure, simplified fuzzy rules in (77.6) may have higher interpretability than Takagi–Sugeno fuzzy rules in (77.5). However, it is usually difficult to linguistically interpret a consequent real number. Thus, the linguistic interpretability of simplified fuzzy rules in (77.6) is usually viewed as being limited if compared with Mamdani fuzzy rules with a linguistic value in their consequent part in (77.1).

For pattern classification problems, three types of fuzzy rules have been used in the literature [77.30]. The simplest structure of fuzzy rules for pattern classification problems is as follows

$$\text{Rule } R_q : \text{If } x_1 \text{ is } A_{q1} \text{ and } \dots \text{ and } x_n \text{ is } A_{qn} \quad (77.7) \\ \text{then Class } C_q ,$$

where  $C_q$  is a consequent class.

The compatibility grade of an input pattern  $x_p = (x_{p1}, x_{p2}, \dots, x_{pn})$  with the antecedent part of the fuzzy rule  $R_q$  in (77.7) is usually calculated by the minimum or product operator. In this chapter, we use the following product operator

$$\mu_{A_q}(x_p) = \mu_{A_{q1}}(x_{p1})\mu_{A_{q2}}(x_{p2}) \dots \mu_{A_{qn}}(x_{pn}) \quad (77.8)$$

where  $A_q = (A_{q1}, A_{q2}, \dots, A_{qn})$  is an antecedent fuzzy set vector, and  $\mu_{A_q}(x_p)$  shows the compatibility of  $x_p$  with the antecedent fuzzy set vector  $A_q$ .

Let  $S$  be a set of fuzzy rules of the form in (77.7). The rule set  $S$  can be viewed as a fuzzy rule-based classifier. When an input pattern  $x_p = (x_{p1}, x_{p2}, \dots, x_{pn})$  is presented to  $S$ ,  $x_p$  is classified

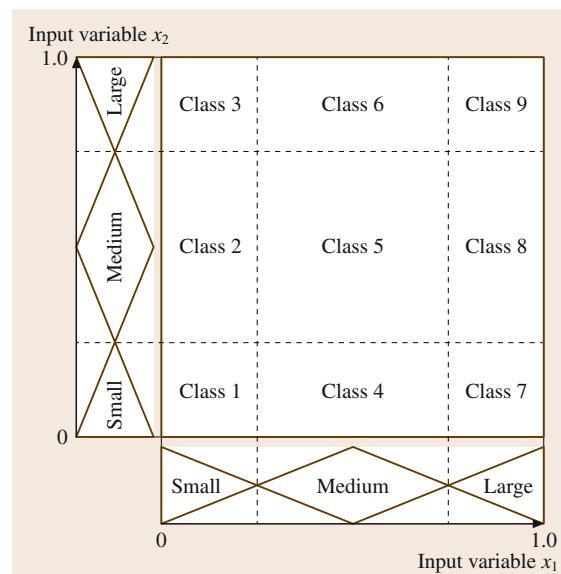

by a single winner rule with the maximum compatibility. Such a single winner-based fuzzy reasoning method has been frequently used in fuzzy rule-based classifiers.

Let us assume that we have nine fuzzy rules in Fig. 77.5 for a pattern classification problem with the two-dimensional pattern space  $[0, 1] \times [0, 1]$ . A different consequent class is assigned to each rule in Fig. 77.5 for explanation purposes. The grid lines in the pattern space in Fig. 77.5 show the classification boundary between different classes when we use the single winner-based fuzzy reasoning method together with the product operator-based compatibility calculation. It should be noted that the classification boundary by the nine fuzzy rules in Fig. 77.5 can also be generated by nine non-fuzzy rules with interval antecedent conditions [77.31, 32].

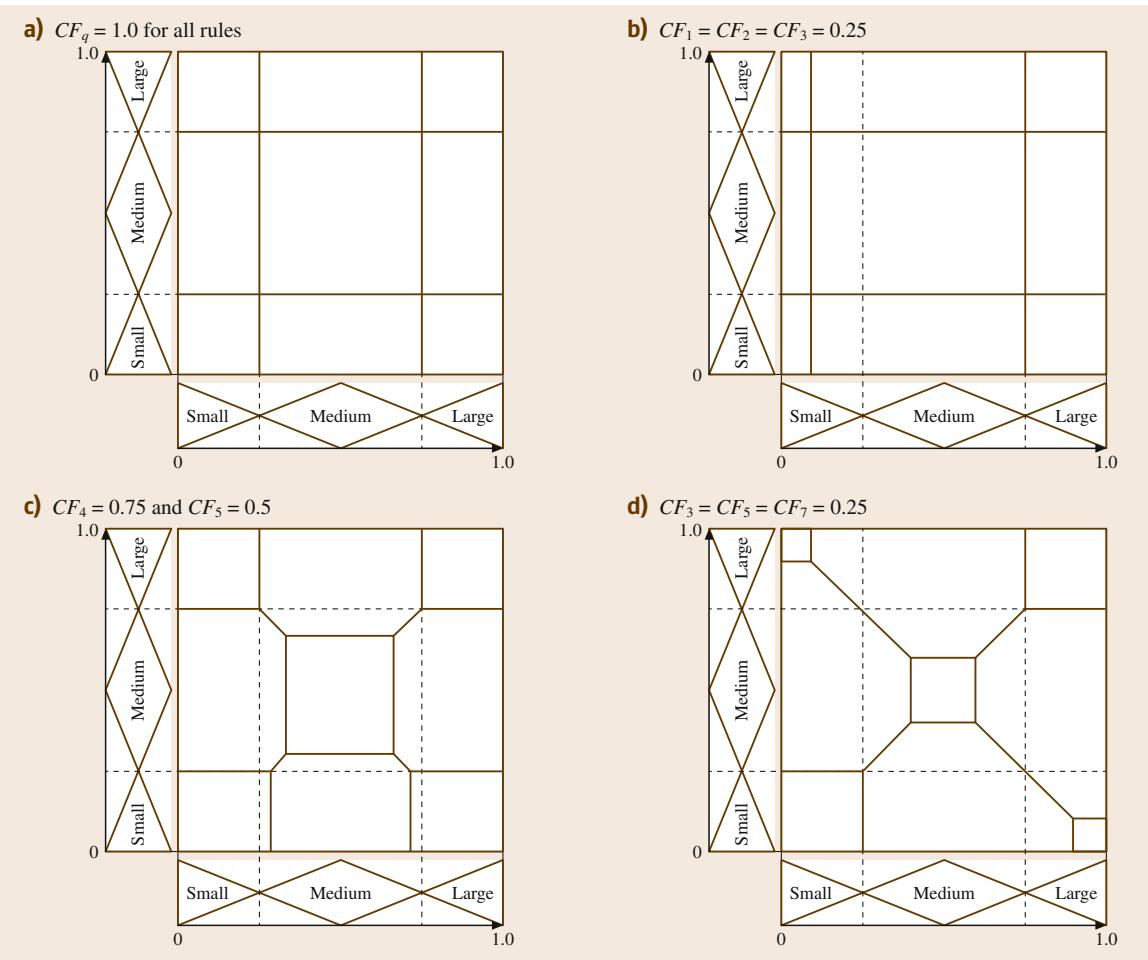

The second type of fuzzy rules for pattern classification problems has a rule weight [77.30]

$$\text{Rule } R_q : \text{If } x_1 \text{ is } A_{q1} \text{ and } \dots \text{ and } x_n \text{ is } A_{qn} \quad (77.9) \\ \text{then Class } C_q \text{ with } CF_q ,$$

where  $CF_q$  is a real number in the unit interval  $[0, 1]$ , which is called a rule weight or a certainty factor. This type of fuzzy rules has been used in many studies on fuzzy rule-based classifiers since the early 1990s [77.33, 34].

**Fig. 77.5** A fuzzy rule-based classifier with nine fuzzy classification rules

**Fig. 77.6a-d** Classification boundaries generated by assigning a different rule weight to each of the nine fuzzy rules in Fig. 77.5. In each plot, the default setting of  $CF_q$  is 1.0 (e.g.,  $CF_q = 1.0$  for  $q = 4, 5, 6, 7, 8, 9$  in (b))

When an input pattern  $x_p$  is presented to a fuzzy rule-based classifier with fuzzy rules of the form in (77.9), a single winner rule is determined using the product of the compatibility  $\mu_{A_q}(x_p)$  of  $x_p$  with each rule  $R_q$  and its rule weight  $CF_q$ :  $\mu_{A_q}(x_p)CF_q$ .

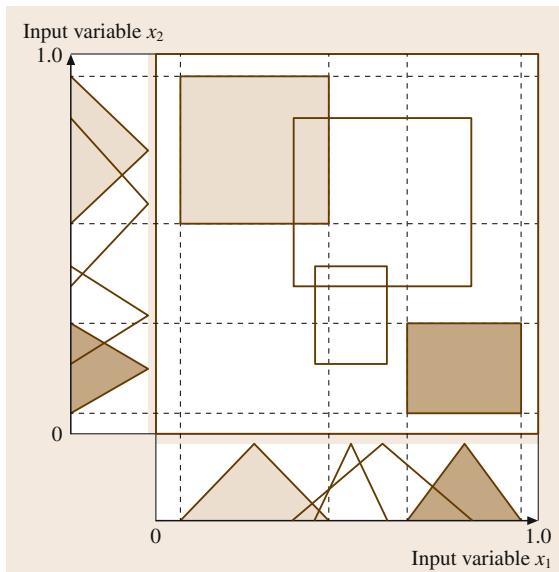

Fuzzy rules with a rule weight have higher classification ability than those with no rule weight. For example, the classification boundary in Fig. 77.5 can be adjusted by assigning a different rule weight to each rule (without changing the shape of each antecedent fuzzy set). Examples of the adjusted classification boundaries are shown in Fig. 77.6. As shown in Fig. 77.6, the accuracy of fuzzy rule-based classifiers can be improved by using fuzzy rules with a rule weight. However, the use of a rule weight degrades

the interpretability of fuzzy rule-based classifiers. It is a controversial issue to compare the interpretability of fuzzy rule-based classifiers between the following two approaches: One is the use of fuzzy rules with a rule weight and the other is the modification of antecedent fuzzy sets [77.35, 36].

The third type of fuzzy rules has multiple rule weights as follows [77.30]

Rule  $R_q$  : If  $x_1$  is  $A_{q1}$  and ... and  $x_n$  is  $A_{qn}$   
then Class  $C_1$  with  $CF_{q1}, \dots, C_m$  (77.10)  
with  $CF_{qm}$ ,

where  $m$  is the number of classes and  $CF_{qj}$  is a real number in the unit interval  $[0, 1]$ , which can be viewed

**Fig. 77.7** Examples of fuzzy rules in an approximative fuzzy rule-based system

as a rule weight for the  $j$ th class  $C_j$  ( $j = 1, 2, \dots, m$ ). When we use the single winner-based fuzzy reasoning method, the classification result of each pattern depends only on the maximum rule weight  $CF_q$  of each rule (i.e.,  $CF_q = \max\{CF_{q1}, CF_{q2}, \dots, CF_{qm}\}$ ). Thus, the use of multiple rule weights in (77.9) is meaningless under the single winner rule-based fuzzy reasoning method. However, they can improve the accuracy of fuzzy rule-based classifiers when we use a voting-based fuzzy reasoning method [77.30, 37]. Of course, the use of multiple rule weights further degrades the interpretability of fuzzy rule-based classifiers.

### 77.2.2 Types of Fuzzy Partitions

Since Mamdani's pioneering work in the 1970s [77.23, 24], grid-type fuzzy partitions have frequently been used in fuzzy control (e.g., the  $3 \times 3$  fuzzy partition in Fig. 77.2). Such a grid-type fuzzy partition has high interpretability when it is used for two-dimensional problems (i.e., for the design of two-input single-output fuzzy rule-based systems). However, grid-type fuzzy partitions have the following two difficulties. One difficulty is the inflexibility of membership function tuning. Since each antecedent fuzzy set is used in multiple fuzzy rules, membership function tuning for improving the accuracy of one fuzzy rule may degrade the accuracy of some other fuzzy rules. The other difficulty is

the exponential increase in the number of fuzzy rules with respect to the number of input variables. Let  $L$  be the number of antecedent fuzzy sets for each of the  $n$  variables. In this case, the number of cells in the corresponding  $n$ -dimensional fuzzy grid is  $L^n$  (e.g.,  $5^{10} = 9\,765\,625$  when  $L = 5$  and  $n = 10$ ).

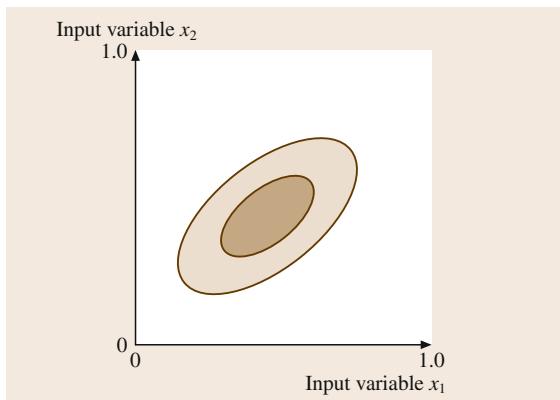

These two difficulties can be removed by assigning different antecedent fuzzy sets to each fuzzy rule as shown in Fig. 77.7. Each fuzzy rule has its own antecedent fuzzy sets. That is, no antecedent fuzzy set is shared by multiple fuzzy rules.

Fuzzy rule-based systems with this type of fuzzy rules are referred to as approximative models whereas grid-type fuzzy rule-based systems such as Fig. 77.2 are called descriptive models [77.38, 39]. If the accuracy of fuzzy rule-based systems is much more important than their interpretability, approximative models may be a better choice than descriptive models. Approximative models have been used as fuzzy rule-based classifiers since the early 1990s [77.40, 41].

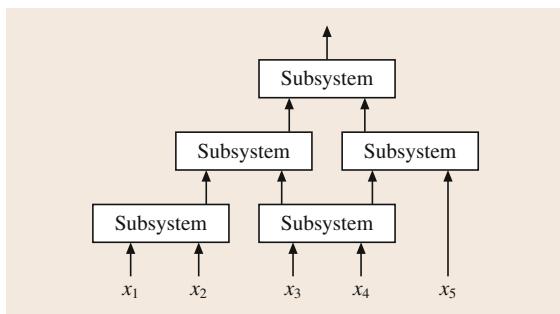

One limitation of approximative models with respect to accuracy maximization is that every antecedent fuzzy set is defined on a single input variable. As a result, the shape of a fuzzy subspace covered by the antecedent part of each fuzzy rule is rectangular as shown in Fig. 77.7. This means that such a fuzzy subspace cannot handle any correlation among input variables. One approach to the handling of correlated subspaces is the use of a single high-dimensional antecedent fuzzy set in each fuzzy rule

$$\text{Rule } R_q : \text{If } \mathbf{x} \text{ is } A_q \text{ then Class } C_q , \quad (77.11)$$

where  $\mathbf{x}$  is an  $n$ -dimensional input vector (i.e.,  $\mathbf{x} = (x_1, x_2, \dots, x_n)$ ) and  $A_q$  is a  $n$ -dimensional antecedent fuzzy set directly defined in the  $n$ -dimensional input space. This type of fuzzy rules has also been used for pattern classification problems since the 1990s [77.42]. Figure 77.8 illustrates an example of the  $n$ -dimensional antecedent fuzzy set  $A_q$  in the case of  $n = 2$ . As we can see from Fig. 77.8, antecedent fuzzy sets in fuzzy rules of the type in (77.11) can cover correlated fuzzy subspaces of the input space. This characteristic feature is an advantage over single-dimensional antecedent fuzzy sets with respect to the accuracy of fuzzy rule-based systems. However, as we can see from Fig. 77.8, it is almost impossible to linguistically interpret a high-dimensional antecedent fuzzy set. That is, the use of high-dimensional antecedent fuzzy sets may improve the accuracy of fuzzy rule-based systems but degrade their interpretability.

**Fig. 77.8** Illustration of an  $n$ -dimensional antecedent fuzzy set  $A_q$  in the two-dimensional input space

**Fig. 77.9** A five-input single-output fuzzy rule-based system with a hierarchical structure

### 77.2.3 Handling of High-Dimensional Problems with Many Input Variables

As we have already explained, the number of fuzzy rules exponentially increases with the number of input variables when we use a descriptive model with a grid-based fuzzy partition. Thus, it looks impractical to design a descriptive model for high-dimensional problems.

Approximative models do not have such a difficulty of grid-based fuzzy partitions. This is because the number of fuzzy rules in an approximative model is independent from the number of input variables. That

is, we can design fuzzy rule-based systems for high-dimensional problems by using approximative models.

One difficulty in the use of approximative models is poor interpretability of fuzzy rule-based systems due to the following two reasons: (i) it is difficult to linguistically interpret antecedent fuzzy sets in approximative models as shown in Fig. 77.7, and (ii) it is also difficult to understand a fuzzy rule with a large number of antecedent conditions.

### 77.2.4 Hybrid Approaches with Neural Networks and Genetic Algorithms

In the 1990s, a large number of learning and optimization methods were proposed for accuracy maximization of fuzzy rule-based systems. Almost all of those approaches were hybrid approaches with neural networks called *neuro-fuzzy systems* [77.27–29, 43, 44] and with genetic algorithms called *genetic fuzzy systems* [77.45–48]. In neuro-fuzzy systems, learning algorithms of neural networks were utilized for parameter tuning (e.g., for membership function tuning). As shown in Fig. 77.3, parameter tuning in fuzzy rule-based systems usually leads to accuracy improvement and interpretability deterioration.

Genetic fuzzy systems can be used not only for parameter tuning but also for structure optimization such as rule selection, input selection and fuzzy partition. As we will explain in the next section, rule selection, and input selection can improve the interpretability of fuzzy rule-based systems by decreasing their complexity whereas parameter tuning almost always deteriorates their interpretability. Genetic fuzzy systems were also used for constructing a hierarchical structure of fuzzy rule-based systems [77.49]. Figure 77.9 shows an example of a fuzzy rule-based system with a hierarchical structure. The use of hierarchical structures can prevent the exponential increase in the number of fuzzy rules because each subsystem has only a few inputs (e.g., in Fig. 77.9, each subsystem has only two inputs). However, it significantly degrades the interpretability of fuzzy rule-based systems. This is because the interpretation of intermediate variables between subsystems is usually impossible.

## 77.3 Complexity Minimization

In this section, we briefly explain various approaches proposed for decreasing the complexity of fuzzy rule-based systems. Those approaches improve the interpretability of fuzzy rule-based systems but often degrade their accuracy.

### 77.3.1 Decreasing the Number of Fuzzy Rules

A simple idea for complexity reduction of fuzzy rule-based systems is to decrease the number of fuzzy rules. Let us consider a three-class pattern classification problem in Fig. 77.10. All patterns in Fig. 77.10 can be correctly classified by the following nine fuzzy rules with the  $3 \times 3$  fuzzy grid in Fig. 77.10

Rule  $R_1$  : If  $x_1$  is *small* and  $x_2$  is *small*  
then Class 2 ,

Rule  $R_2$  : If  $x_1$  is *small* and  $x_2$  is *medium*  
then Class 2 ,

Rule  $R_3$  : If  $x_1$  is *small* and  $x_2$  is *large*  
then Class 1 ,

Rule  $R_4$  : If  $x_1$  is *medium* and  $x_2$  is *small*  
then Class 2 ,

Rule  $R_5$  : If  $x_1$  is *medium* and  $x_2$  is *medium*  
then Class 2 ,

Rule  $R_6$  : If  $x_1$  is *medium* and  $x_2$  is *large*  
then Class 1 ,

Rule  $R_7$  : If  $x_1$  is *large* and  $x_2$  is *small*  
then Class 3 ,

Rule  $R_8$  : If  $x_1$  is *large* and  $x_2$  is *medium*  
then Class 3 ,

Rule  $R_9$  : If  $x_1$  is *large* and  $x_2$  is *large*  
then Class 3 .

That is, all patterns in Fig. 77.10 can be correctly classified by a fuzzy rule-based classifier with these nine fuzzy rules. It is also possible to correctly classify all patterns in Fig. 77.10 using a simple fuzzy rule-based classifier only with the four fuzzy rules around the top-right corner (i. e., fuzzy rules  $R_5$ ,  $R_6$ ,  $R_8$ , and  $R_9$ ). This example illustrates the simplification of fuzzy rule-based systems through rule selection.

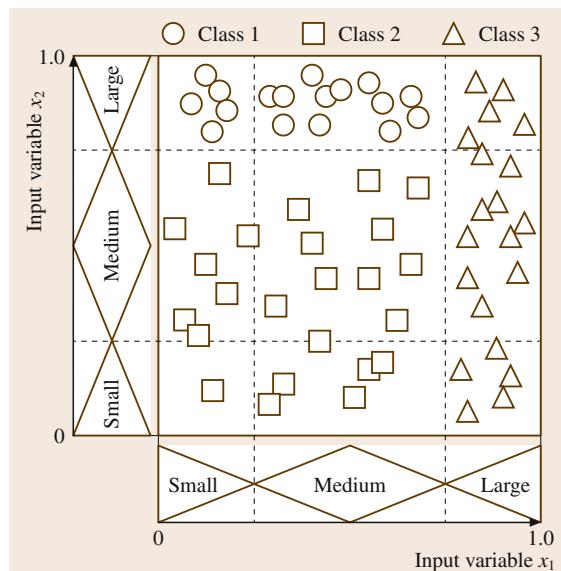

The use of genetic algorithms for fuzzy rule selection was proposed by Ishibuchi et al. [77.13, 14] in the

1990s. Let  $S_{\text{All}}$  be a set of all fuzzy rules. Since an arbitrary subset of  $S_{\text{All}}$  can be represented by a binary string of length  $|S_{\text{All}}|$ , standard genetic algorithms for binary strings can be directly applied to fuzzy rule selection [77.13, 14]. The number of fuzzy rules, which should be minimized, was used as a part of a fitness function in single-objective approaches [77.13, 14]. It was also used as a separate objective in multiobjective approaches [77.15].

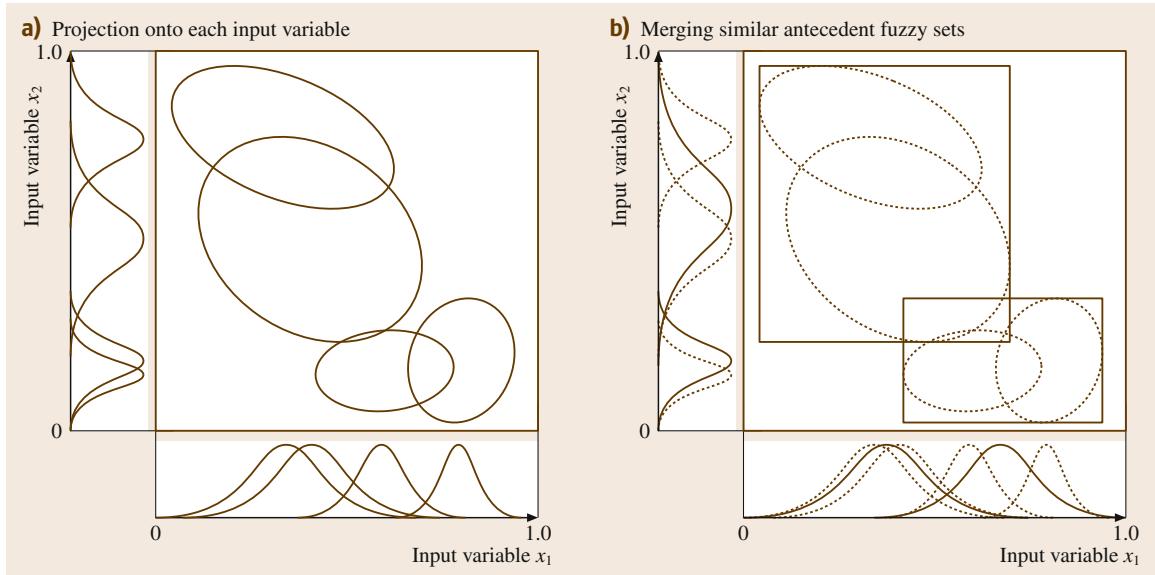

### 77.3.2 Decreasing the Number of Antecedent Conditions

In Fig. 77.10, the rightmost three fuzzy rules (i. e.,  $R_7$ ,  $R_8$  and  $R_9$  with the same antecedent condition on  $x_1$ ) can be combined into a single fuzzy rule: If  $x_1$  is *large* then Class 3. This fuzzy rule has no condition on the second input variable  $x_2$ . In this manner, the  $3 \times 3$  fuzzy rule-based classifier with the nine fuzzy rules can be simplified to a simpler classifier with the seven fuzzy rules.

The fuzzy rule If  $x_1$  is *large* then Class 3 is viewed as having a *don't care* condition on the second input variable  $x_2$ : If  $x_1$  is *large* and  $x_2$  is *don't care* then Class 3. In this fuzzy rule, *don't care* is a special antecedent fuzzy set that is fully compatible with

**Fig. 77.10** A three-class pattern classification problem and a  $3 \times 3$  fuzzy grid

**Fig. 77.11a,b** Projection of two-dimensional fuzzy sets and the merge of similar antecedent fuzzy sets. **(a)** Projection onto each input variable, **(b)** merging similar antecedent fuzzy sets

any input values. The use of *don't care* enables us to perform rule-level input selection, which significantly improves the applicability of descriptive fuzzy rule-based systems to high-dimensional problems [77.50].

When we use *don't care* as a special antecedent fuzzy set, the number of antecedent conditions in a fuzzy rule excluding *don't care* conditions is referred to as the rule length since *don't care* conditions are usually omitted (e.g., If  $x_1$  is *large* and  $x_2$  is *don't care* then Class 3 is usually written as If  $x_1$  is *large* then Class 3). A short fuzzy rule with a small number of antecedent conditions covers a large fuzzy subspace of a high-dimensional pattern space while a long fuzzy rule covers a small fuzzy subspace. For example, let us consider a 50-dimensional pattern classification problem with the pattern space  $[0, 1]^{50}$ . A fuzzy rule with the antecedent fuzzy set *small* on all the 50 input variables covers less than  $1/10^1$  of the pattern space  $[0, 1]^{50}$ . However, a short fuzzy rule with the antecedent fuzzy set *small* on only two input variables (e.g., If  $x_1$  is *small* and  $x_{49}$  is *small* then Class 3) covers  $1/4$  of the pattern space  $[0, 1]^{50}$ . As a result, almost all of the entire high-dimensional pattern space can be covered by a small number of short fuzzy rules. That is, we can design a simple fuzzy rule-based classifier with a small number of short fuzzy rules for a high-dimensional pattern classification problem. It should be noted that different fuzzy rules may have antecedent conditions

on different input variables. Moreover, the rule length of each fuzzy rule may be different (e.g., one fuzzy rule has an antecedent condition only on  $x_1$  while another fuzzy rule has antecedent conditions on  $x_2$ ,  $x_3$  and  $x_4$ ).

The total rule length (i.e., the total number of antecedent conditions), which should be minimized, was used as a part of a fitness function in single-objective approaches [77.51]. It was also used as a separate objective in multiobjective approaches [77.52, 53]. In multiobjective approaches, the total rule length instead of the average rule length has been used in the literature. This is because the minimization of the average rule length does not necessarily mean the complexity minimization of fuzzy rule-based systems. In many cases, the average rule length can be decreased by adding a new fuzzy rule with a single antecedent condition, which leads to the increase in the complexity of a fuzzy rule-based system.

### 77.3.3 Other Interpretability Improvement Approaches

For the design of accurate fuzzy rule-based systems for high-dimensional problems, clustering techniques such as fuzzy c-means [77.54–56] have often been used to generate fuzzy rules [77.42, 57–61]. Fuzzy rules with ellipsoidal high-dimensional antecedent fuzzy sets are

often obtained from clustering-based fuzzy rule generation methods. Fuzzy rules of this type have high accuracy but low interpretability. Their interpretability is improved by projecting high-dimensional antecedent fuzzy sets onto each input variable. As a result, we have approximative fuzzy rule-based systems (Fig. 77.11a). The interpretability of the obtained fuzzy rule-based systems can be further improved by merging similar antecedent fuzzy sets on each input variable into a single one (Fig. 77.11b). Each of the generated antecedent fuzzy sets by a merging procedure is replaced with a linguistic value to further improve the interpretability of fuzzy rule-based systems.

It should be noted that each of the abovementioned interpretability improvement steps (i.e., projec-

tion of high-dimensional antecedent fuzzy sets, merging similar fuzzy sets, and replacement with linguistic values) deteriorates the accuracy of fuzzy rule-based systems. Thus, the design of fuzzy rule-based systems can be viewed as being the search for a good tradeoff solution between accuracy and interpretability. From this viewpoint, some sophisticated approaches were proposed [77.62–68] after a large number of accuracy improvement algorithms were proposed in 1990s. Some of those approaches tried to improve the accuracy of fuzzy rule-based systems without severely deteriorating their interpretability. Other approaches tried to improve the interpretability of fuzzy rule-based systems without severely deteriorating their accuracy.

## 77.4 Single-Objective Approaches

As we have already explained, the simplest multiobjective formulation of fuzzy system design has two objectives (i.e., error minimization and complexity minimization) as follows

$$\begin{aligned} \text{Minimize } f(S) &= (f_1(S), f_2(S)) \\ &= (\text{Complexity}(S), \text{Error}(S)), \end{aligned} \quad (77.12)$$

where  $f(S)$  shows an objective vector. In this section, we explain how the two-objective problem in (77.12) can be handled by single-objective approaches. For more general and comprehensive explanations on the handling of multiobjective problems through single-objective optimization, see textbooks on multicriteria decision making such as *Miettinen* [77.69].

### 77.4.1 Use of Scalarizing Functions

One of the most frequently used approaches to multiobjective optimization is the use of scalarizing functions. Multiple objective functions are combined into a single scalarizing function. That is, a multiobjective problem is handled as a single-objective problem. Our two objectives in multiobjective fuzzy system design are combined as follows

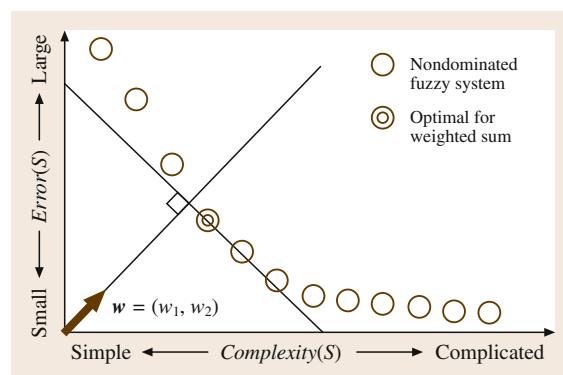

$$\begin{aligned} \text{Minimize } f(S) &= f(f_1(S), f_2(S)) \\ &= f(\text{Complexity}(S), \text{Error}(S)), \end{aligned} \quad (77.13)$$

where  $f(S)$  is a scalarizing function to be minimized. A simple but frequently used scalarizing function is the weighted sum

$$\begin{aligned} \text{Minimize } f(S) &= w_1 f_1(S) + w_2 f_2(S) \\ &= w_1 \text{Complexity}(S) \\ &\quad + w_2 \text{Error}(S), \end{aligned} \quad (77.14)$$

where  $w_1$  and  $w_2$  are nonnegative weights ( $w$  is a weight vector:  $w = (w_1, w_2)$ ).

Single-objective optimization algorithms such as genetic algorithms are used to search for the optimal solution (i.e., optimal fuzzy rule-based system) of the minimization problem in (77.13). In Fig. 77.12, we

**Fig. 77.12** The optimal fuzzy rule-based system of the weighted-sum minimization problem in (77.14) and the nondominated fuzzy rule-based systems of the original two-objective problem

illustrate the search for the optimal fuzzy rule-based system of the weighed-sum minimization problem in (77.14) together with the nondominated fuzzy rule-based systems of the original two-objective problem in (77.12).

As shown in Fig. 77.12, a single optimal fuzzy rule-based system is obtained from a scalarizing function-based approach. The main difficulty of this approach is the dependency of the obtained fuzzy rule-based system on the choice of a scalarizing function. A different fuzzy rule-based system is likely to be obtained from a different scalarizing function. For example, a different specification of the weight vector in Fig. 77.12 leads to a different fuzzy rule-based system. Moreover, an appropriate choice of a scalarizing function is not easy.

#### 77.4.2 Handling of Objectives as Constraint Conditions

If we have a pre-specified requirement about the complexity or the accuracy, we can use it as a constraint condition. For example, let us assume that the error measure  $Error(S)$  in our two-objective problem is the classification error rate. We also assume that the upper bound of the allowable error rate is given as  $\alpha\%$ . In this case, our two-objective problem can be reformulated as the following single-objective problem with a constraint condition

$$\begin{aligned} \text{Minimize } f_1(S) &= Complexity(S) \\ \text{subject to } Error(S) &\leq \alpha . \end{aligned} \quad (77.15)$$

This single-objective problem is to find the simplest fuzzy rule-based system among those with a pre-specified accuracy (i. e., with error rates smaller than or equal to  $\alpha\%$ ).

It is also possible to use a constraint condition on the complexity measure  $Complexity(S)$ . For example, let us assume that  $Complexity(S)$  is the number of fuzzy rules. We also assume that the upper bound of the allowable number of fuzzy rules is given as  $\beta$ . In this case, the following single-objective problem is formulated

$$\begin{aligned} \text{Minimize } f_2(S) &= Error(S) \\ \text{subject to } Complexity(S) &\leq \beta . \end{aligned} \quad (77.16)$$

This formulation is illustrated in Fig. 77.13 where the optimal solution is the most accurate fuzzy rule-based

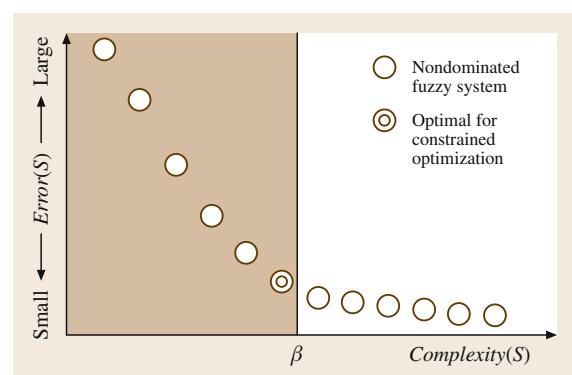

system under the constraint condition  $Complexity(S) \leq \beta$ .

When we have more than two objectives, only a single objective is used as an objective function while all the others are used as constraint conditions in this approach. That is, an  $m$ -objective problem is reformulated as a single-objective problem with  $(m - 1)$  constraint conditions. The main difficulty in this constraint condition-based approach is an appropriate specification of the upper bound for each objective.

#### 77.4.3 Minimization of the Distance to the Reference Point

In the abovementioned constraint condition-based approach, the right-hand side constant for each objective is the upper bound of the allowable error or complexity (e.g., the error rate should be at least smaller than or equal to  $\alpha\%$ ). The right-hand side constant should be specified so that the formulated constrained optimization problem has feasible fuzzy rule-based systems.

A single-objective problem can be also formulated when an ideal fuzzy rule-based system is given as a reference point in the objective space. We assume that the given reference point is outside the feasible region of the original two-objective problem in (77.12). That is, the ideal fuzzy rule-based system does not exist as a feasible solution of the two-objective problem. Let the reference point in the two-dimensional objective space be  $f^* = (f_1^*, f_2^*)$ . The following single-objective problem can be formulated to search for the fuzzy rule-based system closest to the reference

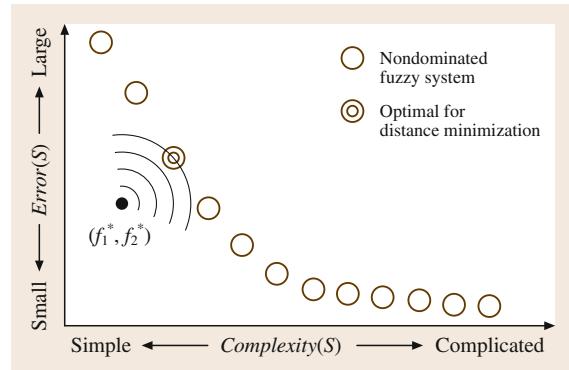

**Fig. 77.13** The optimal fuzzy rule-based system of the constrained optimization problem in (77.15) and the non-dominated fuzzy rule-based systems of the original two-objective problem

point

$$\text{Minimize distance } (f(S), f^*) , \quad (77.17)$$

where  $f(S)$  is the objective vector (i.e.,  $f(S) = (f_1(S), f_2(S))$ ), and  $\text{distance}(A, B)$  is a distance measure between the two points A and B in the objective space. Various distance measures can be used in (77.17). We illustrate the reference point-based approach in Fig. 77.14 where the Euclidean distance is used. As shown in Fig. 77.14, the fuzzy rule-based system closest to the given reference point  $(f_1^*, f_2^*)$  is the optimal solution of the single-objective problem in (77.17).

The main difficulty of the reference point-based approach is an appropriate specification of the reference point. When we have no information about the complexity and the accuracy of fuzzy rule-based systems, it is very difficult to appropriately specify the reference point in the reference point-based approach as well as the right-hand side constant for each objective in the constraint condition-based approach. However, if we know the shape of the complexity–accuracy trade-

**Fig. 77.14** The optimal fuzzy rule-based system of the distance minimization problem from the reference point in (77.17) and the nondominated fuzzy rule-based systems of the original two-objective problem

off surface in the objective space (i.e., if we know the nondominated fuzzy rule-based systems in the objective space), such a parameter specification becomes much easier.

## 77.5 Evolutionary Multiobjective Approaches

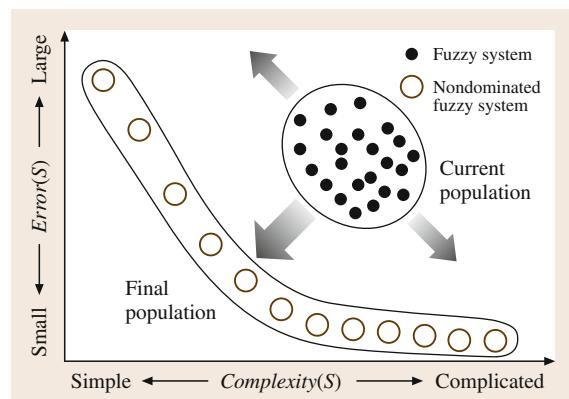

Since an early study in the 1990s [77.15], various multiobjective approaches have been proposed to search for a large number of nondominated solutions of multiobjective fuzzy system design problems. In this section, we explain the basic idea of those multiobjective approaches, recent studies on multiobjective fuzzy system design, and future research directions.

### 77.5.1 Basic Idea of Evolutionary Multiobjective Approaches

Multiobjective fuzzy system design was first formulated as a two-objective optimization problem to maximize the accuracy of fuzzy rule-based classifiers and to minimize the number of fuzzy rules in the 1990s [77.15]. Then this two-objective optimization problem was extended to a three-objective problem by including an additional objective to minimize the total rule length (i.e., the total number of antecedent conditions) in [77.52].

The main characteristic feature of evolutionary multiobjective approaches to fuzzy system design is that a number of nondominated fuzzy rule-based systems are obtained by a single run of an evolutionary multiobjective optimization (EMO) algorithm. This is clearly

different from the single-objective approaches where a single fuzzy rule-based system is obtained by a single run of a single-objective optimization algorithm. In Fig. 77.15, we illustrate the search for nondominated fuzzy rule-based systems in evolutionary multiobjective approaches. The population of solutions (i.e., fuzzy rule-based systems) is pushed toward the Pareto

**Fig. 77.15** Search for a variety of nondominated fuzzy rule-based systems along the Pareto front by evolutionary multiobjective approaches

front and widened along the Pareto front to search for a variety of nondominated solutions. Well-known and frequently used **EMO** algorithms such as nondominated sorting genetic algorithm II (**NSGA-II**) [77.70], strength Pareto evolutionary algorithm (**SPEA**) [77.71], multiobjective evolutionary algorithm based on decomposition (**MOEA/D**) [77.72], and S metric selection evolutionary multiobjective optimisation algorithm (**SMS-EMOA**) [77.73] have their own mechanisms to push the population toward the Pareto front and widen the population along the Pareto front.

The obtained set of nondominated solutions can be used to examine the complexity–accuracy tradeoff relation in the design of fuzzy rule-based systems [77.53]. A human decision maker is supposed to choose a final fuzzy rule-based system from the obtained nondominated ones according to his/her preference. It should be noted that the decision maker's preference is needed in the problem formulation phase in the single-objective approaches in the previous section (i.e., in the form of a scalarizing function, the upper bound of the allowable values for each objective, and the reference point in the objective space). However, the evolutionary multiobjective approaches do not need any information on the decision maker's preference in their search for nondominated fuzzy rule-based systems. That is, a number of nondominated fuzzy rule-based systems can be obtained with no information on the decision maker's preference. A human decision maker is needed only in the solution selection phase after a number of nondominated solutions are obtained.

## 77.5.2 Various Evolutionary Multiobjective Approaches

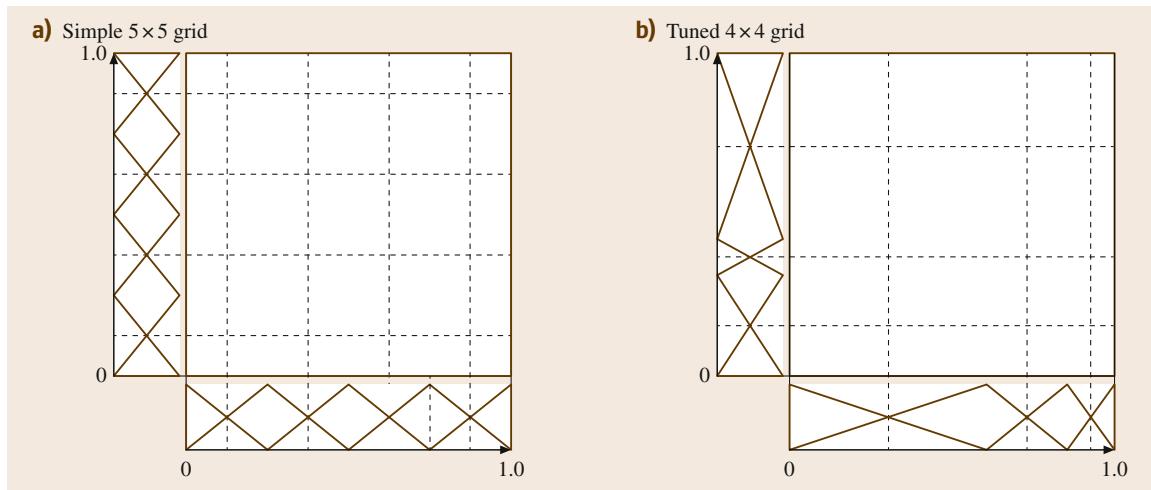

We have explained multiobjective fuzzy rule-based design using the two-objective formulation with the complexity minimization and the error minimization in Fig. 77.15. However, various evolutionary multiobjective approaches have been proposed for multiobjective fuzzy system design (for their review, see [77.19]). In this subsection, we briefly explain some of those evolutionary multiobjective approaches.

In some real-world applications, the design of fuzzy rule-based systems involves multiple performance measures. Especially in multiobjective fuzzy controller design, multiple performance measures have been frequently used with no complexity measures. For example, in *Stewart et al.* [77.74], multiobjective fuzzy controller design was formulated as a three-objective problem with three performance measures: a current

tracking error, a velocity tracking error, and a power consumption. In *Chen and Chiang* [77.75], fuzzy controller design was formulated using no complexity measure and three accuracy measures: the number of collisions, the distance between the target and lead points of the new path, and the number of explored actions. Whereas multiple performance measures have been frequently used in multiobjective fuzzy controller design, a single performance measure such as the error rate has been mainly used in multiobjective fuzzy classifier design. However, for the handling of classification problems with imbalanced and cost-sensitive data sets, multiple performance measures were used in some studies on multiobjective fuzzy classifier design. For example, a true positive rate and a false positive rate were used as separate performance measures together with a complexity measure in three-objective fuzzy classifier design in [77.76].

Multiple complexity measures have been frequently used in multiobjective fuzzy classifier design. In the first study on multiobjective fuzzy classifier design [77.15], the number of fuzzy rules was used as a complexity measure. Then the total rule length (i.e., the total number of antecedent conditions) was added as another complexity measure in three-objective fuzzy classifier design [77.52, 53]. The number of fuzzy rules and the total rule length have been used in many other studies on multiobjective fuzzy classifier design [77.77–79]. In some studies, the number of antecedent fuzzy sets was used instead of the total rule length [77.80, 81].

When membership function tuning is performed together with fuzzy rule generation in fuzzy classifier design, complexity measures such as the number of fuzzy rules and the total rule length are not always enough to evaluate the interpretability of fuzzy rule-based systems. Let us compare two fuzzy partitions in Fig. 77.16 with each other. The  $5 \times 5$  fuzzy partition in Fig. 77.16a has 25 fuzzy rules while the  $4 \times 4$  fuzzy partition in Fig. 77.16b has 16 fuzzy rules. Thus, the fuzzy partition in Fig. 77.16a is evaluated as being more complicated than that of Fig. 77.16b when the abovementioned simple complexity measures are used. However, we intuitively feel that the simple  $5 \times 5$  fuzzy partition in Fig. 77.16a is more interpretable than the tuned  $4 \times 4$  fuzzy partition in Fig. 77.16b. This is because the tuned antecedent fuzzy sets in Fig. 77.16b are not easy to interpret linguistically. These discussions on the comparison between the two fuzzy partitions show the necessity of interpretability measures in addition to the abovementioned simple complexity measures in

**Fig. 77.16a, b** Two fuzzy partitions: (a) simple  $5 \times 5$  grid, (b) tuned  $4 \times 4$  grid

fuzzy classifier design when membership function tuning is performed.

Interpretability of fuzzy rule-based systems has been a hot topic in the field of fuzzy systems [77.82]. Various aspects of fuzzy rule-based systems are related to their interpretability [77.83–88]. Some studies focus on the explanation ability of fuzzy rule-based classifiers to explain why each pattern is classified as a particular class in an understandable manner [77.89].

Whereas a number of studies have already addressed the interpretability of fuzzy rule-based systems [77.82–89], it is still a very difficult open problem to quantitatively define all aspects of the interpretability of fuzzy rule-based systems. This is because the interpretability is totally subjective. That is, its definition totally depends on human users. Each human user may have a different idea about the interpretability of fuzzy rule-based systems.

A number of approaches have been proposed to incorporate the interpretability into evolutionary multiobjective fuzzy system design [77.90–94]. The basic idea is to significantly improve the accuracy of fuzzy rule-based systems by slightly deteriorating their interpretability (e.g., by slightly tuning antecedent fuzzy sets). Since the interpretability is totally subjective, it is not easy to compare those approaches. In this sense, experimental studies on the interpretability of fuzzy rule-based systems seem to be one of the promising research directions [77.83].

Whereas multiobjective genetic algorithms have been mainly used in evolutionary multiobjective fuzzy system design, the use of other algorithms was also ex-

amined. This is closely related to the increase in the popularity of not only multiobjective genetic algorithms but also other multiobjective algorithms. For example, multiobjective versions of particle swarm optimization (**PSO**) have been actively studied in the field of evolutionary computation [77.95–99]. In response to those active studies, multiobjective **PSO** algorithms were used for multiobjective fuzzy system design [77.100–104].

### 77.5.3 Future Research Directions

Formulation of interpretability is still an important issue to be further studied. As pointed out by many studies [77.83–88], various aspects are related to the interpretability of fuzzy rule-based systems. One problem is to quantitatively formulate those aspects so that they can be used as objectives in evolutionary multiobjective fuzzy system design. Another problem is how to use them. We may have several options: the use of all aspects as separate objectives, the choice of only a few aspects as separate objectives, and the integration of all or some aspects into a few interpretability measures. If we use all aspects as separate objectives, multiobjective fuzzy system design is formulated as a many-objective problem. It is well-known that many-objective problems are usually very difficult for evolutionary multiobjective optimization problems [77.105–107]. However, both the choice of only a few aspects and the integration into a few interpretability measures are also difficult.

The main advantage of multiobjective approaches to fuzzy system design over single-objective approaches is that a number of nondominated fuzzy rule-based sys-

tems are obtained along the interpretability–accuracy tradeoff surface as we explained in the complexity–accuracy objective space. One issue, which has not been discussed in many studies, is how to choose a single fuzzy rule-based system from a large number of obtained ones. It is implicitly assumed that a single fuzzy rule-based system is to be selected by a human decision maker. However, the selection of a single fuzzy rule-based system is an important issue especially when a large number of fuzzy rule-based systems are obtained in a high-dimensional objective space. A related research topic is the elicitation of the decision maker’s preference about interpretability–accuracy tradeoffs and its utilization in evolutionary multiobjective fuzzy system design.

Performance improvement of evolutionary multiobjective approaches is still an important research topic. Since multiobjective fuzzy system design is often formulated as complicated multiobjective optimization problems with many discrete and continuous decision variables, it is very difficult to search for their true Pareto optimal solutions. Thus, it is likely that better fuzzy rule-based systems than reported results in the literature would be obtained by more efficient multiobjective algorithms and/or better problem formulations.

Actually better results are continuously reported in the literature. A related research topic is parallel implementation of evolutionary multiobjective approaches. In general, parallel implementation of evolutionary algorithms is not difficult due to their population-based search mechanisms (i.e., because the fitness evaluation of multiple individual in the current population can be easily performed in parallel).

Multiobjective genetic algorithms have been mainly used for evolutionary multiobjective fuzzy system design. As we have already mentioned, recently the use of multiobjective PSO has been examined [77.100–104]. Since other population-based search algorithms such as ant colony optimization (ACO) have already been used in single-objective approaches to fuzzy system design [77.108–112], the use of their multiobjective versions will be examined for multiobjective fuzzy system design.

A very important and promising research direction is multiobjective design of type-2 fuzzy systems [77.113]. A number of single-objective approaches have already been proposed for type-2 fuzzy system design [77.114–116]. However, multiobjective type-2 fuzzy system design has not been discussed in many studies.

## 77.6 Conclusion

We explained the basic idea of evolutionary multiobjective fuzzy system design using a simple two-objective formulation for complexity and error minimization in comparison with single-objective approaches. The main advantage of multiobjective approaches is that a large number of fuzzy rule-based systems with different complexity–accuracy tradeoffs are obtained from a single run of a multiobjective approach. A human user can choose a single fuzzy rule-based system based on

his/her preference and the requirement in each application field. Highly interpretable fuzzy systems may be needed in some application fields while highly accurate ones may be preferred in other application fields. See [77.19] for more comprehensive review on evolutionary multiobjective approaches to fuzzy rule-based system design, [77.88] for single-objective and multiobjective approaches, and [77.115, 116] for type-2 fuzzy system design.

# Bio-Inspired Optimization of Type-2 Fuzzy Controllers

Oscar Castillo

A review of the bio-inspired optimization methods used in the design of type-2 fuzzy systems, which are relatively novel models of imprecision, is considered in this chapter. The fundamental focus of the work is based on the basic reasons for the need for optimization of type-2 fuzzy systems for different areas of application. Recently, bio-inspired methods have emerged as powerful optimization algorithms for solving complex problems. In the case of designing type-2 fuzzy systems for particular applications, the use of bio-inspired optimization methods has helped in the complex task of finding the appropriate parameter values and structure of fuzzy systems. In this chapter, we consider the application of genetic algorithms, particle swarm optimization, and ant colony optimization as three different paradigms that help in the design of optimal type-2 fuzzy systems. We also provide a comparison of the different optimization

methods for the case of designing type-2 fuzzy systems.

Part G | 78.1

## 78.1 Related Work in Type-2 Fuzzy Control

Uncertainty affects decision-making and appears in a number of different forms. The concept of information is fully connected with the concept of uncertainty [78.1]. The most fundamental aspect of this connection is that the uncertainty involved in any problem-solving situation is a result of some information deficiency, which may be incomplete, imprecise, fragmentary, not fully reliable, vague, contradictory, or deficient in some other way. Uncertainty is an attribute of information [78.2]. The general framework of fuzzy reasoning allows handling much of this uncertainty, and fuzzy systems that employ type-1 fuzzy sets represent uncertainty by numbers in the range  $[0, 1]$ . When something is uncertain, like a measurement, it is difficult to determine its exact value, and of course type-1 using fuzzy sets make more sense than using crisp sets [78.3].

However, it is not reasonable to use an accurate membership function for something uncertain, so in this case what we need are higher-order fuzzy sets, which are able to handle these uncertainties, like the so-called type-2 fuzzy sets [78.3]. So, the degree of uncertainty can be managed by using type-2 fuzzy logic because this offers better capabilities to handle linguistic uncertainties by modeling vagueness and unreliability of information [78.4–6].

Recently, we have seen the use of type-2 fuzzy sets in fuzzy logic systems (FLS) in different areas of application [78.7–11]. In this paper we deal with the application of interval type-2 fuzzy control to non-linear dynamic systems [78.4, 12–15]. It is a well-known fact that in the control of real systems, the instrumentation elements (instrumentation

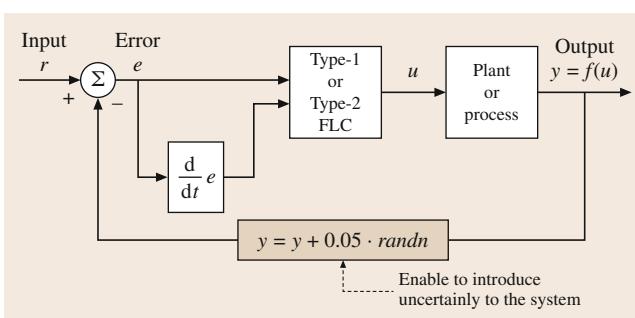

amplifier, sensors, digital to analog, analog to digital converters, etc.) introduce some sort of unpredictable values in the information that has been collected [78.16]. So, the controllers designed under idealized conditions tend to behave in an inappropriate manner [78.17].

## 78.2 Fuzzy Logic Systems

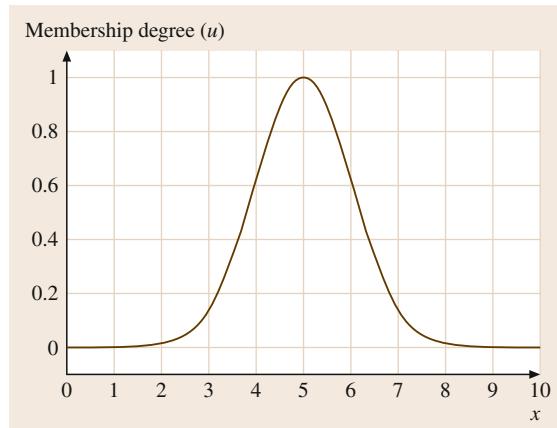

In this section, a brief overview of type-1 and type-2 fuzzy systems is presented. This overview is considered to be necessary to understand the basic concepts needed to develop the methods and algorithms presented later in the chapter.

### 78.2.1 Type-1 Fuzzy Logic Systems

Soft computing techniques have become an important research topic that can be applied in the design of intelligent controllers, which utilize human experience in a more natural form than the conventional mathematical approach [78.18, 19]. An FLS described completely in

**Fig. 78.1** System used to obtain the experimental results

**Fig. 78.2** Type-1 membership function

terms of type-1 fuzzy sets is called a type-1 fuzzy logic system (type-1 FLS). In this paper, the fuzzy controller has two input variables, which are the error  $e(t)$  and the error variation  $\Delta e(t)$ ,

$$e(t) = r(t) - y(t), \quad (78.1)$$

$$\Delta e(t) = e(t) - e(t-1), \quad (78.2)$$

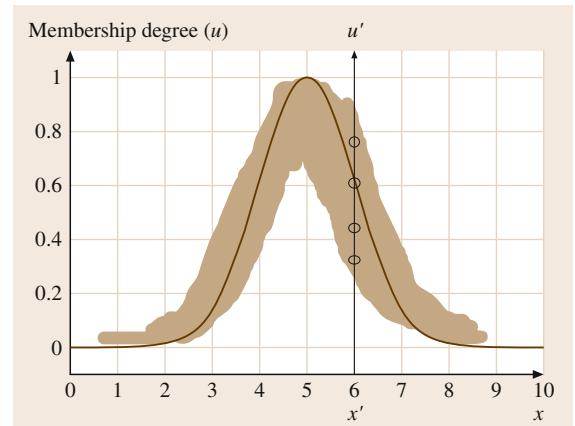

so the control system can be represented as shown in Fig. 78.1.

### 78.2.2 Type-2 Fuzzy Logic Systems

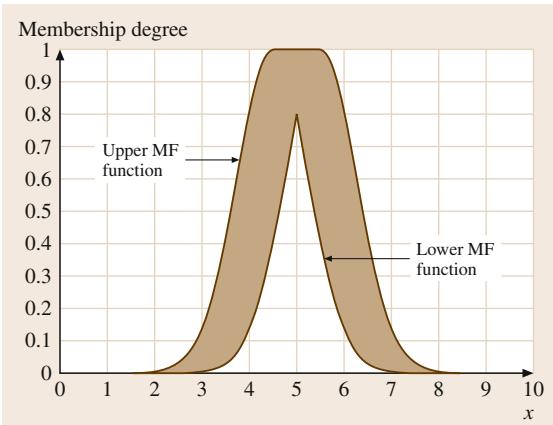

If for a type-1 membership function, as in Fig. 78.2, we blur it to the left and to the right, as illustrated in Fig. 78.3, then a type-2 membership function is obtained. In this case, for a specific value  $x'$ , the membership function ( $u'$ ) takes on different values, which are not all weighted the same, so we can assign an amplitude distribution to all of those points.

A type-2 fuzzy set  $\tilde{A}$  is characterized by the membership function [78.1, 3]

$$\tilde{A} = \{(x, u), \mu_{\tilde{A}}(x, u)\} \mid \forall x \in X, \quad \forall u \in J_x \subseteq [0, 1] \}, \quad (78.3)$$

**Fig. 78.3** Blurred type-1 membership function

**Fig. 78.4** Interval type-2 membership function

in which  $0 \leq \mu_{\tilde{A}}(x, u) \leq 1$ . Another expression for  $\tilde{A}$  is

$$\tilde{A} = \int_{x \in X} \int_{u \in J_x} \frac{\mu_{\tilde{A}}(x, u)}{(x, u)}, \quad J_x \subseteq [0, 1], \quad (78.4)$$

where  $\int \int$  denotes the union over all admissible input variables  $x$  and  $u$ . For discrete universes of discourse  $J$  is replaced by  $\sum$ . In fact  $J_x \subseteq [0, 1]$  represents the primary membership of  $x$ , and  $\mu_{\tilde{A}}(x, u)$  is a type-1 fuzzy set known as the secondary set. Hence, a type-2 membership grade can be any subset in  $[0, 1]$ , the primary membership, and corresponding to each primary membership, there is a secondary membership (which can also be in  $[0, 1]$ ) that defines the possibilities for the primary membership. Uncertainty is represented by a region, which is called the footprint of uncertainty (**FOU**). When  $\mu_{\tilde{A}}(x, u) = 1$ ,  $\forall u \in J_x \subseteq [0, 1]$  we have an interval type-2 membership function, as shown in Fig. 78.4. The uniform shading for the **FOU** repre-

sents the entire interval type-2 fuzzy set and it can be described in terms of an upper membership function  $\bar{\mu}_{\tilde{A}}(x)$  and a lower membership function  $\underline{\mu}_{\tilde{A}}(x)$ .

A **FLS** described using at least one type-2 fuzzy set is called a type-2 **FLS**. Type-1 **FLS**s are unable to directly handle rule uncertainties, because they use type-1 fuzzy sets that are certain [78.3]. On the other hand, type-2 **FLS**s, are very useful in circumstances where it is difficult to determine an exact membership function and there are measurement uncertainties [78.14, 20, 21].

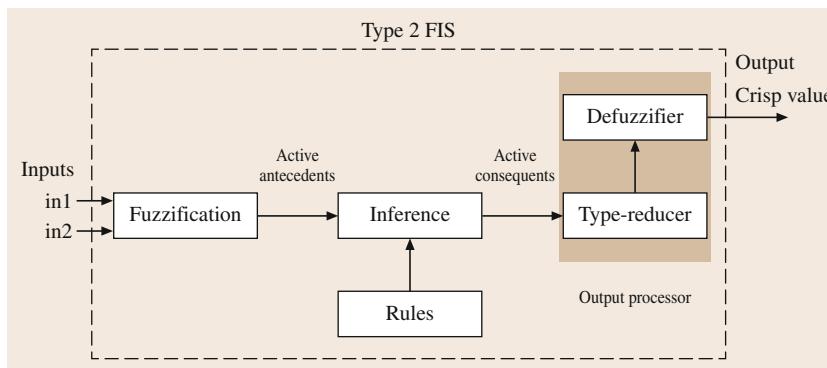

A type-2 **FLS** is again characterized by IF-THEN rules, but its antecedent or consequent sets are now of type-2. Similar to a type-1 **FLS**, a type-2 **FLS** includes a fuzzifier, a rule base, fuzzy inference engine, and an output processor, as we can see in Fig. 78.5. The output processor includes a type-reducer and a defuzzifier; it generates a type-1 fuzzy set output (type-reducer) or a crisp number (defuzzifier).

### Fuzzifier

The fuzzifier maps a crisp point  $\mathbf{x} = (x_1, \dots, x_p)^T \in X_1 \times X_2 \times \dots \times X_p \equiv \mathbf{X}$  into a type-2 fuzzy set  $\tilde{A}_x$  in  $\mathbf{X}$  [78.1], interval type-2 fuzzy sets in this case. We will use type-2 singleton fuzzifier, in a singleton fuzzification, the input fuzzy set has only a single point on nonzero membership [78.3].  $\tilde{A}_x$  is a type-2 fuzzy singleton if  $\mu_{\tilde{A}_x}(x) = 1/1$  for  $\mathbf{x} = \mathbf{x}'$  and  $\mu_{\tilde{A}_x}(x) = 1/0$  for all other  $\mathbf{x} \neq \mathbf{x}'$  [78.1].

### Rules

The structure of rules in a type-1 **FLS** and a type-2 **FLS** is the same, but in the latter the antecedents and the consequents will be represented by type-2 fuzzy sets. So for a type-2 **FLS** with  $p$  inputs  $x_1 \in X_1, \dots, x_p \in X_p$  and one output  $y \in Y$ , multiple input single output (**MISO**). If we assume that there are  $M$  rules, the  $l$ -th rule in the

**Fig. 78.5** Type-2 FLS

type-2 FLS can be written as follows [78.3]

$$\begin{aligned} R^l : & \text{IF } x_1 \text{ is } \tilde{F}_1^l \text{ and } \dots \text{ and } x_p \text{ is } \tilde{F}_p^l, \\ & \text{THEN } y \text{ is } \tilde{G}^l, \\ l = 1, \dots, M. \end{aligned} \quad (78.5)$$

### Inference

In the type-2 FLS, the inference engine combines rules and gives a mapping from input type-2 fuzzy sets to output type-2 fuzzy sets. It is necessary to compute the join  $\sqcup$ , (unions) and the meet  $\Pi$  (intersections), as well as extended sup-star compositions of type-2 relations [78.3]. If

$$\tilde{F}_1^l \times \dots \times \tilde{F}_p^l = \tilde{A}^l,$$

(78.5) can be re-written as

$$R^l : \tilde{F}_1^l \times \dots \times \tilde{F}_p^l \rightarrow \tilde{G}^l = \tilde{A}^l \rightarrow \tilde{G}^l, \quad l = 1, \dots, M. \quad (78.6)$$

$R^l$  is described by the membership function  $\mu_{R^l}(\mathbf{x}, y) = \mu_{R^l}(x_1, \dots, x_p, y)$ , where

$$\mu_{R^l}(\mathbf{x}, y) = \mu_{\tilde{A}^l \rightarrow \tilde{G}^l}(\mathbf{x}, y) \quad (78.7)$$

can be written as [78.3]

$$\begin{aligned} \mu_{R^l}(\mathbf{x}, y) &= \mu_{\tilde{A}^l \rightarrow \tilde{G}^l}(\mathbf{x}, y) = \mu_{\tilde{F}_1^l}(x_1) \\ &\times \Pi \dots \Pi \mu_{\tilde{F}_p^l}(x_p) \Pi \mu_{\tilde{G}^l}(y) \\ &= \left[ \prod_{i=1}^p \mu_{\tilde{F}_i^l}(x_i) \right] \Pi \mu_{\tilde{G}^l}(y). \end{aligned} \quad (78.8)$$

In general, the  $p$ -dimensional input to  $R^l$  is given by the type-2 fuzzy set  $\tilde{A}_x$  whose membership function is

$$\mu_{\tilde{A}_x}(\mathbf{x}) = \mu_{\tilde{X}_1}(x_1) \Pi \dots \Pi \mu_{\tilde{X}_p}(x_p) = \prod_{i=1}^p \mu_{\tilde{X}_i}(x_i), \quad (78.9)$$

where  $\tilde{X}_i (i = 1, \dots, p)$  are the labels of the fuzzy sets describing the inputs. Each rule  $R^l$  determines a type-2 fuzzy set  $\tilde{B}^l = \tilde{A}_x \circ R^l$  such that [78.3]

$$\begin{aligned} \mu_{\tilde{B}^l}(y) &= \mu_{\tilde{A}_x \circ R^l} = \sqcup_{x \in \mathbf{X}} [\mu_{\tilde{A}_x}(\mathbf{x}) \Pi \mu_{R^l}(\mathbf{x}, y)], \\ y \in Y, \quad l &= 1, \dots, M. \end{aligned} \quad (78.10)$$

This equation is the input/output relation in Fig. 78.5 between the type-2 fuzzy set that activates one rule in

the inference engine and the type-2 fuzzy set at the output of that engine [78.3]. In the FLS we used interval type-2 fuzzy sets and meet under product  $t$ -norm, so the result of the input and antecedent operations, which are contained in the firing set  $\prod_{i=1}^p \mu_{\tilde{F}_i^l}(x'_i \equiv F^l(\mathbf{x}'))$ , is an interval type-1 set [78.3],

$$F^l(\mathbf{x}') = \left[ \underline{f}^l(\mathbf{x}'), \bar{f}^l(\mathbf{x}') \right] \equiv \left[ \underline{f}^l, \bar{f}^l \right], \quad (78.11)$$

where

$$\underline{f}^l(\mathbf{x}') = \underline{\mu}_{\tilde{F}_1^l}(x'_1) * \dots * \underline{\mu}_{\tilde{F}_p^l}(x'_p), \quad (78.12)$$

$$\bar{f}^l(\mathbf{x}') = \bar{\mu}_{\tilde{F}_1^l}(x'_1) * \dots * \bar{\mu}_{\tilde{F}_p^l}(x'_p), \quad (78.13)$$

where  $*$  is the product operation.

### Type-Reducer

The type-reducer generates a type-1 fuzzy set output, which is then converted in a crisp output through the defuzzifier. This type-1 fuzzy set is also an interval set, for the case of our FLS we used center of sets (cosss) type reduction,  $Y_{\text{cos}}$ , which is expressed as [78.3]

$$\begin{aligned} Y_{\text{cos}}(\mathbf{x}) &= [y_l, y_r] = \int_{y^1 \in [y_l^1, y_r^1]} \dots \int_{y^M \in [y_l^M, y_r^M]} \\ &\times \int_{f^1 \in [\underline{f}^1, \bar{f}^1]} \dots \int_{f^M \in [\underline{f}^M, \bar{f}^M]} 1 \left/ \frac{\sum_{i=1}^M f^i y^i}{\sum_{i=1}^M f^i} \right.. \end{aligned} \quad (78.14)$$

This interval set is determined by its two end points,  $y_l$  and  $y_r$ , which correspond to the centroid of the type-2 interval consequent set  $\tilde{G}^l$  [78.3],

$$C_{\tilde{G}^l} = \int_{\theta_1 \in J_{y^1}} \dots \int_{\theta_N \in J_{y^N}} 1 \left/ \frac{\sum_{i=1}^N y_i \theta_i}{\sum_{i=1}^N \theta_i} \right. = [y_l^i, y_r^i]. \quad (78.15)$$

Before the computation of  $Y_{\text{cos}}(\mathbf{x})$ , we must evaluate (78.15) and its two end points,  $y_l$  and  $y_r$ . If the values of  $f_i$  and  $y_i$  that are associated with  $y_l$  are denoted  $f_l^i$  and  $y_l^i$ , respectively, and the values of  $f_i$  and  $y_i$  that are associated with  $y_r$  are denoted  $f_r^i$  and  $y_r^i$ , respectively, from (78.14), we have [78.3]

$$y_l = \frac{\sum_{i=1}^M f_l^i y_l^i}{\sum_{i=1}^M f_l^i}, \quad (78.16)$$

$$y_r = \frac{\sum_{i=1}^M f_r^i y_r^i}{\sum_{i=1}^M f_r^i}. \quad (78.17)$$

### Defuzzifiers

From the type-reducer we obtain an interval set  $Y_{\text{cos}}$ ; to defuzzify it we use the average of  $y_l$  and  $y_r$ , so the defuzzified output of an interval singleton type-2 FLS

is [78.3]

$$y(\mathbf{x}) = \frac{y_l + y_r}{2}. \quad (78.18)$$

## 78.3 Bio-Inspired Optimization Methods

In this section a brief overview of the basic concepts from bio-inspired optimization methods needed for this work is presented.

### 78.3.1 Particle Swarm Optimization

Particle swarm optimization is a population-based stochastic optimization technique, which was developed by Eberhart and Kennedy in 1995. It was inspired by the social behavior of bird flocking or fish schooling [78.7]. (PSO) shares many similarities with evolutionary computation techniques such as the genetic algorithm (GA) [78.22].

The system is initialized with a population of random solutions and searches for optima by updating generations. However, unlike the GA, PSO has no evolution operators such as crossover and mutation. In PSO, the potential solutions, called particles, fly through the problem space by following the current optimum particles [78.18]. Each particle keeps track of its coordinates in the problem space, which are associated with the best solution (fitness) it has achieved so far (the fitness value is also stored). This value is called *pbest*. Another *best* value that is tracked by the particle swarm optimizer is the best value, obtained so far by any particle in the neighbors of the particle. This location is called *lbest*. When a particle takes all the population as its topological neighbors, the best value is a global best and is called *gbest* [78.15].

The particle swarm optimization concept consists of, at each time step, changing the velocity of (accelerating) each particle toward its *pbest* and *lbest* locations (local version of PSO). Acceleration is weighted by a random term, with separate random numbers being generated for acceleration toward *pbest* and *lbest* locations [78.7]. In the past several years, PSO has been successfully applied in many research and application areas. It has been demonstrated that PSO obtains better results in a faster, cheaper way compared with other methods [78.15]. Another reason that PSO is attractive is that there are few parameters to

adjust. One version, with slight variations, works well in a wide variety of applications. Particle swarm optimization has been considered for approaches that can be used across a wide range of applications, as well as for specific applications focused on a specific requirement.

The basic algorithm of PSO has the following nomenclature:

- $x_z^i$ : Particle position
- $v_z^i$ : Particle velocity
- $w_{ij}$ : Inertia weight
- $p_z^i$ : Best remembered individual particle position
- $p_z^g$ : Best remembered swarm position
- $c_1, c_2$ : Cognitive and social parameters
- $r_1, r_2$ : Random numbers between 0 and 1.

The equation to calculate the velocity is

$$v_{z+1}^i = w_{ij} v_z^i + c_1 r_1 (p_z^i - x_z^i) + c_2 r_2 (p_z^g - x_z^i), \quad (78.19)$$

and the position of the individual particles is updated as follows

$$x_{z+1}^i = x_z^i + v_{z+1}^i. \quad (78.20)$$

The basic PSO algorithm is defined as follows:

- 1) *Initialize*
  - a) Set constants  $z_{\max}, c_1, c_2$
  - b) Randomly initialize particle position  $x_0^i \in D$  in  $R^n$  for  $i = 1, \dots, p$
  - c) Randomly initialize particle velocities  $0 \leq v_0^i \leq v_0^{\max}$  for  $i = 1, \dots, p$
  - d) Set  $Z = 1$
- 2) *Optimize*
  - a) Evaluate function value  $f_k^i$  using design space coordinates  $x_k^i$
  - b) If  $f_z^i \leq f_{\text{best}}^i$  then  $f_{\text{best}}^i = f_z^i, p_z^i = x_z^i$ .
  - c) If  $f_z^i \leq f_{\text{best}}^g$  then  $f_{\text{best}}^g = f_z^i, p_z^g = x_z^i$ .
  - d) If stopping condition is satisfied then go to 3.

- e) Update all particle velocities  $v_z^i$  for  $i = 1, \dots, p$
  - f) Update all particle positions  $x_z^i$  for  $i = 1, \dots, p$
  - g) Increment  $z$ .
  - h) Goto 2(a).
- 3) Terminate.

### 78.3.2 Genetic Algorithms

Genetic algorithms (GAs) are adaptive heuristic search algorithms based on the evolutionary ideas of natural selection and genetic processes [78.21]. The basic principles of GAs were first proposed by Holland in 1975, inspired by the mechanism of natural selection, where stronger individuals are likely to be the winners in a competing environment [78.22]. GA assumes that the potential solution of any problem is an individual and can be represented by a set of parameters. These parameters are regarded as the genes of a chromosome and can be structured by a string of values in binary form. A positive value, generally known as a fitness value, is used to reflect the degree of *goodness* of the chromosome for the problem, which would be highly related with its objective value. The pseudocode of a GA is as follows:

- 1) Start with a randomly generated population of  $n$  chromosomes (candidate solutions to a problem).
1. Calculate the fitness of each chromosome in the population.
2. Repeat the following steps until  $n$  offspring have been created:
  - a) Select a pair of parent chromosomes from the current population, the probability of selection being an increasing function of fitness. Selection is done with replacement, meaning that the same chromosome can be selected more than once to become a parent.
  - b) With probability (crossover rate), perform crossover to the pair at a randomly chosen point to form two offspring.
  - c) Mutate the two offspring at each locus with probability (mutation rate), and place the resulting chromosomes in the new population.
- 2) Replace the current population with the new population.
- 3) Go to step 2.

The simple procedure just described above is the basis for most applications of GAs found in the literature [78.23, 24].

### 78.3.3 Ant Colony Optimization

Ant colony optimization (ACO) is a probabilistic technique that can be used for solving problems that can be reduced to finding good paths along graphs. This method was inspired from the behavior exhibited by ants in finding paths from the nest or colony to the food source.

Simple ant colony optimization (S-ACO) is an algorithmic implementation that adapts the behavior of real ants to solutions of minimum cost path problems on graphs [78.11]. A number of artificial ants build solutions for a certain optimization problem and exchange information about the quality of these solutions making allusion to the communication system of real ants [78.25].

Let us define the graph  $G = (V, E)$ , where  $V$  is the set of nodes and  $E$  is the matrix of the links between nodes.  $G$  has  $n_G = |V|$  nodes. Let us define  $L^k$  as the number of hops in the path built by the ant  $k$  from the origin node to the destiny node. Therefore, it is necessary to find

$$Q = \{q_a, \dots, q_f | q_i \in C\} , \quad (78.21)$$

where  $Q$  is the set of nodes representing a continuous path with no obstacles;  $q_a, \dots, q_f$  are former nodes of the path, and  $C$  is the set of possible configurations of the free space. If  $x^k(t)$  denotes a  $Q$  solution in time  $t$ ,  $f(x^k(t))$  expresses the quality of the solution. The S-ACO algorithm is based on (78.22)–(78.24)

$$p_{ij}^k(t) = \begin{cases} \frac{\tau_{ij}^k}{\sum_{j \in N_{ij}^k} \tau_{ij}^\alpha(t)} & \text{if } j \in N_i^k \\ 0 & \text{if } j \notin N_i^k \end{cases} , \quad (78.22)$$

$$\tau_{ij}(t) \leftarrow (1 - \rho) \tau_{ij}(t) , \quad (78.23)$$

$$\tau_{ij}(t+1) = \tau_{ij}(t) + \sum_{k=1}^{n_k} \tau_{ij}(t) . \quad (78.24)$$

Equation (78.22) represents the probability for an ant  $k$  located on a node  $i$  selects the next node denoted by  $j$ , where,  $N_i^k$  is the set of feasible nodes (in a neighborhood) connected to node  $i$  with respect to ant  $k$ ,  $\tau_{ij}$  is the total pheromone concentration of link  $ij$ , and  $\alpha$  is a positive constant used as a gain for the pheromone influence.

Equation (78.23) represents the evaporation pheromone update, where  $\rho \in [0, 1]$  is the evaporation rate value of the pheromone trail. The evaporation is

added to the algorithm in order to force the exploration of the ants and avoid premature convergence to sub-optimal solutions. For  $\rho = 1$  the search becomes completely random.

Equation (78.24), represents the concentration pheromone update, where  $\Delta\tau_{ij}^k$  is the amount of pheromone that an ant  $k$  deposits in a link  $ij$  in a time  $t$ .

The general steps of S-ACO are the following:

1. Set a pheromone concentration  $\tau_{ij}$  to each link  $(i,j)$ .
2. Place a number  $k = 1, 2, \dots, n_k$  in the nest.
3. Iteratively build a path to the food source (destiny node), using (78.22) for every ant.
  - Remove cycles and compute each route weight  $f(x^k(t))$ . A cycle could be generated when there are no feasible candidates nodes, that is, for any  $i$  and any  $k$ ,  $N_i^k = \emptyset$ ; then the predecessor of that node is included as a former node of the path.
4. Apply evaporation using (78.2).
5. Update of the pheromone concentration using (78.24)
6. Finally, finish the algorithm in any of the three different ways:

- When a maximum number of epochs has been reached.
- When it has found an acceptable solution, with  $f(x_k(t)) < \varepsilon$ .
- When all ants follow the same path.

### 78.3.4 General Remarks About Optimization of Type-2 Fuzzy Systems

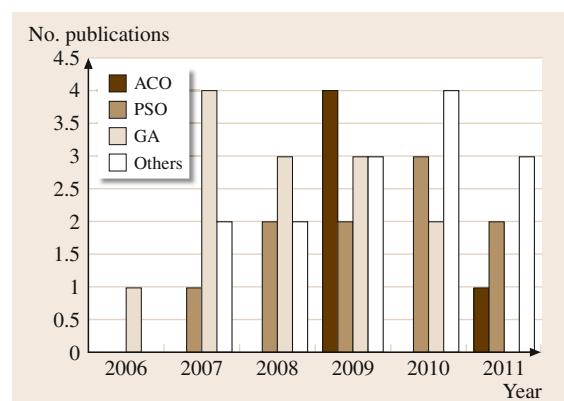

The problem of designing type-2 fuzzy systems can be solved with any of the above-mentioned optimization methods. The main issue in any of these methods is to decide on the appropriate representation of the type-2 fuzzy system in the corresponding optimization paradigm. For example, in the case of **GAs**, the type-2 fuzzy systems must be represented in the chromosomes. On the other hand, in **PSO** the fuzzy system is represented as a particle in the optimization process. In the **ACO** method, the fuzzy system can be represented as one of the paths that the ants can follow in a graph. Also, the evaluation of the fuzzy system must be represented as an objective function in any of the methods.

## 78.4 General Overview of the Area and Future Trends

In this section, a general overview of the area of type-2 fuzzy system optimization is presented. Also, possible future trends that we can envision based on the review of this area are presented. It has been well known for a long time that to design fuzzy systems is a difficult task, and this is especially true in the case of type-2 fuzzy systems [78.4]. The use of **GAs**, **ACO**, and **PSO** in designing type-1 fuzzy systems has become standard practice for automatically designing this sort of system [78.7, 8, 23, 25]. This trend has also continued to the type-2 fuzzy systems area, which has been accounted for with the review of papers presented in the previous sections. In the case of designing type-2 fuzzy systems the problem is more complicated due to the higher number of parameters to consider, making it of very important to use bio-inspired optimization techniques to achieve the optimal designs of this sort of system. In this section, a summary of the total number of papers published in the area of type-2 fuzzy system optimization is presented, so that the increasing trend occurring in this area can be better appreciated. Also, the distribution of papers according to the optimization technique used is presented, so that a general

idea of how these different techniques contribute to the automatic design of optimal type-2 fuzzy systems is obtained.

Figure 78.6 shows the distribution of the papers published on the optimization of type-2 fuzzy systems according to the different bio-inspired optimization techniques previously mentioned. From Fig. 78.6 it can

**Fig. 78.6** Distribution of publications per area and year

be noted that the use of **GAs** has been decreasing recently. On the other hand, the use of **PSO**, **ACO**, and other methods have been increasing. The reason for the increase in use of **PSO** and **ACO** may be due to recent work in which either **PSO** or **ACO** have been able to outperform **GAs** for different applications. Regarding the question of which method would be the most appropriate for optimizing type-2 fuzzy systems, there is no easy answer. At the moment, what we can be sure of is that the techniques mentioned in this paper, and probably newer ones that may appear in the future, would certainly be tested in the optimization of type-2 fuzzy systems because the problem of automatically designing these types of systems is complex enough to require their use.

There are other bio-inspired or nature-inspired techniques that at the moment have not been applied to the optimization of type-2 fuzzy systems that may be worth mentioning. For example, membrane computing, harmony computing, electromagnetism-based computing, and other similar approaches have not been applied (to date) in the optimization of type-2 fuzzy systems. It is expected that these approaches and similar ones could be applied in the near future in the area of type-2 fuzzy system optimization. Of course, as new bio-inspired and nature-inspired optimization methods are continuously being proposed in this fruitful area of research, it is expected that newer optimization techniques will also be tried in the near future in the automatic design of optimal type-2 fuzzy systems.

## 78.5 Conclusions

In this chapter we have presented a representative account of the different optimization methods that have been applied in the optimal design of type-2 fuzzy systems. To date, genetic algorithms have been used more frequently to optimize type-2 fuzzy systems. However, more recently **PSO** and **ACO** have attracted more attention and have also been applied with some degree of success to the problem of the optimal design of type-2 fuzzy systems. There have been also other optimization methods applied

to the optimization of type-2 fuzzy systems, like artificial immune systems and the chemical optimization paradigm. At this time, it would be very difficult to declare one of these optimization techniques as the best for optimizing type-2 fuzzy systems, because different techniques have had success in different applications of type-2 fuzzy logic. In any case, the need for bio-inspired optimization methods is justified due to the complexity of designing type-2 fuzzy systems.

# 79. Pattern Recognition with Modular Neural Networks and Type-2 Fuzzy Logic

Patricia Melin

Interval type-2 fuzzy systems can be of great help in image analysis and pattern recognition applications. In particular, edge detection is a process usually applied to image sets before the training phase in recognition systems. This preprocessing step helps to extract the most important shapes in an image, ignoring the homogeneous regions and remarking the real objective to classify or recognize. Many traditional and fuzzy edge detectors can be used, but it is very difficult to demonstrate which one is better before the recognition results are obtained. In this chapter, we show experimental results where several edge detectors were used to preprocess the same image sets. Each resulting image set was used as training data for a modular neural network recognition system, and the recognition rates were compared. The goal of these experiments is to find the better edge detector that can be used to improve the training

data of a modular neural network for an image recognition system.

## 79.1 Related Work in the Area

In previous work, we have proposed extensions to the traditional edge detectors to improve their performance by using fuzzy systems [79.1–3]. The performed experiments have shown that the resulting images obtained with fuzzy edge detectors were visually better than the ones obtained with the traditional edge detection methods.

There is still work to be done on developing formal validation metrics for fuzzy edge detectors. In the literature, we can find comparison of edge detectors based on human observations [79.4–8], and some others that found the optimal values for parametric edge detectors [79.9].

Edge detectors can be used in recognition systems for different purposes, but in this work we are particularly interested in knowing, which is the best edge

detector for a neural recognition system. In this chapter, we present some experiments which show that fuzzy edge detectors are a good method to improve the performance of neural recognition systems, and for this reason we propose that the recognition rate of the neural networks can be used as an edge detection performance index.

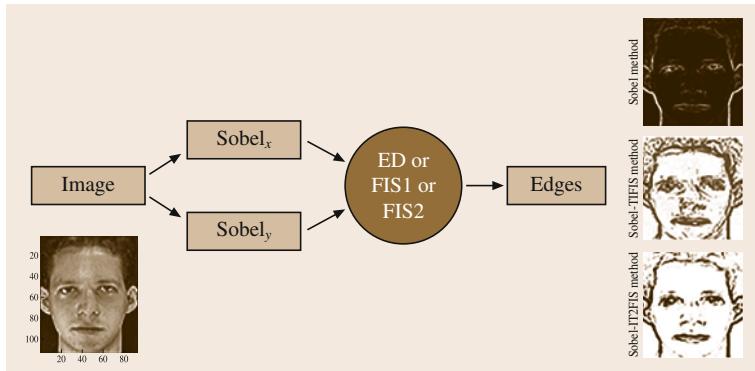

The rest of the chapter is organized as follows. Section 79.2 presents an overview of fuzzy edge detectors. Section 79.3 describes the experimental setup used to test the proposed fuzzy edge detectors in a modular neural recognition system. Section 79.4 presents the experimental results achieved with the proposed fuzzy edge detectors. Finally, Sect. 79.5 outlines the conclusions and future work.

## 79.2 Overview of Fuzzy Edge Detectors

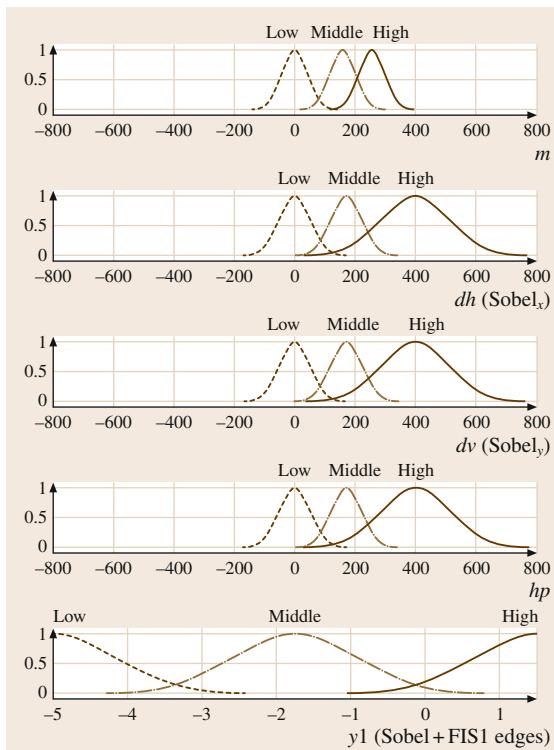

In this section, an overview of the previously proposed fuzzy edge detectors is presented. First, the Sobel edge detector improved with fuzzy logic is presented. Second, the morphological gradient edge detector enhanced with fuzzy logic is also presented.

### 79.2.1 Sobel Edge Detector Improved with Fuzzy Logic

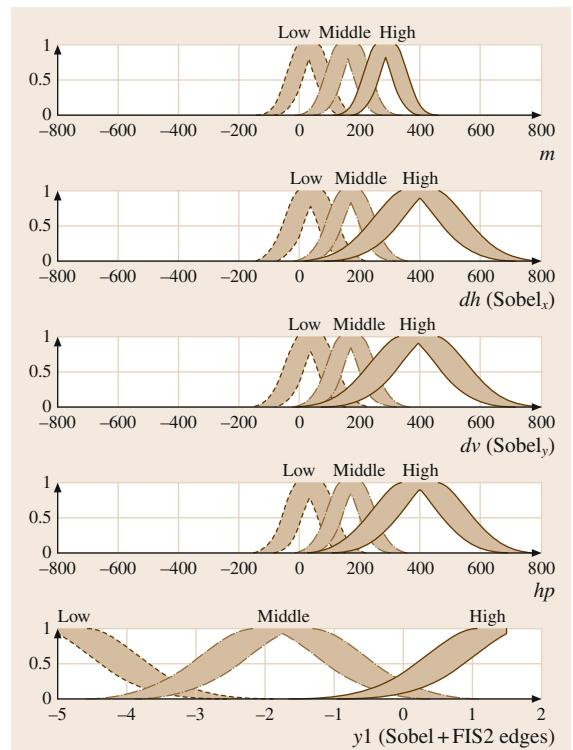

In the Sobel fuzzy edge detector we used the individual operators  $Sobel_x$  and  $Sobel_y$  as in the traditional method,

**Fig. 79.1** Sobel edge detector enhanced with fuzzy logic

**Fig. 79.2** Membership functions of the variables for the Sobel + FIS1 edge detector

**Fig. 79.3** Membership functions of the variables for the Sobel + FIS2 edge detector

and then we substitute the Euclidean distance of (79.1) by a fuzzy system, as shown in Fig. 79.1 [79.3].

$$\text{Sobel\_edges} = \sqrt{\text{Sobel}_x^2 + \text{Sobel}_y^2} \quad (79.1)$$

The individual Sobel operators are the main inputs to the type-1 fuzzy inference system (**FIS1**) and type-2 fuzzy inference system (**FIS2**), and we have also considered adding two more inputs, which are filters that improve the final edge image. The fuzzy variables used in the Sobel+**FIS1** and Sobel+ **FIS2** edges detectors are shown in Fig. 79.2 and Fig. 79.3, respectively.

The use of the **FIS2** [79.10, 11] provided images with better defined edges than the **FIS1**, which is a very important result in providing better inputs to the neural networks that will perform the recognition task.

The fuzzy rules for both the **FIS1** and **FIS2** are the same and are shown below:

1. If ( $dh$  is LOW) and ( $dv$  is LOW) then ( $y_1$  is HIGH)
2. If ( $dh$  is MIDDLE) and ( $dv$  is MIDDLE) then ( $y_1$  is LOW)
3. If ( $dh$  is HIGH) and ( $dv$  is HIGH) then ( $y_1$  is LOW)
4. If ( $dh$  is MIDDLE) and ( $hp$  is LOW) then ( $y_1$  is LOW)
5. If ( $dv$  is MIDDLE) and ( $hp$  is LOW) then ( $y_1$  is LOW)
6. If ( $m$  is LOW) and ( $dv$  is MIDDLE) then ( $y_1$  is HIGH)
7. If ( $m$  is LOW) and ( $dh$  is MIDDLE) then ( $y_1$  is HIGH)

The fuzzy rule base shown above infers the gray tone of each pixel for the edge image with the following reasoning: When the horizontal gradient  $d_h$  and vertical

gradient  $d_v$  are LOW means that there is not enough difference between the gray tones in its neighbors pixels, then the output pixel must belong of an homogeneous or not edges region, then the output pixel is HIGH or near WHITE. In the opposite case, when  $d_h$  and  $d_v$  are both HIGH this means that there is enough difference between the gray tones in its neighborhood, then the output pixel is an EDGE.

### 79.2.2 Morphological Gradient Edge Detector Improved with Fuzzy Logic

In the morphological gradient (**MG**), we calculated the four gradients as in the traditional method [79.12, 13], and substitute the sum of gradients in (79.2) with a fuzzy inference system, as shown in Fig. 79.4.

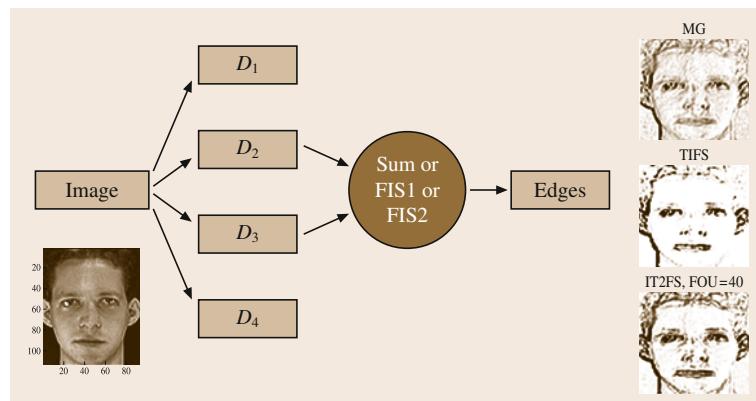

$$\text{MG\_edges} = D_1 + D_2 + D_3 + D_4 \quad (79.2)$$

The linguistic variables used in the MG+**FIS1** and MG+**FIS2** edges detectors are shown in Fig. 79.5 and Fig. 79.6, respectively.

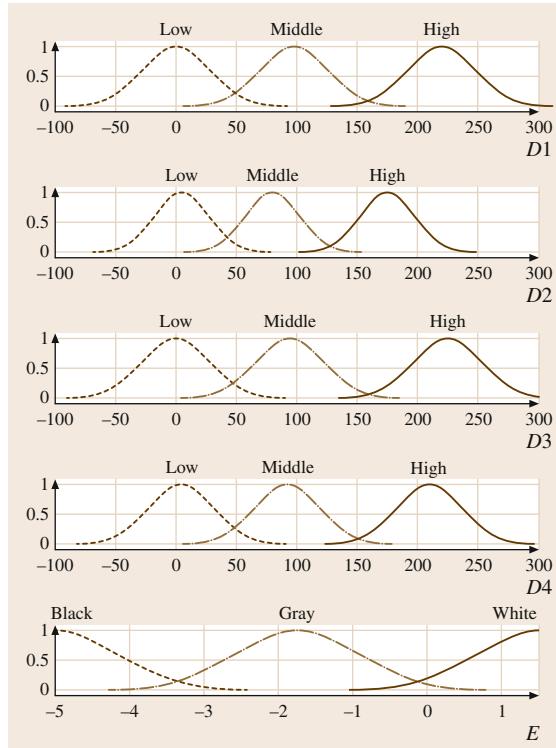

The rules for both the **FIS1** and **FIS2** are the same and are shown below:

1. If ( $D_1$  is HIGH) or ( $D_2$  is HIGH) or ( $D_3$  is HIGH) or ( $D_4$  is HIGH) then ( $E$  is BLACK)
2. If ( $D_1$  is MIDDLE) or ( $D_2$  is MIDDLE) or ( $D_3$  is MIDDLE) or ( $D_4$  is MIDDLE) then ( $E$  is GRAY)
3. If ( $D_1$  is LOW) and ( $D_2$  is LOW) and ( $D_3$  is LOW) and ( $D_4$  is LOW) then ( $E$  is WHITE)

After many experiments, we found that an edge exists when any gradient  $D_i$  is HIGH, which means that a difference of gray tones in any direction of the image must produce a pixel with a BLACK value or EDGE. The same behavior occurs when any gradient  $D_i$  is

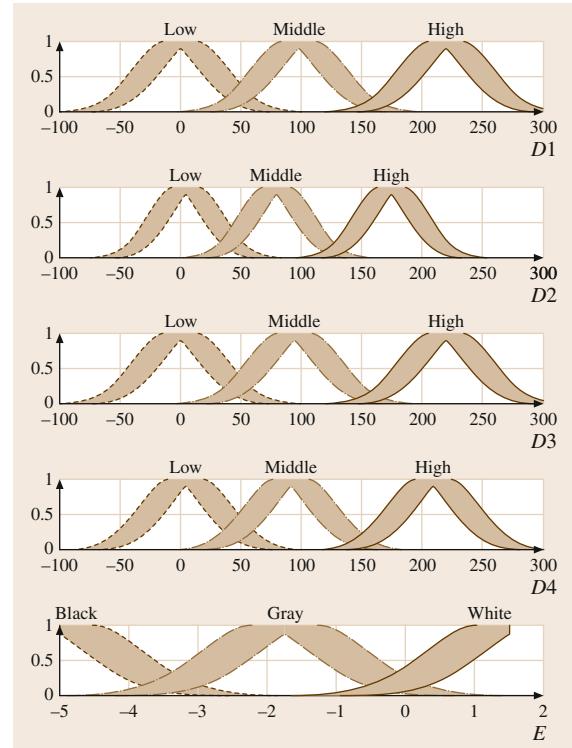

**Fig. 79.4** Morphological gradient edge detector enhanced with fuzzy systems

**Fig. 79.5** Membership functions of the variables for the MG+FIS1 edge detector

MIDDLE, which means that even when the differences in the gray tones are not maximal, the pixel is an EDGE, then the only rule that found a non edge pixel is the

**Fig. 79.6** Membership functions of the variables for the MG+FIS2 edge detector

number 3, where only when all the gradients are LOW, the output pixel is WHITE, which means a pixel belonging to an homogeneous region.

## 79.3 Experimental Setup

The experiment consists on applying a neural recognition system using each of the previously presented edge detectors: Sobel, Sobel+FIS1, Sobel+FIS2, morphological gradient (MG), morphological gradient+FIS1 and morphological gradient+FIS2 and then comparing the results.

### 79.3.1 General Algorithm used for the Experiments

1. Define the database folder.
2. Define the edge detector.
3. Detect the edges of each image as a vector and store it as a column in a matrix.

4. Calculate the recognition rate using the  $k$ -fold cross-validation method.
  - a) Calculate the indices for training and test  $k$ -folds.
  - b) Train the neural network  $k-1$  times, one for each training fold calculated previously.
  - c) Test the neural network  $k$  times, one for each fold test set calculated previously.
5. Calculate the mean rate for all the  $k$ -folds.

### 79.3.2 Parameters for the Images Databases

The experiments can be performed with benchmark image databases used for identification purposes. This

**Table 79.1** Particular information for the tested benchmark face databases

| Database     | Person number ( $p$ ) | Samples number ( $s$ ) | Fold size ( $m$ ) | Training set size ( $i$ ) | Test set size ( $t$ ) |
|--------------|-----------------------|------------------------|-------------------|---------------------------|-----------------------|
| ORL          | 40                    | 10                     | 80                | 320                       | 80                    |
| Cropped Yale | 38                    | 10                     | 76                | 304                       | 76                    |
| FERET        | 74                    | 4                      | 74                | 222                       | 74                    |

is the case of face recognition applications, then we used three of the most popular benchmark sets of images, the ORL face database [79.14], the Cropped Yale face database [79.15, 16], and the FERET face database [79.17].

For the three databases, we defined the variable  $p$  as the person number and  $s$  as number of samples for each person. The tests were made with  $k$ -fold cross-validation method, with  $k = 5$  for the three databases. We can generalize the calculation of fold size  $m$  or number of samples in each fold, dividing the total number of samples for each person  $s$  by the fold number, and then multiplying the result by the person number  $p$  (3), then the train data set size  $i$  (4) can be calculated as the number of samples in  $k - 1$  folds  $m$ , and test data set size  $t$  (5) are the number of samples in only one fold.

$$m = (s/k)^* p \quad (79.3)$$

$$i = m(k - 1) \quad (79.4)$$

$$t = m. \quad (79.5)$$

The total number of samples used for each person were of 10 for the ORL and YALE databases; then if the

size  $m$  of each 5-fold is 2, the number of samples for training for each person is 8 and for testing is 2. For the experiments with the FERET face database, we use only the samples of 74 persons who have 4 frontal sample images. The particular information for each database is shown in Tab. 79.1.

### 79.3.3 The Modular Neural Network

In previous experiments with neural networks for image recognition, we have found a general structure with acceptable performance, even if it is not optimized. We used the same structure for multinet modular neural networks, in order to establish a standard for comparison for all the experiments [79.3, 18–23]. The general structure for the monolithic neural network is indicated below:

- Two hidden layers with 200 neurons.
- Learning algorithm: Gradient descent with momentum and adaptive learning rate backpropagation.
- Error goal 0.0001.

## 79.4 Experimental Results

In this section, we show the numerical results of the experiments. Table 79.2 contains the results for the ORL face database, Table 79.3 contains the results for the Cropped Yale database, and Table 79.4 contains the results for the FERET face database.

For a better appreciation of the results, we made plots for the values presented in Tables 79.2–79.4. Even

if this work does not pretend to make a comparison based on the training times as performance index for the edge detectors, it is interesting to note that the necessary time to reach the error goal is established for each experiment.

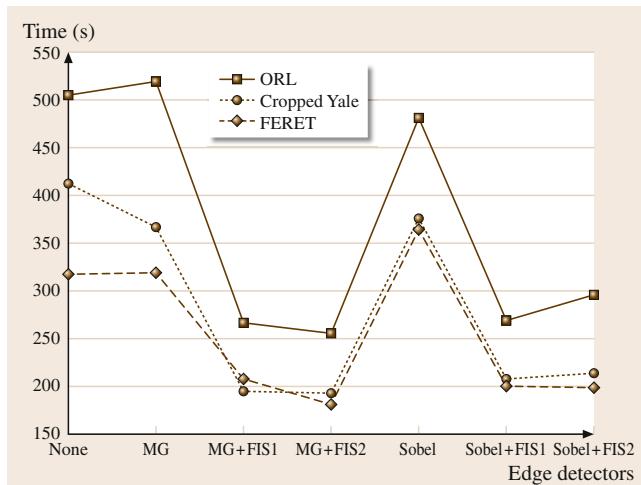

As we can see in Fig. 79.7, the lowest training times are for the morphological gradient+FIS2 edge

**Table 79.2** Recognition rates for the ORL database of faces

| Training set preprocessing method | Mean time (s) | Mean rate (%) | Standard deviation | Max rate (%) |
|-----------------------------------|---------------|---------------|--------------------|--------------|
| MG+FIS1                           | 1.2694        | 89.25         | 4.47               | 95.00        |
| MG+FIS2                           | 1.2694        | 90.25         | 5.48               | 97.50        |
| Sobel+FIS1                        | 1.2694        | 87.25         | 3.69               | 91.25        |
| Sobel+FIS2                        | 1.2694        | 90.75         | 4.29               | 95.00        |

**Table 79.3** Recognition rates for the cropped Yale database of faces

| Training set preprocessing method | Mean time (s) | Mean rate (%) | Standard deviation | Max rate (%) |
|-----------------------------------|---------------|---------------|--------------------|--------------|
| MG+FIS1                           | 1.76          | 68.42         | 29.11              | 100          |
| MG+FIS2                           | 1.07          | 88.16         | 21.09              | 100          |
| Sobel+FIS1                        | 1.17          | 79.47         | 26.33              | 100          |
| Sobel+FIS2                        | 1.1321        | 90            | 22.36              | 100          |

**Fig. 79.7** Training time for the compared edge detectors tested with the ORL, Cropped Yale and FERET face databases

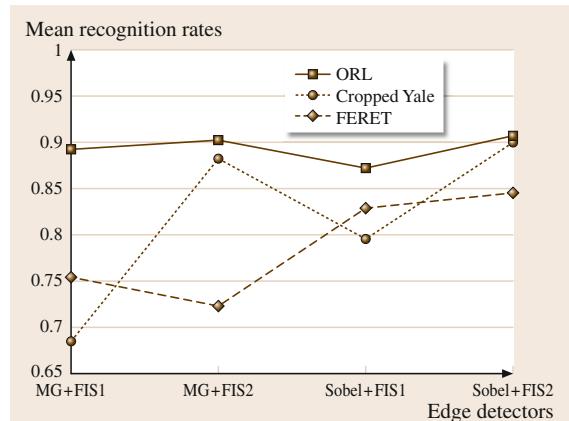

**Table 79.4** Recognition rates for the FERET database of faces

| Training set preprocessing method | Mean time (s) | Mean rate (%) | Standard deviation | Max rate (%) |
|-----------------------------------|---------------|---------------|--------------------|--------------|
| MG+FIS1                           | 1.17          | 75.34         | 5.45               | 79.73        |
| MG+FIS2                           | 1.17          | 72.30         | 6.85               | 82.43        |
| Sobel+FIS1                        | 1.17          | 82.77         | 00.68              | 83.78        |
| Sobel+FIS2                        | 1.17          | 84.46         | 03.22              | 87.84        |

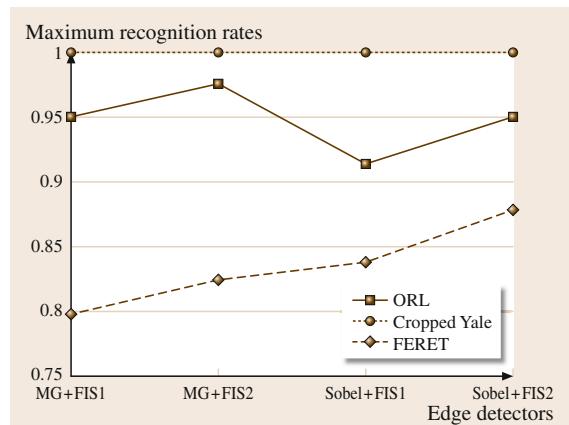

detector and Sobel+FIS2 edge detector. That is because both edge detectors were improved with interval type-2 fuzzy systems and produce images with more homogeneous areas; which means a high frequency of pixels near the WHITE linguistic values.

However, the main advantages of the interval type-2 edges detectors are the recognition rates plotted in Fig. 79.8, where we can notice that the best mean performance of the neural network was achieved when it was trained with the data sets obtained with the MG+FIS2 and Sobel+FIS2 edge detectors.

Figure 79.9 shows that the recognition rates are also better for the edge detectors improved with interval type-2 fuzzy systems. The maximum recognition rates could not be the better parameter to compare the

**Fig. 79.8** Mean recognition rates for the compared edge detectors with ORL, Cropped Yale and FERET face databases

**Fig. 79.9** Maximum recognition rates for the compared edge detectors with ORL, Cropped Yale and FERET face database

performance of the neural networks depending on the training set; but it is interesting to note that the maximum recognition rate of 97.5% was achieved when the neural network was trained with the ORL data set preprocessed with the MG+FIS2. This is important because in a real-world system, we can use this as the best configuration for images recognition, expecting to obtain good results.

## 79.5 Conclusions

This chapter is one of the first efforts to develop a comparison method for edge detectors as a function of their performance in different types of recognition systems. In this chapter, we show that Sobel and Morphologi-

cal Gradient edge detectors improved with type-2 fuzzy logic have better performance than the type-1 fuzzy edge detector and traditional methods in an image recognition system based on neural networks.

# 80. Fuzzy Controllers for Autonomous Mobile Robots

Patricia Melin, Oscar Castillo

This chapter addresses the tracking problem for the dynamic model of a unicycle mobile robot. A novel optimization method inspired from the chemical reactions is applied to solve this motion problem by integrating a kinematic and a torque controller based on fuzzy logic theory. Computer simulations are presented confirming that this optimization paradigm is able to outperform other optimization techniques applied to this particular robot application.

## 80.1 Fuzzy Control of Mobile Robots

Optimization is an activity carried out in almost every aspect of our life, from planning the best route of our way back home from work to more sophisticated approximations on the stock market, or the parameter optimization for a wave soldering process used in the manufacture of a printed circuit board assembly, optimization theory has gained importance over the last decades. From science to applied engineering (to name a few), there is always something to optimize and, of course, more than one way to do it.

In a generic definition, we may say that optimization aims to find the *best* available solution among a set of potential solutions in a defined search space. For almost every problem there exists a solution, not necessarily the best one, but we can always find an approximation to the *ideal solution*, and while in some cases or processes it is still common to use our own experience to qualify a process, a part of the research community has dedicated a considerable amount of time and effort to help find robust optimization methods for optima found in a vast range of applications.

That it is difficult to solve different problems by applying the same methodology, and even the most robust optimization approaches may be outperformed by other optimization techniques, depending on the problem to be solved.

When the complexity and the dimension of the search space make a problem unsolvable by a deterministic algorithm, probabilistic algorithms deal with this problem by going through a diverse set of possible solutions or candidate solutions. Many metaheuristic algorithms can be considered probabilistic because they apply probability tools to solve a problem; metaheuristic algorithms seek good solutions by mimicking natural processes or paradigms. Most of these novel optimization paradigms that were inspired by nature were conceived by mere observation of an existing process and their main characteristics were embodied as computational algorithms.

The importance of the optimization theory and its application has grown in the past few decades, from the well known genetic algorithm paradigm to particle swarm optimization (**PSO**), ant colony optimization

(ACO), harmonic search, deoxyribonucleic acid (DNA) computing, among others, abd they were all were introduced with the expectation that they would improve the results obtained with existing strategies.

There is no doubt that there could be some optimization strategies presented at some point that were left behind due their complexity and poor performance. Novel optimization paradigms should be able to perform well in comparison with another optimization techniques and must be *easily adaptable* to different kinds of problems.

Optimization based on chemical processes is a growing field that has been satisfactorily applied to several problems. In [80.1] a DNA-based algorithm was introduced to solve the small hitting set problem. A catalytic search algorithm was explored in [80.2], where some physical laws such as mass and energy conservation were taken into account. In [80.3], the potential roles of energy in algorithmic chemistries were illustrated. An energy framework was introduced, which keeps the molecules within reasonable length bounds, allowing the algorithm to behave thermodynamically and kinetically, similarly to real chemistry. A chemical reaction optimization was applied to a grid scheduling problem in [80.4], where molecules interact with each other aiming to reach the minimum state of free potential and kinetic energies. The main difference between these metaheuristics is the parameter representation, which can be explicit or implicit.

In this paper, we introduce an optimization method inspired by chemical reactions and its application for the optimization of the tracking controller of the dynamic model of the unicycle mobile robot.

The importance of applying this chemical optimization algorithm is that different methods have been applied to solve motion control problems. Kanayama et al. [80.5] propose a stable tracking control method for a nonholonomic vehicle using a Lyapunov function. Lee et al. [80.6] solved tracking control using backstepping and in [80.7] saturation constraints were used. Furthermore, most reported designs rely on intelligent control approaches such as fuzzy logic control [80.8–13] and neural networks [80.14, 15].

However, the majority of the publications mentioned above concentrated on kinematic models of mobile robots, which are controlled by the velocity input, while less attention has been paid to the control problems of nonholonomic dynamic systems, where forces and torques are the true inputs. Bloch and Drakunov [80.16] and Chwa [80.17] used sliding mode control for the tracking control problem. Fierro and Lewis [80.18] proposed a dynamical extension that makes the integration of kinematics and torque controller possible for a nonholonomic mobile robot. Fukao et al. [80.19] introduced an adaptive tracking controller for the dynamic model of mobile robots with unknown parameters using backstepping methodology, which has been recognized as a tool for solving several control problems [80.20, 21].

Motivated by this, herein a Mamdani fuzzy logic controller is introduced in order to drive the kinematic model to a desired trajectory in a finite time; considering the torque as the real input, a chemical reaction optimization paradigm is applied and simulations are shown.

Further publications [80.22–24] applied bio-inspired optimization techniques to find the parameters of the membership functions for the fuzzy tracking controller that solves the problem for the dynamic model of a unicycle mobile robot, using a fuzzy logic controller that provides the required torques to reach the desired velocity and trajectory inputs.

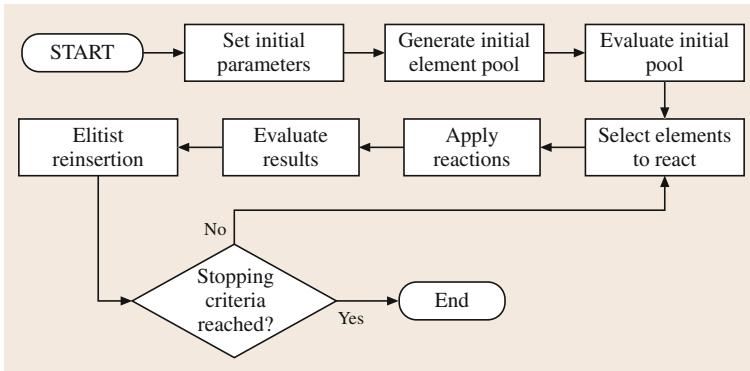

In this paper, the main contribution is the representation of the fuzzy controller in the chemical paradigm to search for the optimal parameters. Simulation results show that the proposed approach outperforms other nature-inspired computing paradigms, such as genetic algorithms, particle swarm, and ant colony optimization.

The rest of this chapter is organized as follows. Section 80.2 illustrates the proposed methodology. Section 80.3 describes the problem formulation and control objective. Section 80.4 describes the proposed fuzzy logic controller of the robot. Section 80.5 shows some experimental results of the tracking controller. In Sect. 80.6 some conclusions and future work are presented.

## 80.2 The Chemical Optimization Paradigm

The proposed chemical reaction algorithm is a metaheuristic strategy that performs a stochastic search for optimal solutions within a defined search space. In this

optimization strategy, every solution is represented as an element (or compound), and the fitness or performance of the element is evaluated in accordance with

**Fig. 80.1** General flowchart of the chemical reaction algorithm

the objective function. The general flowchart of the algorithm is shown in Fig. 80.1.

The main difference with other optimization techniques [80.1–4] is that no external parameters are taken into account to evaluate the results, while other algorithms introduce additional parameters (kinetic/potential energies, mass conservation, thermodynamic characteristics, etc.). This is a very straightforward methodology that takes the characteristics of the chemical reactions (synthesis, decomposition, substitution, and double-substitution) to find the optimal solution.

This approach is a static population-based metaheuristic that applies an abstraction of the chemical reactions as intensifiers (substitution, double substitution reactions) and diversifying (synthesis, decomposition reactions) mechanisms. The elitist reinsertion strategy allows the permanence of the best elements, and thus the average fitness of the entire element pool increases with every iteration. The algorithm may trigger only one reaction or all of them, depending on the nature of the problem to solve. For example, we may use only the decomposition reaction subroutine to find the minimum value of a mathematical function.

The pseudocode for the chemical reaction algorithm is as follows:

#### Algorithm 80.1 Chemical Reaction Algorithm

Input: *problem\_definition*, *objective\_function*, *dimensions*,

- 1: Assign values to variables: *pool\_size*, *trials*, *upper\_boundary*, *lower\_boundary*, *synthesis\_rate*, *decomposition\_rate*, *singlesubstitution\_rate*, *doublesubstitution\_rate*.
- 2: Generate randomly *Initial\_Pool* in interval [*lower\_boundary*, *upper\_boundary*]
- 3: Evaluate *Initial\_Pool*

```

4: Identify best_solution
5: while ( stopping criteria not met ) do
6:   Perform Synthesis_Procedure; Get Synthesis_vector
7:   Perform Decomposition_Procedure; Get Decomposition_vector
8:   Perform SingleSubstitution_Procedure; Get SingleSubstitution_vector
9:   Perform DoubleSubstitution_Procedure; Get DoubleSubstitution_vector
10:  Evaluate Synthesis_vector, Decomposition_vector, SingleSubstitution_vector, DoubleSubstitution_vector
11:  Apply elitist_reinsertion; Get improved_pool
12:  Update best_solution
13: end while
Output: best_solution

```

All nature-inspired paradigms have their own way to encode candidate solutions. When these parameters are defined, a set of processes or procedures are applied to lead the population to an optimal result. The main components of this chemical reaction algorithm are described below.

#### 80.2.1 Elements/Compounds

These are the basic components of the algorithm. Each element or compound represents a solution within the search space. The initial definition of elements and/or compounds depends on the problem itself and can be represented as binary numbers, integer, floating, etc. They interact with each other implicitly; that is, the definition of the interaction is independent of the real molecular structure. In this approach the potential and kinetic energies and other molecular characteristics are not taken into account.

## 80.2.2 Chemical Reactions

A chemical reaction is a process in which at least one substance changes its composition and its sets of properties. In this approach, the chemical reactions behave as intensifiers (substitution, double substitution reactions) and diversifying (synthesis, decomposition reactions) mechanisms. The four chemical reactions considered in this approach are the *synthesis*, *decomposition*, *single and double-substitution reactions*. The objective of these operators is to explore or exploit new possible solutions within a slightly larger hypercube than the original elements/compounds, but within the previously specified range.

The *synthesis* and *decomposition* reactions are used to diversify the resulting solutions; these procedures were shown to be highly effective and to rapidly lead the results to a desired value. They can be described as follows.

### 80.2.3 Synthesis Reactions

This is a reaction of two reactants to produce one product. By combining two (or more) elements, this procedure allows us to explore higher-valued solutions within the search space. The result can be described as a compound ( $B + C \rightarrow BC$ ). The pseudocode for the synthesis reaction procedure is as follows:

#### Algorithm 80.2 Synthesis\_Procedure

```
Input: selected_elements, synthesis_rate
1: n = size ( selected_elements )
2: i = floor ( n/2 )
3: for j = 1 to i - 1
4:   Synthesis = selected_elementsi
      + selected_elementsj+1
5:   j = j + 2
6: end for
Output: Synthesis_vector
```

### 80.2.4 Decomposition Reactions

In this reaction, typically, only one reactant is given, which allows a compound to be decomposed into smaller instances ( $BC \rightarrow B + C$ ). The pseudocode for the decomposition reaction procedure is as follows:

#### Algorithm 80.3 Decomposition\_Procedure

```
Input: selected_elements, decomposition_rate
1: n = size ( selected_elements )
```

**Table 80.1** Main elements of several nature-inspired paradigms

| Paradigm | Parameter representation | Basic operations                                                                    |
|----------|--------------------------|-------------------------------------------------------------------------------------|
| GA       | Genes                    | Crossover, mutation                                                                 |
| ACO      | Ants                     | Pheromone                                                                           |
| PSO      | Particles                | Cognitive, social coefficients                                                      |
| GP       | Trees                    | Crossover, mutation<br>(In some cases)                                              |
| CRM      | Elements,<br>Compounds   | Reactions (combination,<br>decomposition,<br>Substitution, double-<br>substitution) |

```
2: Get randval randomly in interval [ 0, 1 ]
3: for i = 1 to n
4:   Deco1 = selected_elementsi × randval
5:   Deco2 = selected_elementsi × ( 1 - randval )
6:   i = i + 1
7: end for
Output: Decomposition_vector ( Deco1, Deco2)
```

The *single* and *double-substitution* reactions allow the algorithm to search for optima around a previously found good solution and they are described below.

### 80.2.5 Single-Substitution Reactions

When a free element reacts with a compound of different elements, the free element will replace one of the elements in the compound if the free element is more reactive than the element it replaces. A new compound and a new free element are produced. In the algorithm, a compound and an element are selected and a decomposition reaction is applied to the compound; two elements are generated from this operation. Then, one of the new generated elements is combined with the non-decomposed selected element ( $C + AB \rightarrow AC + B$ ). The pseudocode for the single-substitution reaction procedure is as follows:

#### Algorithm 80.4 SingleSubstitution\_Procedure

```
Input: selected_elements, singlesubstitution_rate
1: n = size ( selected_elements )
2: i = floor ( n/2 )
3: a = selected_elements1, selected_elements2, ..., selected_elementsi
4: b = selected_elementsi+1, selected_elementsi+2, ..., selected_elementsn
5: Apply Decomposition_Procedure to a; Get Deco1, Deco2
```

6: Apply *Synthesis\_Procedure* ( $b + Deco_1$ ); Get *Synthesis\_vector* Output: *SingleSubstitution\_vector*  
 ( *Synthesis\_vector*, *Deco<sub>2</sub>* )

4:  $b = selected\_elements_{i+1}, selected\_elements_{i+2}, \dots, selected\_elements_{i\times 2}$   
 5: Apply *Decomposition\_Procedure* to  $a$  and  $b$ ; Get (*Deco<sub>1</sub>*, *Deco<sub>2</sub>*), (*Deco<sub>1</sub>'*, *Deco<sub>2</sub>'*)  
 6: Apply *Synthesis\_Procedure* (*Deco<sub>1</sub>* + *Deco<sub>1</sub>'*), (*Deco<sub>2</sub>* + *Deco<sub>2</sub>'*); Get *Synthesis\_vector<sub>1</sub>*, *Synthesis\_vector'<sub>1</sub>*  
 Output: *SingleSubstitution\_vector*  
 ( *Synthesis\_vector<sub>1</sub>*, *Synthesis\_vector'<sub>1</sub>* )

### 80.2.6 Double-Substitution Reactions

Double-substitution or double-replacement reactions, also called double-decomposition reactions or metathesis reactions, involve two ionic compounds, most often in aqueous solution. In this type of reaction, the cations simply swap anions; in the algorithm, a similar process to that in the previous reaction happens. The difference is that in this reaction both of the selected compounds are decomposed, and the resulting elements are combined with each other ( $AB + CD \rightarrow CB + AD$ ). The pseudocode for the double-substitution reaction procedure is as follows:

#### Algorithm 80.5 DoubleSubstitution\_Procedure

Input: *selected\_elements*, *doublesubstitution\_rate*

- 1:  $n = size ( selected\_elements )$
- 2:  $i = floor ( n/2 )$
- 3:  $a = selected\_elements_1, selected\_elements_2, \dots, selected\_elements_i$

In this chemical reaction algorithm we may trigger only one reaction or all of them, depending on the nature of the problem to be solved, e.g., we can apply only the decomposition reaction subroutine to find the minimum value of a mathematical function.

Throughout the execution of the algorithm, whenever a new set of elements/compounds is created, an elitist reinsertion criterion is applied, allowing the permanence of the best elements, and thus the average fitness of the entire element pool increases through iterations.

In order to have a better picture of the general schema for this proposed chemical reaction algorithm, a comparison with other nature-inspired paradigms is shown in Table 80.1.

## 80.3 The Mobile Robot

Mobile robots are non-nonholonomic systems due to the constraints imposed on their kinematics. The equations describing the constraints cannot be integrated symbolically to obtain explicit relationships between robot positions in local and global coordinates' frames. Hence, control problems that involve them have attracted attention in the control community in recent years [80.25].

The model considered is that of a unicycle mobile robot (see Fig. 80.2) that has two driving wheels fixed to the axis and one passive orientable wheel placed in front of the axis and normal to it [80.26].

The two fixed wheels are controlled independently by the motors, and the passive wheel prevents the robot from overturning when moving on a plane.

It is assumed that the motion of the passive wheel can be ignored from the dynamics of the mobile robot, which is represented by the following set of equations [80.18]

$$\dot{q} = \begin{vmatrix} \cos \theta & 0 \\ \sin \theta & 0 \\ 0 & 1 \end{vmatrix} \begin{vmatrix} v \\ w \end{vmatrix} \mathbf{M}(q)\dot{v} + V(q, \dot{q})v + G(q) = \tau, \quad (80.1)$$

where  $\mathbf{q} = [x, y, \theta]^T$  is the vector of generalized coordinates that describes the robot's position,  $(x, y)$  are the Cartesian coordinates, which denote the mobile center

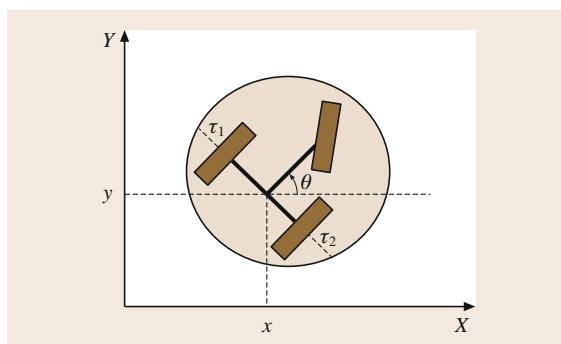

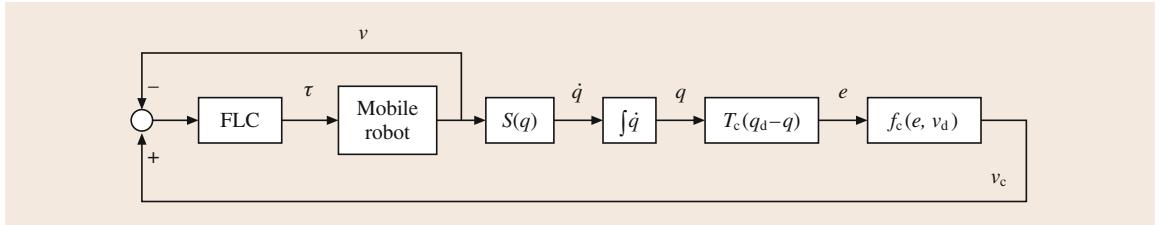

Fig. 80.2 Diagram of a wheeled mobile robot

**Fig. 80.3** Tracking control structure

of mass, and  $\theta$  is the angle between the heading direction and the  $x$ -axis (which is taken in counterclockwise form);  $v = [v, w]^T$  is the vector of velocities,  $v$  and  $w$  are linear and angular velocities respectively;  $\tau \in R^r$  is the input vector,  $M(q) \in R^{rxn}$  is a symmetric and positive-definite inertia matrix,  $V(q, \dot{q}) \in R^{nxn}$  is the centripetal and Coriolis matrix, and  $G(q) \in R^n$  is the gravitational vector. Equation (80.1) represents the kinematics or steering system of a mobile robot.

Notice the no-slip condition imposed a nonholonomic constraint described by (80.2), which means that the mobile robot can only move in the direction normal to the axis of the driving wheels.

$$\dot{y} \cos \theta - \dot{x} \sin \theta = 0. \quad (80.2)$$

The control objective will be established as follows: given a desired trajectory  $q_d(t)$  and the orientation of the mobile robot, we must design a controller that applies an adequate torque  $\tau$  such that the measured positions  $q(t)$  achieve the desired reference  $q_d(t)$  represented as (80.3)

$$\lim_{t \rightarrow \infty} \|q_d(t) - q(t)\| = 0. \quad (80.3)$$

To reach the control objective, the method is based on the procedure of [80.18], and we derive  $\tau(t)$  of a specific  $v_c(t)$  that controls the steering system (80.1) using a fuzzy logic controller (FLC). The general structure of a tracking control system is presented in Fig. 80.3.

The control is based on the procedure proposed by Kanayama et al. [80.5] and Nelson and Cox [80.27]

to solve the tracking problem for the kinematic model  $v_c(t)$ . Suppose that the desired trajectory  $q_d$  satisfies (80.4)

$$\dot{q}_d = \begin{vmatrix} \cos \theta_d & 0 \\ \sin \theta_d & 0 \\ 0 & 1 \end{vmatrix} \begin{vmatrix} v_d \\ w_d \end{vmatrix}. \quad (80.4)$$

Using the robot local frame (the moving coordinate system  $x$ - $y$  in Fig. 80.1), the error coordinates can be defined as (80.5)

$$e = T_e(q_d - q), \begin{vmatrix} e_x \\ e_y \\ e_\theta \end{vmatrix} = \begin{vmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{vmatrix} \begin{vmatrix} x_d - x \\ y_d - y \\ \theta_d - \theta \end{vmatrix}. \quad (80.5)$$

Moreover, the auxiliary velocity control input that achieves tracking for (80.1) is given by (80.6)

$$v_c = f_c(e, v_d), \begin{vmatrix} v_c \\ w_c \end{vmatrix} = \begin{vmatrix} v_d + \cos e_\theta + k_1 e_x \\ w_d + v_d k_2 e_y + v_d k_3 \sin e_\theta \end{vmatrix}, \quad (80.6)$$

where  $k_1$ ,  $k_2$  and  $k_3$  are positive gain constants.

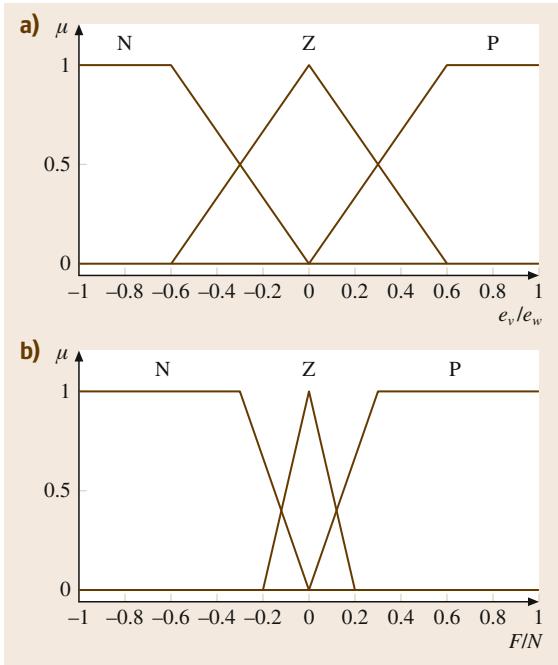

The first part for this work is to apply the proposed method to obtain the values of  $k_i$  ( $i = 1, 2, 3$ ) to achieve the optimal behavior of the controller, and the second part is to optimize the fuzzy controller.

## 80.4 Fuzzy Logic Controller

The purpose of the fuzzy logic controller (FLC) is to find a control input  $\tau$  such that the current velocity vector  $v$  is able to reach the velocity vector  $v_c$ , and this is

denoted as

$$\lim_{t \rightarrow \infty} \|v_c - v\| = 0. \quad (80.7)$$

**Fig. 80.4a,b** Membership functions of (a) input  $e_v$  and  $e_w$ , and (b) output variables  $F$  and  $N$

The input variables of the FLC correspond to the velocity errors obtained in (80.5) using the derivatives of

**Table 80.2** Fuzzy rule set

| $e_v/e_w$ | <b>N</b> | <b>Z</b> | <b>P</b> |
|-----------|----------|----------|----------|
| N         | N/N      | N/Z      | N/P      |
| Z         | Z/N      | Z/Z      | Z/P      |
| P         | P/N      | P/Z      | P/P      |

the position and angular errors (denoted as  $e_v$  and  $e_w$ ). The initial membership functions (MF) are defined by one triangular and two trapezoidal functions for each variable involved. Figure 80.4 depicts the MFs in which N, Z, P represent the fuzzy sets (negative, zero, and positive, respectively) associated to each input and output variable.

The rule set of the FLC contains nine rules, which govern the input–output relationship of the FLC, and this adopts the Mamdani-style inference engine. We use the center of gravity method to realize the defuzzification procedure. In Table 80.2 we present the rule set whose format is established as follows:

Rule i: If  $e_v$  is G1 and  $e_w$  is G2  
then F is G3 and N is G4 ,

where G1 ... G4 are the fuzzy sets associated to each variable  $i = 1 \dots 9$ . In this case, P denotes *positive*, N denotes *negative*, and Z denotes *zero*.

## 80.5 Experimental Results

Several tests of the chemical optimization paradigm were made to test the performance of the tracking controller. First, we need to find the values of  $k_i$  ( $i = 1, 2, 3$ ) shown in (80.6), which will guarantee convergence of the error  $e$  to zero.

To evaluate the constants obtained by the algorithm, the mobile robot tracking system, which consists in (80.5) and (80.6), was modeled using Simulink. Figure 80.5 shows the closed loop for the tracking controller.

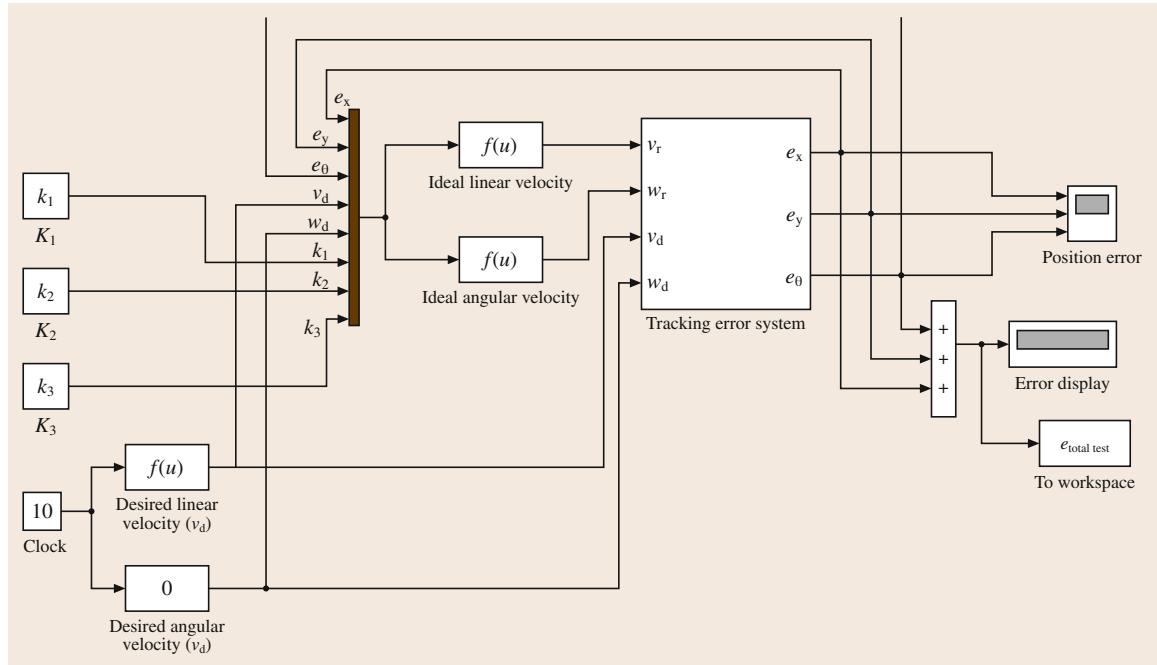

The conditions to evaluate each result, which correspond to the final position error, are given by (80.8):

$$\text{EP} = \sum_{i=1}^n \frac{e_x(i) + e_y(i) + e_\theta(i)}{n} . \quad (80.8)$$

For the first set of experiments only the decomposition reaction mechanism was triggered and the decomposition factor was varied; this factor is the quantity of resulting elements after applying a decomposition reaction to a determined *compound*. The only restriction here is that  $x$  be the selected compound and  $x'_i$  ( $i = 1, 2, \dots, n$ ) the resulting elements. The sum of all values found in the decomposition must be equal to the value of the original compound. This is shown in (80.9)

$$\sum_{i=1}^n x'_i = x . \quad (80.9)$$

Each experiment was executed 35 times and the test parameters for each set of experiments can be observed in Table 80.3.

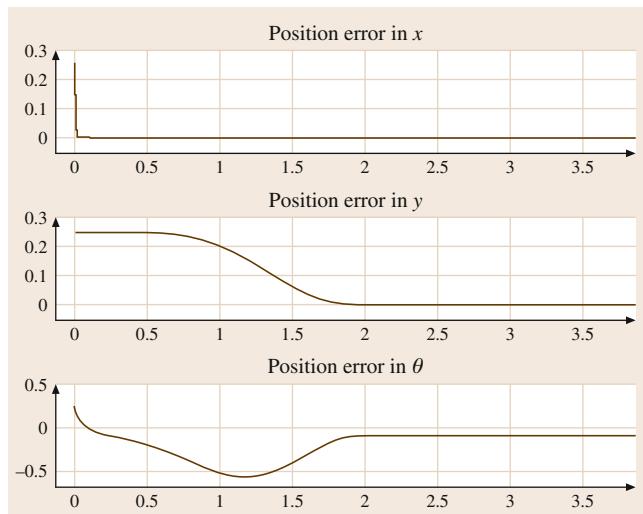

**Fig. 80.5** Closed loop for the tracking controller system

The decomposition rate (Dec. rate) represents the percentage of the pool that are candidates for the decomposition and the decomposition factor (Dec. factor) is the number of elements that are to be decomposed into.

The selection strategy applied was stochastic universal sampling, which uses a single random value to

**Table 80.3** Parameters of the chemical reaction optimization

| No. | Elements | Iterations | Dec. factor | Dec. rate |
|-----|----------|------------|-------------|-----------|

| $k_3$            | 137                           |
| Error            | 2.7736                        |

sample all of the solutions by choosing them at evenly spaced intervals. In the example, for a pool containing five initial compounds, the vector length of decomposed elements when the decomposition factor is 3 and the decomposition rate is 0.4 will be six elements.

By applying this criterion, the initial pool of elements increased with every iteration. This is why the initial element pool was set to ten elements as the maximum. Table 80.4 shows the results after applying the chemical optimization paradigm.

As can be observed in Table 80.4, experiment number 6 seems to have the best result because it reached the smaller final error among all experiments. Figure 80.6 shows the final position errors in  $x$ ,  $y$ , and  $\theta$  for experiment number 6.

**Fig. 80.7** Final position errors in  $x$ ,  $y$ , and  $\theta$  for experiment number 3**Fig. 80.8** Position errors in  $x$ ,  $y$ , and  $\theta$  of best result by applying GAs

By analyzing the graphical results of several sets of exercises, we noticed that the control obtained for some of them was *smoother* despite the average error value. This was the case for experiment number 3, in which the final error value was significantly higher than that obtained in experiment number 6. Figure 80.7 shows the final position errors in  $x$ ,  $y$ , and  $\theta$  for experiment number 3.

Comparing both graphics, we can observe that the average error obtained for  $\theta$  is 0.0338 for experiment

number 6 and 0.0315 for experiment number 3. This smoother control of the tracking system could make a big difference in the complete dynamic system of the mobile robot.

In previous work [80.28], the gain constant values were found by means of genetic algorithms. Table 80.5 shows a comparison of the best results obtained with both algorithms, and we can observe that the result with the chemical optimization outperforms the GA in finding the best gain values.

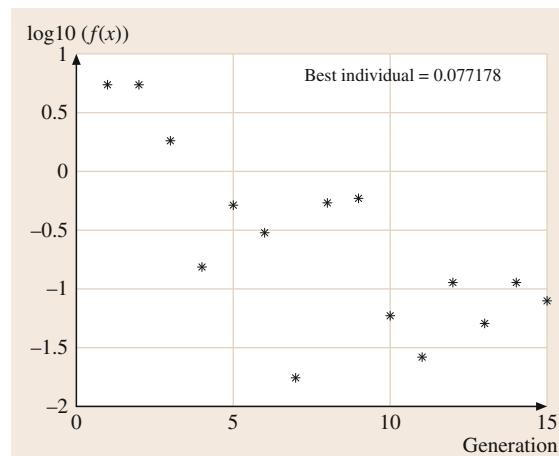

Figure 80.8 shows the result in Simulink for the experiment with the best overall result when applying GAs as the optimization method.

Once we have found optimal values for the gain constants, the next step is to find the optimal values for the input/output membership functions of the fuzzy controller. Our goal is that the lineal and angular velocities reach zero in the simulations. Table 80.6 shows the parameters of the simulations for Type-1 FLC.

Figure 80.9 shows the behavior of the chemical optimization algorithm throughout the experiment.

Figure 80.10 shows the resulted input and output membership functions found by the proposed optimization algorithm.

Figure 80.11 shows the trajectory obtained when simulating the mobile control system including the obtained input and output membership functions.

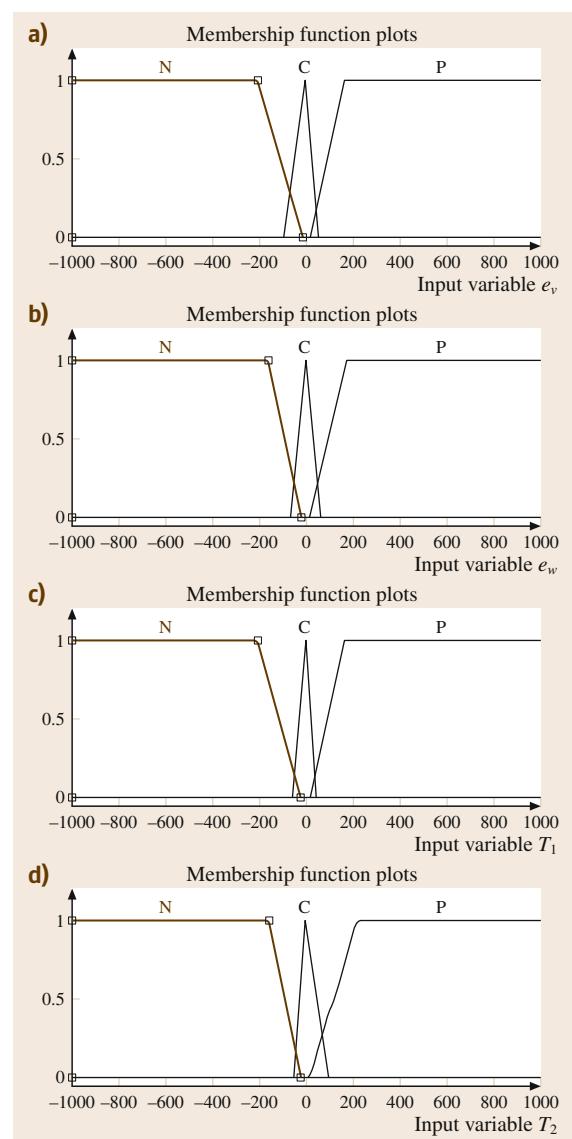

**Fig. 80.9** Best simulation of experiments with the chemical optimization method

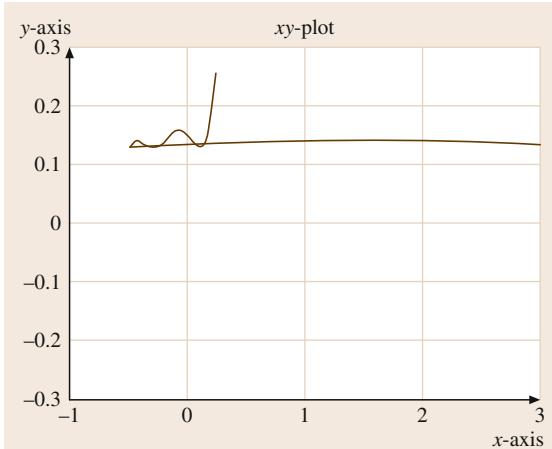

**Fig. 80.10a-d** Resulting input membership functions: (a) linear and (b) angular velocities and output (c) right and (d) left torque ►

Figure 80.12 shows the best trajectory reached by the mobile robot when optimizing the input and output membership functions using genetic algorithms.

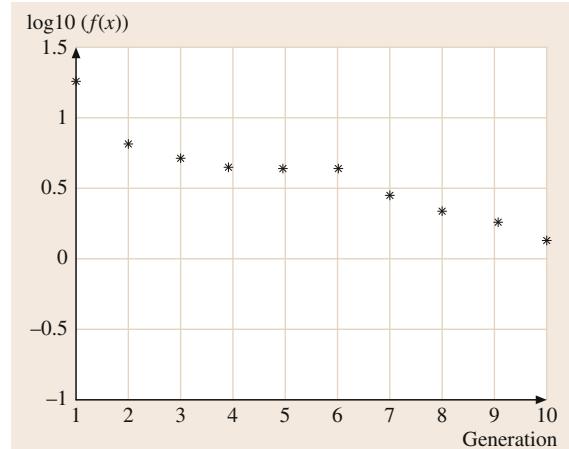

A Type-2 FLC was developed using the parameters of the membership functions found for Type-1 FLC. The parameters searched with the chemical reaction algorithm were for the footprint of uncertainty (FOU).

Table 80.7 shows the parameters used in the simulations and Fig. 80.13 shows the behavior of the chemical optimization algorithm throughout the experiment.

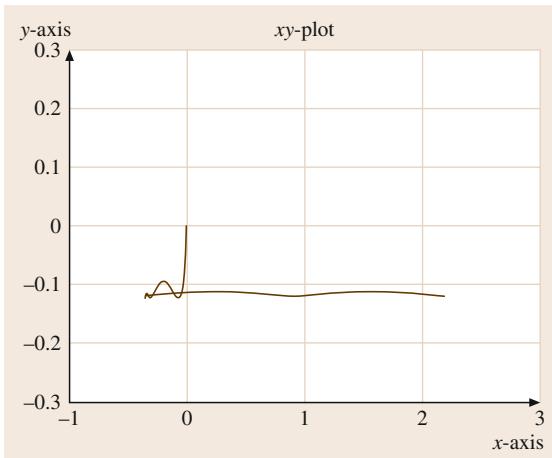

**Fig. 80.11** Trajectory obtained when applying the chemical reaction algorithm

**Fig. 80.13** Behavior of the algorithm when optimizing the Type-2 FLC

**Fig. 80.12** Trajectory obtained using GAs

Figure 80.14 shows the resulting Type-2 input and output membership functions found by the proposed optimization algorithm and Fig. 80.15 shows the obtained trajectory reached by the mobile robot.

As observed in Table 80.7, the final error obtained is not smaller than the final error found for the Type-1 FLC. Despite this, the trajectory obtained, which is shown in Fig. 80.15, is acceptable, taking into account that the reference trajectory is a straight line. In Fig. 80.16 we can observe an *unacceptable* trajectory, which was found in the early attempts of optimization for the Type-1 FLC applying this chemical reaction algorithm. Here, we can observe that the parameters

found were not adequate to make the FLC follow the desired trajectory.

In order to test the robustness of the Type-1 and Type-2 FLC, we added an external signal given by (80.10).

$$F_{\text{ext}}(t) = \varepsilon \times \sin \omega \times t. \quad (80.10)$$

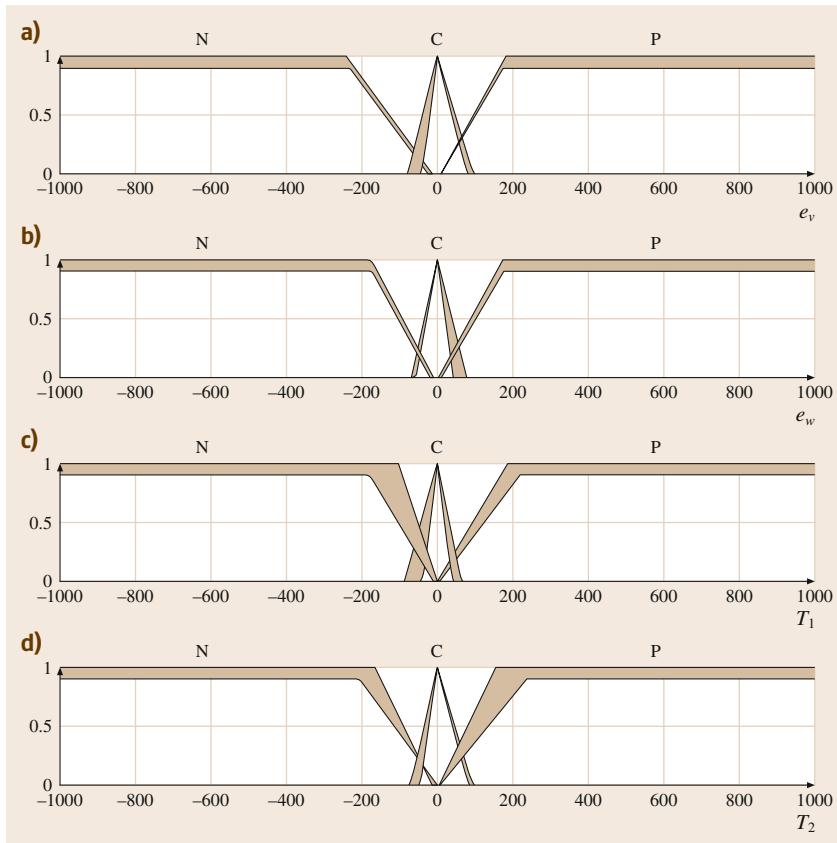

This represents an external force applied in a period of 10 s to the trajectory obtained that will make the mobile robot move out of its path. The idea of adding this disturbance is to measure the errors obtained with the FLC and to test the behavior of the mobile robot under perturbed torques. Table 80.8 shows the parameters for the simulations and the errors obtained during the run of the simulation.

Figure 80.17 show the trajectories obtained for the Type-1 FLC optimized with GAs.

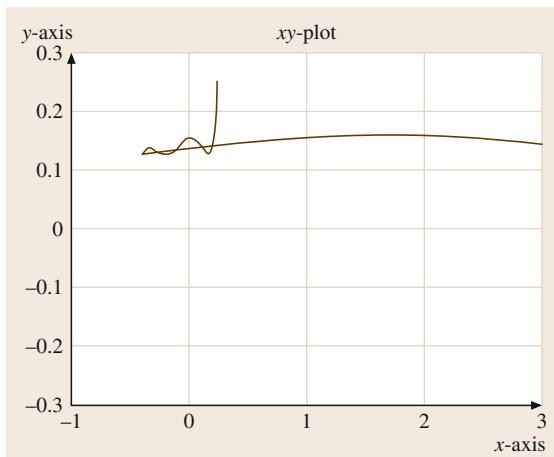

Figure 80.18 shows the trajectories obtained for the Type-1 FLC optimized with the chemical reaction algorithm.

Figure 80.19 shows the trajectories obtained for the Type-2 FLC optimized with the CRA method.

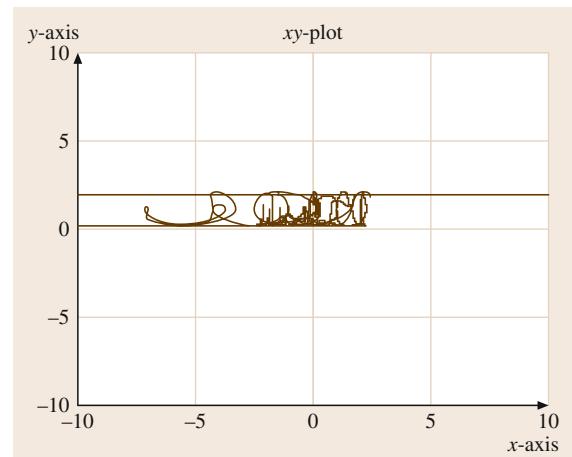

In Table 80.8 and Figs. 80.17 to 80.19 we can observe that the Type-2 FLC was able to maintain a more controlled trajectory in despite of the *large* error found by the algorithm ( $e = 2.7736$ ). For larger epsilon ( $\varepsilon$ ) values, it was difficult for the Type-1 FLCs to keep in the path, and in a determined time the controller was not able to return to the reference trajectory.

## 80.6 Conclusions

In this paper, we presented simulation results from an optimization method that mimics chemical reactions applied to the problem of tracking control. The goal was to find the gain constants involved in the tracking controller for the dynamic model of a unicycle mobile robot. In the figures of the experiments we were able to note the behavior of the algorithm and the solutions found through all the iterations. Simulation results show that the proposed optimization method is able to

outperform the results previously obtained by applying a genetic algorithm optimization technique. The optimal fuzzy logic controller obtained with the proposed chemical paradigm is able to reach smaller error values in less time than genetic algorithms. Also, the Type-2 fuzzy controller was able to perform better in the presence of disturbance in this problem despite the large error obtained ( $e = 2.7736$ ). The design of optimal Type-2 fuzzy controllers is performed at the time.

# Bio-Inspired Optimization Methods

Fevrier Valdez

Although graphic processing units ([GPUs](#)) have been traditionally used only for computer graphics, a recent technique called general-purpose computing on graphics processing units allows [GPUs](#) to perform numerical computations usually handled by the [CPU](#) (central processing unit). The advantage of using [GPUs](#) for general purpose computation is the performance speedup that can be achieved due to the parallel architecture of these devices. This chapter describes the use of bio-inspired optimization methods as particle swarm optimization and genetic algorithms on [GPUs](#) to demonstrate the performance that can be achieved using this technology, primarily with regard to using [CPUs](#).

## 81.1 Bio-Inspired Methods

In this chapter we describe the optimization of a set of mathematical functions using bio-inspired algorithms. We use genetic algorithms ([GAs](#)) and particle swarm optimization ([PSO](#)), simulated annealing ([SA](#)), and pattern search ([PS](#)) to optimize the functions. The main idea is to compare these metaheuristic methods using the [CPU](#) and [GPUs](#). Nowadays several approaches have been taken to optimize mathematical functions, see, for example, [81.1–6]. Our approach, however, differs from these approaches because we make a comparison between the advantage of executing the methods on [CPUs](#) and [GPUs](#) with the aim of achieving the results quickly.

The main contribution of this work is the proposed approach for the implementation of bio-inspired optimization techniques on [GPUs](#) for optimization applications. The approach is illustrated with mathematical function optimization, but could be applicable to other problems.

The introduction to the proposed method, is followed by a description of bio-inspired methods in Sect. 81.2. In Sect. 81.3, a brief history of [GPUs](#) is presented, in Sect. 81.4 the experimental results are shown, and in Sect. 81.5 the conclusions are presented.

## 81.2 Bio-Inspired Optimization Methods

To compare the performance on a [CPU](#) or a [GPU](#), it is necessary evaluate the methods with optimization problems. Some basic concepts of bio-inspired optimization are needed to understand the differences in the corre-

sponding algorithms. Therefore, in this section we offer a brief description about the bio-inspired optimization methods used in this work. The methods used are described in the following sections.

### 81.2.1 Genetic Algorithms

*Holland*, from the University of Michigan initiated his work on genetic algorithms at the beginning of the 1960s. His first achievement was the publication of *Adaptation in Natural and Artificial Systems* [81.7] in 1975.

He had two goals in mind: to improve the understanding of the natural adaptation process and to design artificial systems having properties similar to natural systems [81.8].

The basic idea is as follows: the genetic pool of a given population potentially contains the solution, or a better solution, to a given adaptive problem. This solution is not *active* because the genetic combination on which it relies is split between several subjects. Only the association of different genomes can lead to the solution.

*Holland*'s method is especially effective because it not only considers the role of mutation, but it also uses genetic recombination (crossover) [81.9]. The essence of the **GA** in both theoretical and practical domains has been well demonstrated [81.1, 10]. The concept of applying a **GA** to solve engineering problems is feasible and sound. However, despite the distinct advantages of a **GA** for solving complicated, constrained, and multiobjective functions where other techniques may have failed and the full power of the **GA** application is yet to be exploited [81.11, 12].

### 81.2.2 Particle Swarm Optimization

Particle swarm optimization (**PSO**) is a population-based stochastic optimization technique that was developed by *Eberhart* and *Kennedy* in 1995, inspired by the social behavior of bird flocking or fish schooling [81.3].

**PSO** shares many similarities with evolutionary computation techniques such as **GAs** [81.13]. The system is initialized with a population of random solutions and searches for optima by updating generations. However, unlike the **GA**, the **PSO** has no evolution operators such as crossover and mutation. In **PSO**, the potential solutions, called particles, fly through the problem space by following the current optimum particles [81.14].

Each particle keeps track of its coordinates in the problem space, which are associated with the best solution (fitness) it has achieved so far (the fitness value is also stored). This value is called *pbest*. Another *best* value that is tracked by the particle swarm optimizer is the best value obtained so far by any particle in the

neighbors of the particle. This location is called *lbest*. When a particle takes all the population as its topological neighbors, the best value is a global best and is called *gbest*.

The particle swarm optimization concept consists of, at each time step, changing the velocity of (accelerating) each particle toward its *pbest* and *lbest* locations (the local version of **PSO**). Acceleration is weighted by a random term, with separate random numbers being generated for acceleration toward *pbest* and *lbest* locations.

In the past several years, **PSO** has been successfully applied in many research and application areas. It is demonstrated that **PSO** obtains better results in a faster and cheaper way compared with other methods [81.15].

### 81.2.3 Simulated Annealing

**SA** is a generic probabilistic metaheuristic for the global optimization problem of applied mathematics, namely locating a good approximation to the global optimum of a given function in a large search space. It is often used when the search space is discrete (e.g., all tours that visit a given set of cities). For certain problems, simulated annealing may be more effective than exhaustive enumeration provided that the goal is merely to find an acceptably good solution in a fixed amount of time, rather than the best possible solution.

The name and inspiration come from annealing in metallurgy, a technique involving heating and controlled cooling of a material to increase the size of its crystals and reduce their defects. The heat causes the atoms to become unstuck from their initial positions (a local minimum of the internal energy) and wander randomly through states of higher energy; the slow cooling gives them more chances of finding configurations with lower internal energy than the initial one. By analogy with this physical process, each step of the **SA** algorithm replaces the current solution by a random *nearby* solution, chosen with a probability that depends both on the difference between the corresponding function values and also on a global parameter *T* (called the *temperature*), which is gradually decreased during the process. The dependency is such that the current solution changes almost randomly when *T* is large, but increasingly *downhill* as *T* goes to zero [81.16].

### 81.2.4 Pattern Search

Pattern search is a family of numerical optimization methods that do not require the gradient of

the problem to be optimized, and **PS** can hence be used on functions that are not continuous or differentiable. Such optimization methods are also known as direct-search, derivative-free, or black-box methods.

The name pattern search was coined by *Hooke* and *Jeeves* [81.17]. An early and simple **PS** variant is attributed to Fermi and Metropolis when they worked at the Los Alamos National Laboratory as described by

*Davidon* [81.18], who summarized the algorithm as follows:

*They varied one theoretical parameter at a time by steps of the same magnitude, and when no such increase or decrease in any one parameter further improved the fit to the experimental data, they halved the step size and repeated the process until the steps were deemed sufficiently small.*

## 81.3 A Brief History of GPUs

We have already looked at how central processors evolved in both clock speeds and core count. In the meantime, the state of graphics processing underwent a dramatic revolution. In late 1980s and early 1990s, the growth in popularity of graphically driven operating systems such Microsoft Windows helped create a market for a new type of processor. In the early 1990s, users began purchasing 2-D display accelerators for their personal computers. These display accelerators offered hardware-assisted bitmap operations to assist in the display and usability of graphical operating systems [81.19]. From a parallel-computing standpoint, NVIDIA's release of the GeForce 3 series in 2001 represents arguably the most important breakthrough in **GPU** technology. The GeForce 3 series was the computing industry's first chip to implement Microsoft's then new DirectX 8.0 standard. This standard required that

compliant hardware contain both programmable vertex and programmable pixel shading stages. For the first time, developers had some control over the exact computations that would be performed on their **GPUs** [81.19].

### 81.3.1 CUDA

In November 2006, NVIDIA unveiled the industry's first DirectX 10 **GPU**, the GeForce 8800 GTX. The GeForce 8800 GTX was also the first **GPU** to be built with NVIDIA's **CUDA** architecture. This architecture included several new components designed strictly for **GPU** computing and aimed to alleviate many of the limitations that prevented previous graphics processors from being legitimately useful for general-purpose computation [81.19].

## 81.4 Experimental Results

This section presents the experimental results obtained with the optimization methods analyzed in this research. The main contribution of this paper is to demonstrate the advantages of using **GPUs** to calculate complex processes.

To validate the proposed method we used a set of five benchmark mathematical functions; all functions were evaluated with different numbers of dimensions. In this case, the experimental results were obtained with 32 dimensions.

Table 81.1 shows the definitions of the mathematical functions used in this paper. The global minimum for the test functions is 0.

Tables 81.2 and 81.3 show the experimental results for the benchmark mathematical functions used in this research using the **CPU** and the **GPU** to process the **GA**. The table shows the experimental results of the evalua-

tions for each function with 32 dimensions; the best and worst values obtained with an average of 50 times can

**Table 81.1** Mathematical functions

| Function                | Definition                                                                           |
|-------------------------|--------------------------------------------------------------------------------------|

of the evaluations for each function with 32 dimensions; the best and worst values obtained with the average of 50 times after execution of the method can be seen. The processing time in seconds is also shown.

Tables 81.8 and 81.9 show the experimental results for the benchmark mathematical functions used in this research using the **CPU** and **GPU** to process the **PS**. The table shows the experimental results of the evaluations for each function with 32 dimensions; the best and worst values obtained with the average of 50 times after execution of the method can be seen. The processing time in seconds is also shown.

Figure 81.1 shows the comparison results between the processing time on the **GPU** and the **CPU**. The difference in time of each best time obtained in the experiments discussed in the paper is shown. The blue line represents the processing time in the **CPU** and the brown line represents the processing time in the **GPU**. Is

**Fig. 81.1** Comparison of results between **GPU** and **CPU**

clear how the best time achieved is when the algorithms were executed on the **GPU**.

## 81.5 Conclusions

The analysis of the experimental results of the bio-inspired methods considered in this paper, the **FPSO+FGA (FPSO)**: fuzzy particle swarm optimization; **FGA**: fuzzy generic algorithm), lead us to the conclusion that for the optimization of these benchmark mathematical functions execution on the **GPU** is a good alternative, because it is easier and very fast to optimize and achieve good results than to try it with

**PSO**, **GA**, **SA**, and genetic pattern search (**GPS**) on the **CPU** [81.14], especially when the number of dimensions is increased. This is because processing on **GPUs** is faster than processing on **CPUs**. Also, the experimental results obtained with the use of **GPUs** in this research were compared with another similar approach [81.20, 21] and achieved good results quickly.

**D.36 Cognitive Architectures and Agents**

*by Sébastien Hélie, Ron Sun*

This research was supported by the ONR grant N00014-08-1-0068 to the second author. Requests for reprints should be addressed to Sébastien Hélie, Department of Psychological Sciences, Purdue University, West Lafayette, IN 47907-2081, e-mail: shelie@purdue.edu; or to Ron Sun, Department of Cognitive Science, Rensselaer Polytechnic Institute, email: r.sun@rpi.edu.

**D.40 Evolving Connectionist Systems:  
From Neuro-Fuzzy-, to Spiking-  
and Neuro-Genetic**

*by Nikola Kasabov*

The work presented in this chapter is supported by the Knowledge Engineering and Discovery Research Institute (KEDRI, <http://www.kedri.info>) of the Auckland University of Technology, New Zealand.

**E.43 Genetic Programming**

*by James McDermott, Una-May O'Reilly*

JMcD was funded for this research by the Irish Research Council for Science, Engineering, and Technology, co-funded by Marie Curie. U-MO'R acknowledges the support of the Li Ka Shing Foundation, General Electric, and the US Department of Energy. Thanks to Erik Hemberg for reading early drafts.

**E.45 Estimation of Distribution Algorithms**

*by Martin Pelikan, Mark Hauschild,  
Fernando Lobo*

This project was sponsored by the National Science Foundation under grants ECS-0547013 and IIS-1115352, by the University of Missouri in St. Louis through the High Performance Computing Collaboratory sponsored by Information Technology Services, and by the University of Missouri Bioinformatics Consortium (UMBC). Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation.

**E.46 Parallel Evolutionary Algorithms**

*by Dirk Sudholt*

Part of this work was done while the author was a member of CERCIA, University of Birmingham, supported by EPSRC grant EP/D052785/1. The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007–2013) under grant agreement No. 618091 (SAGE).

**E.49 Multi-Objective  
Evolutionary Algorithms**

*by Kalyanmoy Deb*

This chapter is an updated version of a recent article by the author: K. Deb: Recent developments in evolutionary multi-objective optimization. In: *Trends in Multiple Criteria Decision Analysis Trends in Multiple Criteria Decision Analysis*, International Series in Operations Research & Management Science, Vol. 142, ed. by S.

Greco, M. Ehrgott and J. R. Figueira (Springer, New York 2010), pp. 339–368.

### **E.50 Parallel Multiobjective Evolutionary Algorithms**

*by Francisco Luna, Enrique Alba*

This work has been partially funded by the Spanish Ministry of Science and Innovation and FEDER under contracts TIN2008-06491-C04-01 (the MSTAR project) and TIN2011-28194 (the roadME project), and by the Andalusian Government under contract P07-TIC-03044 (the DIRICOM project).

### **E.51 Many-Objective Problems: Challenges and Methods**

*by Antonio López Jaimes, Carlos Coello Coello*

The second author acknowledges support from CONACYT project no. 103570.

### **E.52 Memetic and Hybrid Evolutionary Algorithms**

*by Jhon Amaya, Carlos Cotta Porras, Antonio Fernández Leiva*

This work was partially supported by the Spanish MICINN under project ANYSELF (TIN2011-28627-C04-01) and by Junta de Andalucía under project TIC-6083.

### **E.54 Stochastic Local Search Algorithms: An Overview**

*by Holger Hoos, Thomas Stützle*

This work has been supported by the Meta-X, an ARC project funded from the Scientific Research Directorate of the French Community of Belgium. Holger H. Hoos acknowledges support provided by a Discovery Grant from the Natural Sciences and Engineering Research Council of Canada (NSERC); Thomas Stützle acknowledges support of the Belgian FNRS, of which he is a research associate.

### **E.56 How to Create Generalizable Results**

*by Thomas Bartz-Beielstein*

This work was kindly supported by the Federal Ministry of Education and Research (BMBF) under the grants MCIOP (FKZ 17N0311) and CIMO (FKZ 17002X11).

In addition, the paper and the corresponding R code are based on Chiarandini and Goegebeur's publication *Mixed models for the analysis of optimization algorithms* [81.3].

### **E.59 Modeling and Optimization of Machining Problems**

*by Dirk Biermann, Petra Kersting, Tobias Wagner, Andreas Zabel*

This work was supported by the Deutsche Forschungsgemeinschaft (DFG) by founding the Collaborative Research Center Computational Intelligence (SFB 531).

### **E.64 Metaheuristic Algorithms and Tree Decomposition**

*by Thomas Hammerl, Nysret Musliu, Werner Schafhauser*

The work was supported by the Austrian Science Fund (FWF): P20704-N18 and P24814-N23. Moreover, the research herein is partially conducted within the competence network Softnet Austria II ([www.soft-net.at](http://www.soft-net.at), COMET K-Projekt) and funded by the Austrian Federal Ministry of Economy, Family and Youth (bmwfj), the province of Styria, the Steirische Wirtschaftsförderungsgesellschaft mbH. (SFG), and the city of Vienna in terms of the center for innovation and technology (ZIT).

### **F.66 Swarm Intelligence in Optimization and Robotics**

*by Christian Blum, Roderich Groß*

This work was supported by grant TIN2012-37930-C02-02 of the Spanish Government. In addition, C. Blum acknowledges support from IKERBASQUE, the Basque Foundation for Science. R. Groß acknowledges support from the Engineering and Physical Sciences Research Council (EPSRC, grant no. EP/K033948/1).

### **F.68 Ant Colony Optimization for the Minimum-Weight Rooted Arborescence Problem**

*by Christian Blum, Sergi Mateo Bellido*

This work was supported by grant TIN2007-66523 (FORMALISM) of the Spanish government.

### **F.71 Fundamental Collective Behaviors in Swarm Robotics**

*by Vito Trianni, Alexandre Campo*

Vito Trianni acknowledges support from the H<sup>2</sup>Swarm project, founded within the EUROCORES Programme EuroBioSAS of the European Science Foundation. The project is partially supported by funds from the Italian CNR and the Belgian F.R.S.-FNRS. Alexandre Campo acknowledges support from the CoCoRo project, funded by the Information and Communication Technologies programme (call FP7-ICT-2009-6) of the European Commission under grant number 270382.

Málaga, Spain  
*eat@lcc.uma.es*

Chapter E.50

Enrique Alba is a Full Professor at the University of Málaga (Spain) where received his degree in Engineering in 1992 and his PhD in Computer Science in 1999. He is an invited professor at INRIA, the University of Luxembourg, and the University of Ostrava. He has published 80 articles in ISI-ranked journals, 40 papers in LNCS, over 250 refereed conference papers, 11 books, and 39 book chapters.

**Jose M. Alonso**

European Centre for Soft Computing  
Cognitive Computing  
Mieres, Spain  
*jose.alonso@softcomputing.es*

Chapter B.14

Jose Alonso received his MSc (2003) and PhD (2007) degrees in Telecommunication Engineering from the Technical University of Madrid, Spain. He has published more than 60 papers in international journals and as book chapters. His main research lines are soft computing, fuzzy logic, computing with perceptions, fuzzy modeling, interpretable fuzzy systems, knowledge extraction and representation, and development of free software tools.

**Jhon Edgar Amaya**

Universidad Nacional Experimental del Táchira  
Dep. Electronic Engineering  
San Cristóbal, Venezuela  
*jedgar@unet.edu.ve*

Chapter E.52

Jhon Edgar Amaya received his degree in Engineering in 1997 from UNET and an MSc degree in Computation in 2003 from ULA. He obtained his PhD degree from the University of Malaga in 2011. He is an Associate Professor in the Department of Electronic Engineering at UNET. His research interests include evolutionary computation and soft computing applications in microelectronic devices.

**Plamen P. Angelov**

Lancaster University  
School of Computing and Communications  
Bailrigg, Lancaster, UK  
*p.angelov@lancaster.ac.uk*

Chapter G.75

Plamen P. Angelov leads the Data Science Group at the School of Computing and Communications, Lancaster University, UK. He has authored or co-authored over 200 peer-reviewed publications in leading journals, five patents, two research monographs, and several edited books. His interests are computational intelligence and autonomous system modeling, identification, and machine learning.

**Dirk V. Arnold**

Dalhousie University  
Faculty of Computer Science  
Halifax, Nova Scotia, Canada  
*dirk@cs.dal.ca*

Chapter E.44

Dirk Arnold is a Professor in the Faculty of Computer Science at Dalhousie University. His research interests include evolutionary computation, image processing, and computer graphics and animation.

**Anne Auger**

University Paris-Sud Orsay  
CR Inria  
Orsay Cedex, France  
*anne.auger@inria.fr*

Chapter E.44

Anne Auger is a permanent researcher at the French National Institute for Research in Computer Science and Control (INRIA). She received her diploma (2001) and PhD (2004) in Mathematics from the Paris VI University. Prior to joining INRIA, she worked for 2 years (2004–2006) at ETH in Zurich. Her main research interest is stochastic continuous optimization, including theoretical aspects and algorithm designs.

**Davide Bacciu**

Università di Pisa  
Dip. Informatica  
Pisa, Italy  
[bacciu@di.unipi.it](mailto:bacciu@di.unipi.it)

**Chapter D.31**

Davide Bacciu received a Laurea degree in Computer Science from the University of Pisa in 2003 and a PhD in Computer Science and Engineering from IMT Lucca in 2008. Currently, he is with the CI and Machine Learning Group, the University of Pisa. His research interests include machine learning, graphical models, neural networks, learning in structured domains, and machine vision.

**Michał Baczyński**

University of Silesia  
Inst. Mathematics  
Katowice, Poland  
[michal.baczynski@us.edu.pl](mailto:michal.baczynski@us.edu.pl)

**Chapter B.12**

Michał Baczyński received his MSc and PhD degrees in Mathematics from the University of Silesia, Poland in 1995 and 2000, respectively. He received the *Habilitation* degree from the Polish Academy of Sciences in 2010. His current research interests include fuzzy aggregation operations, chiefly fuzzy implications, approximate reasoning, fuzzy systems, and functional equations.

**Edurne Barrenechea**

Universidad Pública de Navarra  
Dep. Automática y Computación  
Pamplona (Navarra), Spain  
[edurne.barrenechea@unavarra.es](mailto:edurne.barrenechea@unavarra.es)

**Chapter A.6**

Edurne Barrenechea received the PhD degree in Computer Science from the Public University of Navarra in 2005 where she is an Associate Professor in the Department of Automatics and Computation. Her publications comprise more than 30 papers and about 20 book chapters. Her research interests include fuzzy techniques for image processing, and medical and industrial applications of soft computing techniques.

**Thomas Bartz-Beielstein****Chapter E.56**

For biographical profile, please see the section "About the Part Editors".

**Lubica Benuskova**

University of Otago  
Dep. Computer Science  
Dunedin, New Zealand  
[lubica@cs.otago.ac.nz](mailto:lubica@cs.otago.ac.nz)

**Chapter D.27**

Lubica Benuskova is an Associate Professor at the Department of Computer Science at the University of Otago, Dunedin, New Zealand. She is also a Professor at Comenius University, Bratislava, Slovakia. Her research activities are mainly in the area of computational neuroscience. Currently she serves as a member of the Neural Networks Technical Committee of the of the IEEE/CIS.

**Dirk Biermann**

TU Dortmund University  
Dep. Mechanical Engineering  
Dortmund, Germany  
[biermann@isf.de](mailto:biermann@isf.de)

**Chapter E.59**

Dirk Biermann studied Mechanical Engineering and obtained his doctoral degree from the University of Dortmund (now TU Dortmund University). He has been Head of the Institute of Machining Technology (ISF) since 2007. He is an associate member of the International Academy of Production Engineering (CIRP) and of the German Academic Society for Production Engineering (WGP).

**Sašo Blažič**

University of Ljubljana  
Faculty of Electrical Engineering  
Ljubljana, Slovenia  
[saso.blazic@fe.uni-lj.si](mailto:saso.blazic@fe.uni-lj.si)

**Chapter G.75**

Sašo Blažič received his BSc, MSc and PhD degrees in 1996, 1999, and 2002, respectively, from the Faculty of Electrical Engineering, University of Ljubljana, where he currently holds the position of Full Professor. His research interests include adaptive, fuzzy, and predictive control. Recently, he has focused on autonomous mobile systems, mobile robotics, and satellite systems.

**Christian Blum****Chapters F.66, F.68**

For biographical profile, please see the section "About the Part Editors".

**Andrea Bobbio**

Università del Piemonte Orientale  
DiSit – Computer Science Section  
Alessandria, Italy  
[andrea.bobbio@unipmn.it](mailto:andrea.bobbio@unipmn.it)

## Chapter F.69

Andrea Bobbio is Professor of Computer Science at the Università del Piemonte Orientale, Alessandria, Italy. He graduated from Politecnico di Torino in 1969, and in 1971 he joined the Istituto Elettrotecnico Nazionale Galileo Ferraris di Torino. His activity focuses on the modeling and analysis of the performance and reliability of stochastic systems.

**Josh Bongard**

University of Vermont  
Dep. Computer Science  
Burlington, USA  
[josh.bongard@uvm.edu](mailto:josh.bongard@uvm.edu)

## Chapter D.37

Josh Bongard is an Associate Professor at the University of Vermont. He is the Director of the Morphology, Evolution, and Cognition Laboratory there, as well as the Vice Chair of the UVM Complex Systems Center. He is the recipient of an NSF PECASE award and has served as a Microsoft Research New Faculty Fellow.

**Piero P. Bonissone**

Piero P. Bonissone Analytics, LLC  
San Diego, USA  
[bonissone@gmail.com](mailto:bonissone@gmail.com)

## Chapter D.41

Piero Bonissone is a Coolidge Fellow and a Fellow of AAAI, IEEE, and IFSA. He has published over 150 articles and has received 65 US patents. Recently, he was bestowed the 2012 Fuzzy Systems Pioneer Award from the IEEE Computational Intelligence Society.

**Dario Bruneo**

Universita' di Messina  
Dip. Ingegneria Civile, Informatica  
Messina, Italy  
[dbruneo@unime.it](mailto:dbruneo@unime.it)

## Chapter F.69

Dario Bruneo is Assistant Professor in the Department of Engineering at the University of Messina. His research activity focuses on the study of distributed systems in particular on the management of advanced service provisioning, system modeling, and performance evaluation. His current research topics include sensor networks, Internet of Things, monitoring and performance and reliability of complex systems.

**Alberto Bugarín Díz**

University of Santiago de Compostela  
Research Centre for Information  
Technologies  
Santiago de Compostela, Spain  
[alberto.bugarin.diz@usc.es](mailto:alberto.bugarin.diz@usc.es)

## Chapter B.20

Alberto Bugarín is a full Professor of Artificial Intelligence at the Research Centre for Information Technologies of the University of Santiago de Compostela (CiTIUS). His research interests focus on modeling intelligent systems with uncertainty (fuzzy rule-based systems) and their applications in adaptive business intelligence (planning/scheduling), automatic building of linguistic descriptions of data, and mobile robotics.

**Humberto Bustince**

Universidad Pública de Navarra  
Dep. Automática y Computación  
Pamplona (Navarra), Spain  
[bustince@unavarra.es](mailto:bustince@unavarra.es)

## Chapter A.6

Humberto Bustince received his BSc degree in Physics from Salamanca University, Spain, and his PhD degree in Mathematics from the Public University of Navarra. He is a full Professor in the Department of Automatics and Computation at the Public University of Navarra. He has authored more than 120 journal papers and more than 100 contributions to international conferences. He has also co-authored four books.

**Martin V. Butz**

University of Tübingen  
Computer Science, Cognitive Modeling  
Tübingen, Germany  
[martin.butz@uni-tuebingen.de](mailto:martin.butz@uni-tuebingen.de)

## Chapter E.47

Martin V. Butz is a full Professor of Cognitive Modeling at the University of Tübingen, Department of Computer Science and Department of Psychology. His research group focuses on how the brain develops anticipatory representations of the body, the surrounding space for controlling predictive interactions with the environment maximally effectively.

**Alexandre Campo**

Université Libre de Bruxelles  
Unit of Social Ecology  
Brussels, Belgium  
[alexandre.campo@ulb.ac.be](mailto:alexandre.campo@ulb.ac.be)

**Chapter F.71**

Alexandre Campo is a Postdoctoral Fellow at the Unit of Social Ecology at the Université Libre de Bruxelles. He received his PhD there in Applied Sciences in 2011. His research interests include the study and design of complex systems applied to swarm robotics. He has participated in several projects funded by the European Commission.

**Angelo Cangelosi**

Plymouth University  
Centre for Robotics and Neural Systems  
Plymouth, UK  
[A.Cangelosi@plymouth.ac.uk](mailto:A.Cangelosi@plymouth.ac.uk)

**Chapter D.37**

Angelo Cangelosi is Professor of Artificial Intelligence and Cognition and directs the Centre for Robotics and Neural Systems at Plymouth University, UK. His main expertise is on language and cognitive modeling in humanoid robots. He has coordinated UK and FP7 projects (RobotDoC ITN, ITALK, BABEL), and is the 2012 Chair of the IEEE Autonomous Mental Development Technical Committee.

**Robert Carrese**

LEAP Australia Pty. Ltd.  
Clayton North, Australia  
[robert.carrese@leapaust.com.au](mailto:robert.carrese@leapaust.com.au)

**Chapter F.67**

Robert Carrese graduated as an Aerospace Engineer and then received his PhD degree in Aerodynamic Design and Optimization from RMIT University. Since 2012, he has been a Senior Engineer at LEAP Australia Pty. Ltd. His research interests include the development of evolutionary design processes for key aerodynamic deliverables and mitigation of adverse aeroelastic and aeroacoustic effects.

**Ciro Castiello**

University of Bari  
Dep. Informatics  
Bari, Italy  
[ciro.castiello@uniba.it](mailto:ciro.castiello@uniba.it)

**Chapter B.14**

Ciro Castiello graduated in Informatics in 2001 and received his PhD in Informatics in 2005. He is currently a researcher in the Informatics Department at the University of Bari, Italy. His research interests include soft computing techniques, inductive learning mechanisms, and interpretability of fuzzy systems. He has published more than 50 peer-reviewed papers.

**Oscar Castillo****Chapters G.78, G.80**

For biographical profile, please see the section "About the Part Editors".

**Davide Cerotti**

Politecnico di Milano  
Dip. Elettronica, Informazione e  
Bioingegneria  
Milano, Italy  
[davide.cerotti@polimi.it](mailto:davide.cerotti@polimi.it)

**Chapter F.69**

Davide Cerotti obtained his degree in Computer Science from the University of Piemonte Orientale, Italy and his PhD in Computer Science in 2010 from the University of Turin, Italy. Currently he is a postdoctoral scholar at the Politecnico di Milano, Italy. His main research topics are Markovian agents, queueing networks, and performance evaluation of large-scale distributed systems.

**Badong Chen**

Xi'an Jiaotong University  
Inst. Artificial Intelligence and Robotics  
Xi'an, China  
[chenbd@mail.xjtu.edu.cn](mailto:chenbd@mail.xjtu.edu.cn)

**Chapter D.30**

Badong Chen received his PhD degree in Computer Science and Technology from Tsinghua University, China, in 2008. He was a Postdoctoral Associate at the University of Florida from 2010 to 2012. He is currently a Professor at Xi'an Jiaotong University, China. His research interests are in signal processing and machine learning, and their applications in cognition and neuroscience.

**Ke Chen**

The University of Manchester  
School of Computer Science  
Manchester, UK  
[chen@cs.manchester.ac.uk](mailto:chen@cs.manchester.ac.uk)

## Chapter D.28

Ke Chen has been an academic staff member at The University of Manchester since 2003. He has worked at Birmingham University, Peking University, Ohio State University, Kyushu Institute of Technology, and Tsinghua University. His main research interests lie in neural computation with an emphasis on deep and modular neural networks, machine learning, machine perception and their applications in intelligent systems.

**Davide Ciucci**

University of Milano-Bicocca  
Dep. Informatics, Systems and  
Communications  
Milano, Italy  
[ciucci@disco.unimib.it](mailto:ciucci@disco.unimib.it)

## Chapter C.25

Davide Ciucci received a PhD in 2004 in Computer Science from the University of Milan and the Habilitation (HdR) from the University of Toulouse III in 2013. Since 2005, he has held a permanent research position at the University of Milano-Bicocca. His research activity concerns uncertainty management, with particular reference to rough sets, many-valued logics, and ontologies.

**Carlos A. Coello Coello**

## Chapter E.51

For biographical profile, please see the section "About the Part Editors".

**Chris Cornelis**

Ghent University  
Dep. Applied Mathematics and Computer  
Science  
Ghent, Belgium  
[chriscornelis@ugr.es](mailto:chriscornelis@ugr.es)

## Chapter C.26

Chris Cornelis has an MSc and a PhD degree in Computer Science from Ghent University (Belgium). Currently, he is a Postdoctoral Fellow at the University of Granada, supported by the Ramón y Cajal program, as well as a Guest Professor at Ghent University. His current research interests include fuzzy sets, rough sets, and machine learning.

**Nikolaus Correll**

University of Colorado at Boulder  
Dep. Computer Science  
Boulder, USA  
[ncorrell@colorado.edu](mailto:ncorrell@colorado.edu)

## Chapter F.74

Nikolaus Correll has been an Assistant Professor of Computer Science at the University of Colorado at Boulder since 2009. He obtained a PhD from EPFL in 2007 and did postdoctoral studies at MIT CSAIL. His research interests are modeling and design of large-scale distributed swarming systems and smart materials.

**Carlos Cotta Porras**

Universidad de Málaga  
Dep. Lenguajes y Ciencias de la  
Computación  
Málaga, Spain  
[ccottap@lcc.uma.es](mailto:ccottap@lcc.uma.es)

## Chapter E.52

Carlos Cotta received his MSc and PhD degrees in Computer Science from the University of Málaga in 1994 and 1998, respectively. He has held a tenured professorship at this university since 2001. His main research areas involve metaheuristic optimization – in particular hybrid and memetic approaches – with a focus on both algorithmic and applied aspects (particularly combinatorial optimization) and complex systems.

**Damien Coyle**

University of Ulster  
Intelligent Systems Research Centre  
Derry, Northern Ireland, UK  
[dh.coyle@ulster.ac.uk](mailto:dh.coyle@ulster.ac.uk)

## Chapter D.39

Damien Coyle is a Senior Lecturer at the School of Computing and Intelligent Systems, University of Ulster. His research interests include brain-computer interfaces, computational intelligence and neuroscience, neuroimaging, and biosignal processing. He is a recipient of the IEEE Computational Intelligence Society's Outstanding Doctoral Dissertation Award and the International Neural Network Society's Young Investigator of the Year Award.

**Guy De Tré**

Ghent University  
Dep. Telecommunications and  
Information Processing  
Ghent, Belgium  
*guy.detre@ugent.be*

**Chapter B.19**

Guy De Tré received his MSc in Computer Science in 1994 and his PhD in Engineering in 2000 from Ghent University (Belgium). He is Associate Professor in Fuzzy Information Processing in the Department of Telecommunications and Information Processing at Ghent University. His research is centred on soft computing techniques for database modeling, flexible querying, and decision support.

**Kalyanmoy Deb**

Michigan State University  
Dep. Electrical and Computer Engineering  
East Lansing, USA  
*kdeb@egr.msu.edu*

**Chapter E.49**

Kalyanmoy Deb is a Koenig Endowed Chair Professor at Michigan State University. His research interests are in evolutionary optimization and their application in optimization, modeling, and machine learning. He has published 375 research papers with h-index 85. He is on the Editorial Board of 18 major international journals.

**Clarisse Dhaenens**

University of Lille  
CRISTAL laboratory  
Villeneuve d'Ascq Cedex, France  
*clarisse.dhaenens@univ-lille1.fr*

**Chapter E.61**

Clarisse Dhaenens is Professor at the University of Lille. She obtained her PhD in 1998 from the Polytechnic University of Grenoble (INPG). She became Associate Professor in 1999 at the University of Lille and a full Professor in 2006. Her work deals with operations research, combinatorial optimization with applications in knowledge discovery for bioinformatics and healthcare.

**Luca Di Gaspero**

Università degli Studi di Udine  
Dip. Ingegneria Elettrica, Gestionale e  
Meccanica  
Udine, Italy  
*luca.digaspero@uniud.it*

**Chapter E.62**

Luca Di Gaspero graduated and received a PhD in Computer Science from the University of Udine, where he is currently Senior Lecturer of Information Technology. In 2011 he was Visiting Professor at Vienna University of Technology, where he also received his Habilitation in 2014. His research focus is boosting metaheuristic techniques by hybridizing them with other optimization methods, mainly from the AI field.

**Didier Dubois**

Université Paul Sabatier  
IRIT – Equipe ADRIA  
Toulouse Cedex 9, France  
*dubois@irit.fr*

**Chapter A.3**

Didier Dubois is a Research Advisor at IRIT, the Computer Science Department of Paul Sabatier University, Toulouse, France. He has co-authored 2 books, a monograph, and over 15 edited volumes on uncertain reasoning and fuzzy sets. His interests range from knowledge representation and reasoning to decision sciences and representation and processing of imprecise information.

**Antonio J. Fernández Leiva**

Universidad de Málaga  
Dep. Lenguajes y Ciencias de la  
Computación  
Málaga, Spain  
*afdez@lcc.uma.es*

**Chapter E.52**

Antonio J. Fernández-Leiva received his PhD degree in Computer Science from the University of Málaga in 2002 and later became an Associate Professor. In the past he has worked in private companies as a computer engineer. His main areas of research involve both the application of metaheuristics techniques to combinatorial optimization and the employment of computational intelligence in games.

**Javier Fernández**

Universidad Pública de Navarra  
Dep. Automática y Computación  
Pamplona (Navarra), Spain  
*fcojavier.fernandez@unavarra.es*

**Chapter A.6**

Javier Fernández received his PhD in Mathematics from the University of the Basque Country in 2003. He was a postdoc researcher at the CNRS and currently he is a member of the GIARA research group at the Public University of Navarra. He has authored more than 30 papers in JCR journals. His main research interests are fuzzy sets and extensions, aggregation functions, image processing, and harmonic analysis.

**Martin H. Fischer**

University of Potsdam  
Psychology Dep.  
Potsdam OT Golm, Germany  
[martinf@uni-potsdam.de](mailto:martinf@uni-potsdam.de)

**Chapter D.37**

Martin Fischer obtained a PhD from the University of Massachusetts in 1997 through graduate studies on motor control and visual attention. He then worked at LMU Munich for 3 years before moving to University of Dundee in Scotland. In 2011 he became Professor of Cognitive Sciences at the University of Potsdam in Germany, where he investigates embodied numerical cognition.

**János C. Fodor**

Óbuda University  
Dep. Applied Mathematics  
Budapest, Hungary  
[fodor@uni-obuda.hu](mailto:fodor@uni-obuda.hu)

**Chapter B.10**

János Fodor is a Full Professor and the Rector of Óbuda University, Budapest, Hungary. He received his Master's degree in 1981 and his PhD in 1991, both in Mathematics. He is a Doctor of the Hungarian Academy of Sciences and is pursuing research in mathematical foundations of fuzzy logic, computational intelligence, and preference modeling. He has published 2 monographs and over 250 scientific papers.

**Jairo Alonso Giraldo**

Universidad de los Andes  
Dep. Electrical and Electronics  
Engineering  
Bogotá, Colombia  
[ja.giraldo908@uniandes.edu.co](mailto:ja.giraldo908@uniandes.edu.co)

**Chapter F.70**

Jairo Giraldo is a PhD student in the Department of Electrical and Electronics Engineering at Universidad de los Andes, Colombia. His research interests include distributed control algorithms for power grids, multi-agent-based control, networked systems, and cybersecurity and privacy. He is a member of the IEEE Control Systems Society and the Power and Energy Society.

**Siegfried Gottwald**

Leipzig University  
Inst. Philosophy  
Leipzig, Germany  
[gottwald@uni-leipzig.de](mailto:gottwald@uni-leipzig.de)

**Chapter A.2**

Siegfried Gottwald was Full Professor for Nonclassical and Mathematical Logic at Leipzig University until 2008. He obtained a PhD in Mathematics in 1969. His research areas include many-valued and fuzzy logic, fuzzy sets, fuzzy relations and fuzzy control, and history of mathematics and logic. He is IFSA Fellow and he received the *Forschungspreis Technische Kommunikation* of the SEL-Alcatel foundation (1992).

**Salvatore Greco**

University of Catania  
Dep. Economics and Business  
Catania, Italy  
[salgreco@unict.it](mailto:salgreco@unict.it)

**Chapters C.22, C.24**

Salvatore Greco is Professor at the University of Catania, Italy, and part-time Professor at the University of Portsmouth, UK. He is an active researcher in the area of rough set theory, multiple criteria decision aiding (MCDA), and non-additive integrals. He received the Multiple Criteria Decision Making Gold Medal in 2013.

**Marco Gribaudo**

Politecnico di Milano  
Dip. Elettronica, Informazione e  
Bioingegneria  
Milano, Italy  
[marco.gribaudo@polimi.it](mailto:marco.gribaudo@polimi.it)

**Chapter F.69**

Marco Gribaudo is a Senior Researcher at the Politecnico di Milano, Italy. His current research interests are multi-formalism modeling, queueing networks, mean-field analysis and spatial models.

**Roderich Groß****Chapter F.66**

For biographical profile, please see the section "About the Part Editors".

**Jerzy W. Grzymala-Busse**

University of Kansas  
Dep. Electrical Engineering and Computer Science  
Lawrence, USA  
*jerzygb@ku.edu*

## Chapter C.23

Jerzy W. Grzymala-Busse has been a Professor of Electrical Engineering and Computer Science at the University of Kansas since August 1993. His research interests include data mining, machine learning, knowledge discovery, expert systems, reasoning under uncertainty, and rough set theory. He is the author, co-author, or editor of 14 books, and has published over 300 articles.

**Hani Hagras**

University of Essex  
The Computational Intelligence Centre  
Colchester, UK  
*hani@essex.ac.uk*

## Chapter B.18

Hani Hagras is a Professor of Computational Intelligence, Director of the Computational Intelligence Centre, Head of the Fuzzy Systems Research Group and Head of the Intelligent Environments Research Group at the University of Essex, UK. He is a Fellow of IEEE and of IET. He has authored more than 250 papers. He was awarded the Outstanding Paper award of the IEEE Computational Intelligence Society, in 2004 and 2013.

**Heiko Hamann**

University of Paderborn  
Dep. Computer Science  
Paderborn, Germany  
*heiko.hamann@uni-paderborn.de*

## Chapter F.74

Heiko Hamann is Assistant Professor at the Computer Science Department of the University of Paderborn. He spent his postdoctoral time at the University of Graz, Austria. He received his PhD from the University of Karlsruhe, Germany. The main focus of his research efforts is on swarm models, swarm robotics, and synthesis of robot controllers.

**Thomas Hammerl**

Vienna, Austria  
*thomas.hammerl@gmail.com*

## Chapter E.64

Thomas Hammerl is working as a self-employed software developer in Vienna, Austria. He received his Master's degree from Vienna University of Technology in 2009. While working on his thesis he did research on metaheuristics, constraint satisfaction, and optimization.

**Julie Hamon**

Ingenomix  
Dep. Research and Development  
Boissey, France  
*julie.hamon@ingenomix.fr*

## Chapter E.61

Julie Hamon graduated as a computer science and statistics engineer from the Ecole Polytechnique Universitaire de Lille (Polytech'Lille), and then received her PhD in Combinatorial Optimization and Statistics from Lille 1 University. She is currently a biostatistician at Ingenomix, a company specialized in genomic selection in bovine. Her main research interests include statistical models applied to genomic data.

**Nikolaus Hansen**

Université Paris-Sud  
Machine Learning and Optimization  
Group (TAO)  
Orsay Cedex, France  
*hansen@lri.fr*

## Chapter E.44

Nikolaus Hansen is a Senior Researcher at Inria, France. After studies in medicine and mathematics he received his PhD in Civil Engineering from the Technical University Berlin in 1998 and his Habilitation in Computer Science from the University Paris-Sud in 2010. Before joining Inria he worked in applied artificial intelligence, evolutionary computation, and genomics in Berlin, and in computational science at the ETH Zurich.

**Mark W. Hauschild**

University of Missouri-St. Louis  
Dep. Mathematics and Computer Science  
St. Louis, USA  
*markhauschild@gmail.com*

## Chapter E.45

Mark Hauschild received his PhD in Applied Mathematics from the University of Missouri in 2014. He is a Visiting Professor at the University of Missouri, where he teaches courses on AI. His research interests include estimation of distribution algorithms, genetic programming, and machine learning. He is currently a member of the Missouri Estimation of Distribution Algorithms Laboratory.

**Sébastien Hélie**

Purdue University  
Dep. Psychological Sciences  
West Lafayette, USA  
[shelie@purdue.edu](mailto:shelie@purdue.edu)

**Chapter D.36**

Sébastien Hélie is Assistant Professor in the Department of Psychological Sciences at Purdue University. He received a PhD in Cognitive Science from the Université du Québec à Montréal. He uses computational cognitive neuroscience and neuroimaging methods to study categorization, automaticity, rule learning, sequence learning, and skill acquisition.

**Jano I. van Hemert**

Optos  
Dunfermline, UK  
[jano@vanhemert.co.uk](mailto:jano@vanhemert.co.uk)

**Chapter E.65**

Dr Jano van Hemert (MSc 1998, PhD 2002; Leiden University, The Netherlands) is a Senior Manager and the Academic Liaison at Optos plc. His main area of research is in computer science and its applications. From 2005 until 2011 he was a visiting researcher at the Human Genetics Unit in Edinburgh of the UK's Medical Research Council.

**Holger H. Hoos**

University of British Columbia  
Dep. Computer Science  
Vancouver, Canada  
[hoos@cs.ubc.ca](mailto:hoos@cs.ubc.ca)

**Chapter E.54**

Holger H. Hoos is a Professor of Computer Science and a Faculty Associate at the Peter Wall Institute for Advanced Studies at the University of British Columbia (Canada). He is a Fellow of the Association for the Advancement of Artificial Intelligence (AAAI) and past President of the Canadian Artificial Intelligence Association (CAIAC). His main research interests span empirical algorithms, artificial intelligence, bioinformatics, and computer music. His research has been published in numerous books and journals.

**Tania Iglesias**

University of Oviedo  
Dep. Statistics and O.R.  
Oviedo, Spain  
[iglesiasctania@uniovi.es](mailto:iglesiasctania@uniovi.es)

**Chapter B.11**

Tania Iglesias received her BSc degree in Mathematics from the University of Oviedo, Spain, in 2006 and her MSc degree from the University of Granada, Spain, in 2013. She is now a technician in the Statistical Consulting Unit of the University of Oviedo. Decision making in fuzzy sets is her main topic of research.

**Giacomo Indiveri**

University of Zurich and ETH Zurich  
Inst. Neuroinformatics  
Zurich, Switzerland  
[giacomo@ini.uzh.ch](mailto:giacomo@ini.uzh.ch)

**Chapter D.38**

Giacomo Indiveri is a Professor at the Faculty of Science of the University of Zurich, Switzerland. He obtained an MSc degree in Electrical Engineering and a PhD degree in Computer Science from the University of Genoa, Italy. His research interests lie in the study of real and artificial neural processing systems, and in the hardware implementation of neuromorphic cognitive systems.

**Masahiro Inuiguchi**

Osaka University  
Dep. Systems Innovation, Graduate School  
of Engineering Science  
Toyonaka, Osaka, Japan  
[inuiguti@sys.es.osaka-u.ac.jp](mailto:inuiguti@sys.es.osaka-u.ac.jp)

**Chapter C.26**

Masahiro Inuiguchi received ME and DE degrees from Osaka Prefecture University in 1987 and 1991. He worked as a Research Associate at Osaka Prefecture University (1987–1992), Associate Professor at Hiroshima University (1992–1997) and Osaka University (1997–2003). At present, he is a Full Professor at Osaka University. His research interests include possibility theory, fuzzy mathematical programming, rough sets, and their applications to decision making.

**Hisao Ishibuchi**

Osaka Prefecture University  
Dep. Computer Science and Intelligent Systems, Graduate School of Engineering  
Osaka, Japan  
[hisaoi@cs.osakafu-u.ac.jp](mailto:hisaoi@cs.osakafu-u.ac.jp)

## Chapter G.77

Hisao Ishibuchi has been a Professor at Osaka Prefecture University since 1999. His research interests include fuzzy rule-based systems, multiobjective optimization, and evolutionary games. He was the IEEE CIS Vice-President for Technical Activities for 2010–2013. Currently he is an IEEE CIS AdCom member (2014–2016), an IEEE CIS Distinguished Lecturer (2015–2017), and the Editor-in-Chief of the IEEE CI Magazine.

**Emiliano Iuliano**

CIRA, Italian Aerospace Research Center  
Fluid Dynamics Lab.  
Capua (CE), Italy  
[e.iuliano@cira.it](mailto:e.iuliano@cira.it)

## Chapter E.60

Emiliano Iuliano received the Laurea (MSc) degree and the Doctorate in Aerospace Engineering from the University of Naples in 2004 and 2012, respectively. He is currently a Senior Researcher at CIRA, the Italian Aerospace Research Center. His research interests include CFD analysis, aircraft aerodynamic design, surrogate-based optimization methods, and aircraft in-flight icing.

**Julie Jacques**

Alicante LAB  
Seclin, France  
[julie.jacques@alicante.fr](mailto:julie.jacques@alicante.fr)

## Chapter E.61

Julie Jacques received her PhD degree in Computer Science from the University of Lille, France, in 2013. She has been working in the industry on applied research projects since 2008. Her research interests are operational research and data mining, with applications to health.

**Andrzej Jankowski**

Knowledge Technology Foundation  
Warsaw, Poland  
[andrzej.adgam@gmail.com](mailto:andrzej.adgam@gmail.com)

## Chapter C.21

Andrzej Jankowski, received his PhD from the University of Warsaw and is one of the founders of the Polish-Japanese Institute of Information Technology. He currently works for R&D and education AI projects at Warsaw University of Technology and the University of Warsaw. He has unique experience in managing complex IT projects in Central Europe and USA.

**Balasubramaniam Jayaram**

Indian Institute of Technology Hyderabad  
Dep. Mathematics  
Hyderabad, India  
[jbala@iith.ac.in](mailto:jbala@iith.ac.in)

## Chapter B.12

Balasubramaniam Jayaram received his MSc and PhD degrees in Mathematics from the Sri Sathya Sai Institute of Higher Learning, India, in 1999 and 2004. He has authored and co-authored more than 50 publications and a research monograph. His current research interests include fuzzy aggregation operations, approximate reasoning, clustering in high dimensions, and kernel learning methods.

**Laetitia Jourdan**

University of Lille 1  
INRIA/UFR IEEA/laboratory CRISTAL/CNRS  
Lille, France  
[laetitia.jourdan@univ-lille1.fr](mailto:laetitia.jourdan@univ-lille1.fr)

## Chapter E.61

Laetitia Jourdan is a full Professor of Computer Sciences at the University of Lille 1/LIFL. She holds a PhD in Combinatorial Optimization from the University of Lille 1 (France). Her areas of research are modeling datamining tasks as combinatorial optimization problems, solving methods based on metaheuristics, and incorporating learning in metaheuristics and multiobjective optimization.

**Nikola Kasabov**

Auckland University of Technology  
KEDRI – Knowledge Engineering and  
Discovery Research Inst.  
Auckland, New Zealand  
[nkasabov@aut.ac.nz](mailto:nkasabov@aut.ac.nz)

**Chapter D.40**

Nikola K. Kasabov obtained his Master's and PhD degrees from the Technical University of Sofia, Bulgaria. He is the Director and the Founder of the Knowledge Engineering and Discovery Research Institute (KEDRI) and Professor of Knowledge Engineering at the School of Computing and Mathematical Sciences at Auckland University of Technology, New Zealand. He has published over 450 papers, books, and patents on informatics, computational intelligence, neural networks, bioinformatics, neuroinformatics.

**Petra Kersting**

TU Dortmund University  
Dep. Mechanical Engineering  
Dortmund, Germany  
[pkersting@ifsf.de](mailto:pkersting@ifsf.de)

**Chapter E.59**

Petra Kersting studied Computer Science and finished her dissertation in Mechanical Engineering at TU Dortmund University. She is Head of the Division *Simulation and Optimization* and holds the junior professorship *Modeling methods for machining processes*. She is Research Affiliate of the International Academy of Production Engineering (CIRP) and Dorothea-Erxleben Visiting Professor 2014/2015 at the OvGU-Magdeburg.

**Erich P. Klement**

Johannes Kepler University  
Dep. Knowledge-Based Mathematical  
Systems  
Linz, Austria  
[ep.klement@jku.at](mailto:ep.klement@jku.at)

**Chapter A.5**

Erich Peter Klement received his PhD degree from the University of Innsbruck. He is Professor of Mathematics at the Johannes Kepler University in Linz, Austria and the Head of the Fuzzy Logic Laboratory in Linz. He has (co-)authored 3 monographs and 80 journal papers and is a Member of the Editorial Boards of 16 journals.

**Anna Kolesárová**

Slovak University of Technology in  
Bratislava  
Faculty of Chemical and Food  
Technology  
Bratislava, Slovakia  
[anna.kolesarova@stuba.sk](mailto:anna.kolesarova@stuba.sk)

**Chapter A.4**

Anna Kolesárová received her MSc degree in Mathematics and Physics from Comenius University in Bratislava and her PhD degree from the Slovak Academy of Sciences. In 2008 she became a Full Professor at the Slovak University of Technology in Bratislava. Her current research interests include aggregation functions, with special stress on copulas, measures and integrals, decision making, and fuzzy mathematics.

**Magda Komorníková**

Slovak University of Technology  
Dep. Mathematics  
Bratislava, Slovakia  
[magda@math.sk](mailto:magda@math.sk)

**Chapter A.4**

Magda Komorníková graduated at Comenius University, Faculty of Mathematics and Physics in 1973 and received her PhD from the same faculty in 1979. Since 1990 she has been a member of the Department of Mathematics at the Slovak University of Technology in Bratislava. She has been a full professor since 2002. Her fields of interest are measure theory, uncertainty modeling, copulas, time series analysis, and aggregation and related operators.

**Mark Kotanchek**

Evolved Analytics LLC  
Midland, USA  
[mark@evolved-analytics.com](mailto:mark@evolved-analytics.com)

**Chapter E.57**

Mark Kotanchek's diverse academic background (Engineering Science BSc, Acoustics MEng, Aerospace Engineering PhD, IEEE Senior Member) is consistent with the diversity of his professional experience. He founded Evolved Analytics in 2005.

**Robert Kozma**

University of Memphis  
Dep. Mathematical Sciences  
Memphis, USA  
[rkozma@mempolis.edu](mailto:rkozma@mempolis.edu)

## Chapter D.33

Robert Kozma has MSc degrees from Moscow Power Engineering University and Eötvös University (Budapest, Hungary), respectively. He received his PhD from Delft University of Technology (The Netherlands). He is a First Tennessee University Professor and recipient of the INNS Gabor Award. His research includes robust decision support for large-scale networks, autonomous robot control, sensor networks, brain networks, and brain-computer interfaces.

**Tomáš Kroupa**

Institute of Information Theory and Automation  
Dep. Decision-Making Theory  
Prague, Czech Republic  
[kroupa@utia.cas.cz](mailto:kroupa@utia.cas.cz)

## Chapter A.9

Tomáš Kroupa obtained his PhD in Mathematical Engineering from the Czech Technical University in 2005. He is affiliated with the Institute of Information Theory and Automation, the Academy of Sciences of the Czech Republic. He has had a Senior Researcher position in the institute since 2014. His area of research is game theory and many-valued logics.

**Rudolf Kruse**

University of Magdeburg  
Faculty of Computer Science  
Magdeburg, Germany  
[kruse@iws.cs.uni-magdeburg.de](mailto:kruse@iws.cs.uni-magdeburg.de)

## Chapter B.17

Rudolf Kruse obtained his PhD in Mathematics in 1980 from the University of Braunschweig. Since 1996 he has been a full professor at the University of Magdeburg where he is leading the computational intelligence research group. He is a Fellow of the International Fuzzy Systems Association and a Fellow of the Institute of Electrical and Electronics Engineers.

**Tufan Kumbasar**

Istanbul Technical University  
Control Engineering Dep.  
Maslak, Istanbul, Turkey  
[kumbasart@itu.edu.tr](mailto:kumbasart@itu.edu.tr)

## Chapter B.18

Tufan Kumbasar is currently working as a Postdoctoral Research Fellow in the Control Engineering Department of Istanbul Technical University. His research interests lie predominately in the area of control engineering, particularly with respect to optimization, intelligent control, process control and mechatronic control methods, and their applications. He is particularly interested in the area of type-2 fuzzy logic systems, especially in their controller applications.

**James T. Kwok**

Hong Kong University of Science and Technology  
Dep. Computer Science and Engineering  
Hong Kong, Hong Kong  
[jamesk@cse.ust.edu.hk](mailto:jamesk@cse.ust.edu.hk)

## Chapter D.29

James Kwok received his PhD degree from the Hong Kong University of Science and Technology in 1996. He then joined the Department of Computer Science, Hong Kong Baptist University as an Assistant Professor. He is now a Professor in the Department of Computer Science and Engineering.

**Rhyd Lewis**

Cardiff University  
School of Mathematics  
Cardiff, UK  
[lewisR9@cf.ac.uk](mailto:lewisR9@cf.ac.uk)

## Chapter E.63

Rhyd Lewis is a lecturer in operational research in the School of Mathematics at Cardiff University. He holds a PhD in Computer Science and Operational Research from Edinburgh Napier University and a degree in Computing from the University of Wales, Swansea. Dr Lewis is the Co-Founder and an Associate Editor of the International Journal of Metaheuristics.

**Xiaodong Li**

RMIT University  
School of Computer Science and Information Technology  
Melbourne, Australia  
[xiaodong.li@rmit.edu.au](mailto:xiaodong.li@rmit.edu.au)

## Chapter F.67

Xiaodong Li received his PhD degree in Artificial Intelligence from the University of Otago. He is currently an Associate Professor at the School of Computer Science and Information Technology, RMIT University. His research interests include evolutionary computation, machine learning, multiobjective optimization, and swarm intelligence.

| University of the Balearic Islands<br>Dep. Mathematics and Computer Science<br>Palma de Mallorca, Spain<br><i>s.massanet@uib.es</i> | Sebastia Massanet received his BS, MSc, and PhD degrees in Mathematics from the University of the Balearic Islands (UIB) in 2008, 2009, and 2012 where he is currently an Assistant Professor in the Department of Mathematics and Computer Science. His current research interests are fuzzy sets theory and related fields such as fuzzy connectives, fuzzy implications, functional equations, and fuzzy mathematical morphology.                                                                  |                                                                            |

**Benedetto Matarazzo**

University of Catania  
Dep. Economics and Business  
Catania, Italy  
*matarazz@unict.it*

**Chapter C.22**

Benedetto Matarazzo is Chairman of the degree course in Corporate Finance at Catania University. He received the Gold Medal of International Society of Multiple Criteria Decision Making in 2009. His main research interests are in the fields of multiple criteria decision analysis, the rough set approach to decision analysis, and preference modeling.

**Sergi Mateo Bellido**

Polytechnic University of Catalonia  
Dep. Computer Architecture  
Barcelona, Spain  
*sergim@ac.upc.edu*

**Chapter F.68**

Sergi Mateo Bellido obtained his degree in Computer Science from the Polytechnic University of Catalonia in 2011. Since then, he has been working in the field of high performance computing at Barcelona Supercomputing Center and recently at the Polytechnic University of Catalonia. He is interested in algorithms, parallel programming models and domain specific languages.

**James McDermott**

University College Dublin  
Lochlann Quinn School of Business  
Dublin 4, Ireland  
*jmmcd@jmmcd.net*

**Chapter E.43**

James McDermott has research interests in evolutionary design and genetic programming. He was an IRC/Marie Curie Post-Doctoral Fellow at Massachusetts Institute of Technology and is now a lecturer and the Program Director in Business Analytics at University College, Dublin. He was Co-Chair of EvoMUSART 2013 and 2014 and Publication Chair of EuroGP 2015.

**Patricia Melin****Chapters G.79, G.80**

For biographical profile, please see the section "About the Part Editors".

**Corrado Mencar**

University of Bari  
Dep. Informatics  
Bari, Italy  
*corrado.mencar@uniba.it*

**Chapter B.14**

Corrado Mencar is Assistant Professor in the Department of Informatics, at the University of Bari, Italy. His research interests are computational intelligence, with a special emphasis on fuzzy logic, granular computing, neuro-fuzzy systems, computational web intelligence, and intelligent data analysis. He has published more than 60 peer-reviewed papers.

**Radko Mesiar****Chapters A.4, A.5**

For biographical profile, please see the section "About the Part Editors".

**Ralf Mikut**

Karlsruhe Institute of Technology (KIT)  
Inst. Applied Computer Science  
Eggental-Leopoldshafen, Germany  
*ralf.mikut@kit.edu*

**Chapter B.17**

Ralf Mikut graduated in automatic control at TU Dresden and received his PhD degree from the University of Karlsruhe in 1999. He is Associate Professor at the Karlsruhe Institute of Technology. His research interests include fuzzy systems, computational intelligence, and data mining in biological and technical applications.

**Ali A. Minai**

University of Cincinnati  
School of Electronic & Computing Systems  
Cincinnati, USA  
*ali.minai@uc.edu*

**Chapter D.35**

Ali A. Minai is Professor in the School of Electronic and Computing Systems at the University of Cincinnati. He received his PhD in Electrical Engineering from the University of Virginia. His areas of research include complex systems, neural networks, cognitive models, computational neuroscience, and computational models of social systems. He is a senior member of IEEE and the International Neural Network Society, and a member of the Society for Neuroscience.

| University of Santiago de Compostela<br>Research Centre for Information Technologies<br>Santiago de Compostela, Spain<br><i>manuel.mucientes@usc.es</i> | Manuel Mucientes is a Ramón y Cajal Research Fellow with the Research Centre for Information Technologies (CiTIUS) of the University of Santiago de Compostela. His current research interests are evolutionary algorithms, genetic fuzzy systems, motion planning and control in robotics, visual SLAM, web services, and process mining.                                                                                                                                    |              |

**Nysret Musliu**

Vienna University of Technology  
Inst. Information Systems  
Vienna, Austria  
[musliu@dbai.tuwien.ac.at](mailto:musliu@dbai.tuwien.ac.at)

**Chapter E.64**

Nysret Musliu is Privat Dozent and Senior Researcher at Vienna University of Technology. He received his PhD in Computer Science from Vienna University of Technology in 2001 and his MSc degree from the University of Prishtina in 1996. His research interests include problem solving and search, metaheuristics, machine learning and optimization, constraint satisfaction, scheduling, and timetabling.

**Yusuke Nojima**

Osaka Prefecture University  
Dep. Computer Science and Intelligent  
Systems, Graduate School of Engineering  
Osaka, Japan  
[nojima@cs.osakafu-u.ac.jp](mailto:nojima@cs.osakafu-u.ac.jp)

**Chapter G.77**

Yusuke Nojima received his BS and MSc degrees from Osaka Institute of Technology, Japan, in 1999 and 2001, respectively, and his PhD from Kobe University, Hyogo, Japan, in 2004. Since 2004, he has been with Osaka Prefecture University, Japan, where he is currently an Associate Professor. His research interests include genetic fuzzy systems, evolutionary multiobjective optimization, and parallel distributed data mining.

**Stefano Nolfi**

Consiglio Nazionale delle Ricerche  
(CNR-ISTC)  
Inst. Cognitive Sciences and Technologies  
Roma, Italy  
[stefano.nolfi@istc.cnr.it](mailto:stefano.nolfi@istc.cnr.it)

**Chapter D.37**

Stefano Nolfi is Director of Research of the Institute of Cognitive Sciences and Technologies (CNR). He is one of the founders of evolutionary robotics. His research activities focus on the evolution and development of behavioral and cognitive skills in embodied agents. He has authored/co-authored more than 130 peer-reviewed scientific publications, including a monograph.

**Una-May O'Reilly**

Massachusetts Institute of Technology  
Computer Science and Artificial  
Intelligence Lab.  
Cambridge, USA  
[unamay@csail.mit.edu](mailto:unamay@csail.mit.edu)

**Chapter E.43**

Una-May O'Reilly leads the AnyScale Learning For All (ALFA) group at Massachusetts Institute of Technology Computer Science and Artificial Intelligence Laboratory. She received the EvoStar Award for Outstanding Achievements in Evolutionary Computation in Europe in 2013 and serves as Vice-Chair of ACM SigEVO.

**Miguel Pagola**

Universidad Pública de Navarra  
Dep. Automática y Computación  
Pamplona (Navarra), Spain  
[miguel.pagola@unavarra.es](mailto:miguel.pagola@unavarra.es)

**Chapter A.6**

Miguel Pagola received his MSc and PhD degrees in Industrial Engineering from the Public University of Navarra, in 2000 and 2008. He is Associate Lecturer with the Department of Automatics and Computation at UPNa. His research interests include fuzzy techniques for image processing, fuzzy set theory, machine learning, and data mining. He is a member of the European Society for Fuzzy Logic and Technology.

**Lynne Parker**

University of Tennessee  
Dep. Electrical Engineering and Computer  
Science  
Knoxville, USA  
[lepark@utk.edu](mailto:lepark@utk.edu)

**Chapter F.72**

Lynne Parker is a Professor in the Department of Electrical Engineering and Computer Science at the University of Tennessee, Knoxville. She received her PhD degree from the Massachusetts Institute of Technology. She previously worked for several years as a full-time researcher at Oak Ridge National Laboratory. Her research focuses on distributed intelligent robotics, human–robot interaction, sensor networks, and machine learning.

**Kevin M. Passino**

The Ohio State University  
Dep. Electrical and Computer Engineering  
Columbus, USA  
[passino@ece.osu.edu](mailto:passino@ece.osu.edu)

## Chapter F.70

Kevin M. Passino is Professor of Electrical and Computer Engineering and Director of the Humanitarian Engineering Center at Ohio State University. He has been Vice-President of Technical Activities of IEEE Control Systems Society, an elected member of IEEE Control Systems Society Board of Governors, Program Chair of the 2001 IEEE Conference on Decision and Control, and is a Distinguished Lecturer for the IEEE Society on Social Implications of Technology.

**Martin Pelikan**

Sunnyvale, USA  
[martin@martinpelikan.net](mailto:martin@martinpelikan.net)

## Chapter E.45

Martin Pelikan received his PhD in Computer Science from the University of Illinois at Urbana-Champaign in 2002. He is now a software engineer at Google. Previously, he was an Associate Professor at the University of Missouri in St. Louis. His research in evolutionary computation focused mainly on estimation of distribution algorithms (EDAs), efficiency enhancement techniques, and scalability of EDAs.

**Irina Perfilieva**

University of Ostrava  
Inst. Research and Applications of Fuzzy  
Modeling  
Ostrava, Czech Republic  
[Irina.Perfilieva@osu.cz](mailto:Irina.Perfilieva@osu.cz)

## Chapter A.7

Irina Perfilieva received her PhD from Moscow State University and is currently a Professor of Applied Mathematics at the University of Ostrava, Czech Republic. Her research interests are fuzzy transforms with applications to image processing and computer vision. She has published more than 300 journal and conference papers and is co-author of 5 books.

**Henry Prade**

Université Paul Sabatier  
IRIT – Equipe ADRIA  
Toulouse Cedex 9, France  
[prade@irit.fr](mailto:prade@irit.fr)

## Chapter A.3

Henri Prade is a Research Director at CNRS at Paul Sabatier University. He is co-author of two monographs on fuzzy sets and possibility theory. His current research interests are uncertainty and preference modeling, non-classical logics, approximate, plausible and analogical reasoning with applications to artificial intelligence, and information systems. He is an ECCAI fellow, an IFSA fellow, a 2001 highly-cited ISI laureate, and received an IEEE pioneer award in 2002.

**Mike Preuss**

WWU Münster  
Inst. Wirtschaftsinformatik  
Münster, Germany  
[mike.preuss@tu-dortmund.de](mailto:mike.preuss@tu-dortmund.de)

## Chapter E.58

Mike Preuss is Research Associate at ERCIS, University of Münster, Germany, and the Chair of Algorithm Engineering at TU Dortmund, Germany, where he received his PhD in 2013. His research interests focus on the field of evolutionary algorithms for real-valued problems, namely on multimodal and multiobjective optimization, and on computational intelligence methods for computer games.

**José C. Principe**

University of Florida  
Dep. Electrical and Computer  
Engineering  
Gainesville, USA  
[principe@cnel.ufl.edu](mailto:principe@cnel.ufl.edu)

## Chapter D.30

José C. Principe is currently a Distinguished Professor of Electrical and Biomedical Engineering at the University of Florida, Gainesville, USA. He is Founder and Director of the University of Florida Computational Neuro-Engineering Laboratory (CNEL). He is an IEEE Fellow and an AIMBE Fellow. He is involved in biomedical signal processing, in particular, the electroencephalogram (EEG) and the modeling and applications of adaptive systems.

**Domenico Quagliarella**

CIRA, Italian Aerospace Research Center  
Fluid Dynamics Lab.  
Capua (CE), Italy  
*d.quagliarella@cira.it*

## Chapter E.60

Domenico Quagliarella received his MSc degree and his PhD in Aerospace Engineering from the University of Naples, Italy. He is currently Senior Researcher at CIRA. His research interests are the application of hybrid multi-objective optimization methods to aerodynamic and multidisciplinary design. He is the author of about 65 publications.

**Nicanor Quijano**

Universidad de los Andes  
Dep. Electrical and Electronics  
Engineering  
Bogotá, Colombia  
*nquijsano@uniandes.edu.co*

## Chapter F.70

Nicanor Quijano received his PhD degree in Electrical and Computer Engineering from The Ohio State University in 2006. Since 2007 he has been with the Electrical Engineering Department, Universidad de los Andes, Colombia, where he is the Director of the Research Group on Control Systems. His research interests include hierarchical and distributed optimization methods using bio-inspired and game-theoretical techniques for dynamic resource allocation problems.

**Jaroslav Ramík**

Silesian University in Opava  
Dep. Informatics and Mathematics  
Karlovy Vary, Czech Republic  
*ramik@opf.slu.cz*

## Chapter A.8

Prof. Jaroslav Ramík, PhD, is a Professor of Mathematics, Statistics, and Operations Research at the Silesian University Opava, in Karlovy Vary, Czech Republic. His interests include optimization methods in economics and decision making. He is the author of 6 books and more than 50 papers listed in WoS. He is also active in the Czech Society for Operations Research and has served as its former president.

**Ismael Rodríguez Fdez**

University of Santiago de Compostela  
Research Centre for Information  
Technologies  
Santiago de Compostela, Spain  
*ismael.rodriguez@usc.es*

## Chapter B.20

Ismael Rodríguez received his MSc in Computer Science in 2011 from the University of Santiago de Compostela. He is presently a PhD student at the Research Centre for Information Technologies of the University of Santiago de Compostela (CiTIUS). His current research interests are regression problems, evolutionary algorithms, and genetic fuzzy systems.

**Franz Rothlauf**

Johannes Gutenberg University Mainz  
Gutenberg School of Management and  
Economics  
Mainz, Germany  
*rothlauf@uni-mainz.de*

## Chapter E.53

Franz Rothlauf received a Diploma in Electrical Engineering from the University of Erlangen, Germany, a PhD in Information Systems from the University of Bayreuth, Germany, and a Habilitation from the University of Mannheim, Germany. He is a Professor for Information Systems at the University of Mainz. His research activities include planning and optimization, evolutionary computation, e-business, and software engineering.

**Jonathan E. Rowe**

University of Birmingham  
School of Computer Science  
Birmingham, UK  
*J.E.Rowe@cs.bham.ac.uk*

## Chapter E.42

Jonathan Rowe received a degree in Mathematics and PhD in Computer Science from the University of Exeter. He has worked in the field of natural computation for 20 years. He joined the University of Birmingham in 2000 and is now the Head of the School of Computer Science. He is Associate Editor for Theoretical Computer Science and Natural Computing journals.

**Imre J. Rudas**

Óbuda University  
Dep. Applied Mathematics  
Budapest, Hungary  
*rudas@uni-obuda.hu*

## Chapter B.10

Imre J. Rudas received his Master's Degree in Mathematics in Budapest, and his Doctor of Science degree from the Hungarian Academy of Sciences. He is a full University Professor and Head of Óbuda University Research and Innovation Center. His present areas of research activities are robotics and computational intelligence. He has published 6 books and more than 690 scientific papers.

**Günter Rudolph**

Technische Universität Dortmund  
Fak. Informatik  
Dortmund, Germany  
[guenter.rudolph@cs.tu-dortmund.de](mailto:guenter.rudolph@cs.tu-dortmund.de)

**Chapter E.58**

Günter Rudolph (PhD in Computer Science, 1996) has been a Professor of Computational Intelligence at the Department of Computer Science at TU Dortmund University since 2005. His research interests include the development and theoretical analysis of bio-inspired methods applied to difficult optimization problems encountered in engineering sciences, logistics, and economics.

**Gabriele Sadowski**

Technische Universität Dortmund  
Bio- und Chemieingenieurwesen  
Dortmund, Germany  
[gabriele.sadowski@bci.tu-dortmund.de](mailto:gabriele.sadowski@bci.tu-dortmund.de)

**Chapter E.58**

Gabriele Sadowski (PhD in Physical Chemistry, 1991) has been a Professor of Thermodynamics in the Department of Biochemical and Chemical Engineering at TU Dortmund since 2001. Her research interests include experimental investigation and thermodynamic modeling of phase behavior in systems containing complex molecules, like polymers, electrolytes, biomolecules, or pharmaceuticals.

**Marco Scarpa**

Università' di Messina  
Dip. Ingegneria Civile, Informatica  
Messina, Italy  
[mscarpag@unime.it](mailto:mscarpag@unime.it)

**Chapter F.69**

Marco Scarpa received his Bachelor degree in Computer Engineering from the University of Catania, Italy and his PhD degree in Computer Science in 2000 from the University of Turin, Italy. He is currently Associate Professor of Computer Engineering at the University of Messina, Italy. His interests include performance and reliability modeling of distributed and real time systems and algorithms for their solution.

**Werner Schafhauser**

XIMES  
Vienna, Austria  
[schafhauser@ximes.com](mailto:schafhauser@ximes.com)

**Chapter E.64**

Werner Schafhauser is a Senior Consultant and a software developer at XIMES in Vienna where, amongst other things, he develops and applies optimization algorithms to real scheduling problems. His research interests include metaheuristic optimization, constraint satisfaction problems, structural decomposition methods, and scheduling. He has a PhD in Computer Science from Vienna University of Technology.

**Roberto Sepúlveda Cruz**

Mesa de Otay, Tijuana, Mexico  
[rsepulve@citedi.mx](mailto:rsepulve@citedi.mx)

**Chapter G.76**

Roberto Sepúlveda Cruz received his MSc from the Tijuana Institute of Technology, México, and his PhD from the Universidad Autónoma of Baja California, Tijuana, México, both in Computer Science in 1999 and 2006, respectively. His research interests include type-2 fuzzy systems, intelligent systems, and robotics. He is a member of the International Association of Engineers (IANG).

**Jennie Si**

Arizona State University  
School of Electrical, Computer and Energy  
Engineering  
Tempe, USA  
[si@asu.edu](mailto:si@asu.edu)

**Chapter D.34**

Jennie Si received her BS and MSc degrees from Tsinghua University, Beijing, China, and her PhD from the University of Notre Dame. She has been on the faculty in the Department of Electrical Engineering at Arizona State University since 1991. Her research focuses on dynamic optimization using learning and neural network approximation approaches, namely approximate dynamic programming. She has served on the Executive Boards of several professional organizations.

**Marco Signoretto**

Katholieke Universiteit Leuven  
Leuven, Belgium  
*marco.signoretto@esat.kuleuven.be*

## Chapter D.32

Marco Signoretto holds a PhD in Mathematical Engineering from Katholieke Universiteit Leuven, Belgium; a Laurea Magistralis in Electronic Engineering from the University of Padova, Italy; and an MSc in Methods for Management of Complex Systems from the University of Pavia, Italy. His research interests include mathematical modeling of structured data. His current work deals with methods based on (convex) optimization, structure-inducing penalties, and spectral regularization.

**Andrzej Skowron**

University of Warsaw  
Faculty of Mathematics, Computer Science  
and Mechanics  
Warsaw, Poland  
*skowron@mimuw.edu.pl*

## Chapter C.21

Andrzej Skowron is a Full Professor at the Institute of Mathematics at the University of Warsaw. He received his PhD and DSc (Habilitation) from the University of Warsaw, and the title of Professor in 1991. He is an ECCAI Fellow. His area of expertise includes reasoning with imperfect data and knowledge, soft computing methods, rough sets, granular computing, data mining, adaptive and autonomous systems, perception-based computing, and interactive computational systems.

**Igor Škrjanc**

University of Ljubljana  
Faculty of Electrical Engineering  
Ljubljana, Slovenia  
*igor.skrjanc@fe.uni-lj.si*

## Chapter G.75

Igor Škrjanc is currently a Professor of Automatic Control with the Faculty of Electrical Engineering, the University of Ljubljana. His main research interests include intelligent, predictive control systems and autonomous mobile systems. In 2009 he received the Humboldt Research Fellowship for Experienced Researchers.

**Roman Słowiński**

## Chapters C.22, C.24

For biographical profile, please see the section "About the Part Editors".

**Guido Smits**

Dow Benelux BV  
Core R&D  
NM Hoek, The Netherlands  
*gfsmits@dow.com*

## Chapter E.57

Guido F. Smits is a Data Scientist at Dow Chemical Company. His main area of interest and expertise is in innovative applications of computational intelligence to new product design and optimization. He has authored more than 70 papers and currently holds 15 patents. He has a PhD from the University of Leiden, NL.

**Ronen Sosnik**

Holon Institute of Technology (H.I.T.)  
Electrical, Electronics and Communication  
Engineering  
Holon, Israel  
*ronens@hit.ac.il*

## Chapter D.39

Ronen Sosnik received his MSc degree in Neuroscience and his Research Doctorate in Neuroscience from Weizmann Institute of Science in 2000 and 2005. His research interests include computational motor control, motor learning, and neural substrates mediating the acquisition, representation, and generation of motion primitives. Currently, he is devising innovative experimental paradigms and mathematical methods for the construction of novel BCI systems.

**Alessandro Sperduti**

University of Padova  
Dep. Pure and Applied Mathematics  
Padova, Italy  
*sperduti@math.unipd.it*

## Chapters D.27, D.31

Alessandro Sperduti has a PhD in Computer Science from the University of Pisa. He has been Professor in Computer Science at the University of Padova since 2002 and Chair of the Data Mining and Neural Networks Technical Committees of IEEE CIS. His research interests include machine learning, neural networks, learning in structured domains, and data and process mining.

**Kasper Støy**

IT University of Copenhagen  
Copenhagen S, Denmark  
[ksty@itu.dk](mailto:ksty@itu.dk)

**Chapter F.73**

Kasper Støy holds an Associate Professorship at The Maersk Mc-Kinney Moller Institute, University of Southern Denmark (USD). His research interests include design of modular robot systems and distributed control. He has authored a monograph. He holds an MSc in Computer Science and Physics, University of Aarhus, Denmark (1999) and a PhD in Computer System Engineering, USD (2003).

**Harrison Stratton**

Arizona State University & Barrow  
Neurological Institute  
Phoenix, USA  
[Harrison.Stratton@asu.edu](mailto:Harrison.Stratton@asu.edu)

**Chapter D.34**

Harrison Stratton obtained his BSc in Physics from Virginia Polytechnic Institute and State University in 2008 and is currently completing his PhD at Arizona State University and Barrow Neurological Institute. His work focuses on the role of the endogenous cannabinoid system in regulating changes of emotion, memory, and learning.

**Thomas Stützle**

Université libre de Bruxelles (ULB)  
IIRIDIA, CP 194/6  
Brussels, Belgium  
[stuetzle@ulb.ac.be](mailto:stuetzle@ulb.ac.be)

**Chapter E.54**

Thomas Stützle is Senior Research Associate of the Belgian FRS-FNRS at the University of Brussels. He received his MSc from Universität Karlsruhe (TH) and his PhD and Habilitation from the Technische Universität Darmstadt, Germany. His interests lie in stochastic local search, swarm intelligence, methodologies for engineering stochastic local search algorithms, multi-objective optimization, and automatic configuration of algorithms.

**Dirk Sudholt**

University of Sheffield  
Dep. Computer Science  
Sheffield, UK  
[d.sudholt@sheffield.ac.uk](mailto:d.sudholt@sheffield.ac.uk)

**Chapter E.46**

Dirk Sudholt obtained Diploma and PhD degrees in Computer Science in 2004 and 2008, respectively, from the Technische Universität Dortmund, Germany. After holding postdoc positions in Berkeley, California, and Birmingham, UK, he joined the University of Sheffield, UK, as Lecturer in 2012. His research focuses on the computational complexity of randomized search heuristics.

**Ron Sun**

Rensselaer Polytechnic Institute  
Cognitive Science Dep.  
Troy, USA  
[rsun@rpi.edu](mailto:rsun@rpi.edu)

**Chapter D.36**

Ron Sun is Professor of Cognitive Sciences and Computer Science at Rensselaer Polytechnic Institute. He received his PhD from Brandeis University in 1992. His research interests center around the study of cognition. He has published many papers in these areas, as well as ten books.

**Johan A. K. Suykens**

Katholieke Universiteit Leuven  
Leuven, Belgium  
[johan.suykens@esat.kuleuven.be](mailto:johan.suykens@esat.kuleuven.be)

**Chapter D.32**

Johan A.K. Suykens is Professor at Katholieke Universiteit Leuven, Belgium, where he obtained a degree in Electro-Mechanical Engineering and a PhD in Applied Sciences. He is a senior IEEE member, has co-authored and edited several books, and received many prestigious awards.

**Roman W. Swiniarski (deceased)****Chapter C.21**

**El-Ghazali Talbi**

University of Lille  
Computer Science CRISTAL  
Villeneuve d'Ascq, France  
*el-ghazali.talbi@univ-lille1.fr*

## Chapter E.55

El-Ghazali Talbi received his Master's and PhD in Computer Science from the Institut National Polytechnique de Grenoble, France. He is a Full Professor at the University of Lille and the Head of the Optimization Team of the Computer Science Laboratory. His research interests are in the field of multi-objective optimization, parallel algorithms, metaheuristics, combinatorial optimization, cluster and grid computing.

**Lothar Thiele**

Swiss Federal Institute of Technology  
Zurich  
Computer Engineering and Networks Lab.  
Zurich, Switzerland  
*thiele@ethz.ch*

## Chapter E.48

Lothar Thiele received his Diploma and Dr.-Ing. degrees in Electrical Engineering from the Technical University of Munich where he also received his Habilitation. He joined ETH Zurich, Switzerland, as a Full Professor of Computer Engineering in 1994. His research interests include models, methods and software tools for the design of embedded systems, embedded software and bioinspired optimization techniques.

**Peter Tino**

University of Birmingham  
School of Computer Science  
Birmingham, UK  
*P.Tino@cs.bham.ac.uk*

## Chapter D.27

Peter Tino has a PhD in Computer Science (Slovak Academy of Sciences) and is a Reader in Complex and Adaptive Systems at the University of Birmingham, UK. He is a Vice-Chair of the Neural Networks Technical Committee of IEEE CIS. His main research interests include dynamical systems, machine learning, probabilistic modeling of structured data, evolutionary computation, and fractal analysis.

**Joan Torrens**

University of the Balearic Islands  
Dep. Mathematics and Computer Science  
Palma de Mallorca, Spain  
*jts224@uib.es*

## Chapter B.12

Joan Torrens received his BSc degree in Mathematics from Universitat Autònoma de Barcelona (1981) and his PhD degree in Computer Science from Universitat de les Illes Balears, Spain (1990). He is a Full Professor in the Department of Mathematics and Computer Science at Universitat de les Illes Balears. His research interests include fuzzy sets theory. He has published over 100 papers in journals.

**Vito Trianni**

Consiglio Nazionale delle Ricerche  
Ist. Scienze e Tecnologie della Cognizione  
Roma, Italy  
*vito.trianni@istc.cnr.it*

## Chapter F.71

Vito Trianni is a tenured researcher at ISTC-CNR, the Institute of Cognitive Sciences and Technologies of the Italian National Research Council. He received his PhD in Applied Sciences from the Université Libre de Bruxelles in 2006. He has thorough expertise, both theoretical and experimental, in the study and design of self-organizing behavior, especially applied to swarm robotics.

**Enric Trillas**

European Centre for Soft Computing  
Fundamentals of Soft Computing  
Mieres, Spain  
*enric.trillas@softcomputing.es*

## Chapter B.16

Enric Trillas, an Emeritus Researcher at ECSC, received a PhD in Mathematics from the University of Barcelona. From 1964–1984 he did research in ordered semigroups, probabilistic and generalized metric spaces, and in 1975 he began working in fuzzy logic. He has published over 400 papers, and published or edited several books. His current interests lie in fuzzy logic and in the mathematical analysis of natural language and commonsense reasoning.

**Fevrier Valdez**

Tijuana Institute of Technology  
Tijuana, Mexico  
*fevrier@tectijuana.mx*

## Chapter G.81

Fevrier Valdez is a Professor in the Computer Science Department of Tijuana Institute of Technology. His research interests are bio-inspired optimization methods, parallel computing, fuzzy logic and neural networks. He has published several papers in journals, conference proceedings, and as book chapters.

**Nele Verbiest**

Ghent University  
Dep. Applied Mathematics, Computer  
Science and Statistics  
Ghent, Belgium  
[nele.verbiest@ugent.be](mailto:nele.verbiest@ugent.be)

## Chapter C.26

Nele Verbiest holds a Master's degree in Mathematical Computer Science and a PhD in Computer Science, both from Ghent University. Her research interests include classification, evolutionary algorithms, instance selection, feature selection, and fuzzy rough set theory.

**Thomas Villmann**

University of Applied Sciences Mittweida  
Dep. Mathematics, Natural and Computer  
Sciences  
Mittweida, Germany  
[thomas.villmann@hs-mittweida.de](mailto:thomas.villmann@hs-mittweida.de)

## Chapter D.31

Thomas Villmann received his PhD in Computer Science in 1996 and his Venia legendi in 2005 from Leipzig University. He has been a Full Professor of Computational Intelligence at the University of Applied Sciences Mittweida, Germany since 2009. His research focus includes the theory of prototype-based clustering and classification, non-standard metrics, information theory, and their application in pattern recognition for use in medicine, bioinformatics, remote sensing, and hyperspectral analysis.

**Milan Vlach**

Charles University  
Theoretical Computer Science and  
Mathematical Logic  
Prague, Czech Republic  
[Milan.Vlach@mff.cuni.cz](mailto:Milan.Vlach@mff.cuni.cz)

## Chapters A.8, A.9

Milan Vlach studied Mathematics at Charles University, Prague (1958–1960) and Moscow State University (1960–1963). Since graduating from Moscow State University (1960), he has been affiliated with Charles University. At present he is also affiliated with the Institute of Information Theory and Automation, Czech Academy of Sciences. His current area of interest includes game theory, fair division, and optimization theory.

**Ekaterina Vladislavleva**

Evolved Analytics Europe BVBA  
Turnhout, Belgium  
[katya@evolved-analytics.com](mailto:katya@evolved-analytics.com)

## Chapter E.57

Ekaterina Vladislavleva is CEO and Co-Founder of Evolved Analytics Europe, a Belgium-based advanced predictive analytics company – creator of DataStories.com. She received her PhD from CentER at Tilburg School of Economics (The Netherlands), her Doctorate in Engineering from Eindhoven University of Technology (The Netherlands) and MSc from Lomonosov Moscow State University (Russia).

**Tobias Wagner**

TU Dortmund University  
Dep. Mechanical Engineering  
Dortmund, Germany  
[wagner@isf.de](mailto:wagner@isf.de)

## Chapter E.59

Tobias Wagner studied computer science and finished his Doctoral degree in Mechanical Engineering at the University of Dortmund (now TU Dortmund University). He has been a Postdoctoral Researcher (Akademischer Rat) at the Institute of Machining Technology (ISF) since 2013. His research interests include the empirical modeling and optimization of machining processes and process chains.

**Jun Wang**

The Chinese University of Hong Kong  
Dep. Mechanical & Automation  
Engineering  
Hongkong, Hong Kong  
[jwang@mae.cuhk.edu.hk](mailto:jwang@mae.cuhk.edu.hk)

## Chapter D.33

Jun Wang is a Professor at the Chinese University of Hong Kong. He has been a National Thousand-Talent Chair Professor at Dalian University of Technology since 2011. He received his BSc degree in Electrical Engineering and his MSc degree in Systems Engineering from Dalian University of Technology, China and his PhD in Systems Engineering from Case Western Reserve University, Cleveland, Ohio, USA.

**Simon Wessing**

Technische Universität Dortmund  
Fak. Informatik  
Dortmund, Germany  
[simon.wessing@tu-dortmund.de](mailto:simon.wessing@tu-dortmund.de)

## Chapter E.58

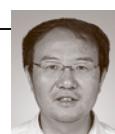

Simon Wessing has been a Research Associate in the Computational Intelligence Group, Technische Universität Dortmund since 2009. His research interest focuses on multimodal and global optimization. He develops new optimization algorithms for these problems based on evolutionary algorithms and other derivative-free methods.

**Wei-Zhi Wu**

Zhejiang Ocean University  
School of Mathematics, Physics and  
Information Science  
Zhoushan, Zhejiang, China  
[wwuz@zjou.edu.cn](mailto:wwuz@zjou.edu.cn)

**Chapter C.26**

Wei-Zhi Wu received his BSc degree in Mathematics from Zhejiang Normal University, his MSc degree from East China Normal University, and his PhD degree from Xi'an Jiaotong University (2002). He is currently a Professor of Mathematics in the School of Mathematics, Physics, and Information Science, Zhejiang Ocean University. His current research interests include approximate reasoning, rough sets, random sets, formal concept analysis, and granular computing.

**Lei Xu**

The Chinese University of Hong Kong  
Dep. Computer Science and Engineering  
Hong Kong, Hong Kong  
[lxu@cse.cuhk.edu.hk](mailto:lxu@cse.cuhk.edu.hk)

**Chapter D.29**

Lei Xu is a Professor at the Chinese University of Hong Kong. He is an IEEE Fellow, an IAPR Fellow, an Academician of the European Academy of Sciences. He has published well-cited papers on neural networks, machine learning, and pattern recognition.

**JingTao Yao**

University of Regina  
Dep. Computer Science  
Regina, Saskatchewan, Canada  
[jtyao@cs.uregina.ca](mailto:jtyao@cs.uregina.ca)

**Chapter C.25**

JingTao Yao is a Professor of Computer Science at the University of Regina. He has published over 100 papers on granular computing, rough sets, data mining, and Web-based support systems. He is the Elected Chair of the Steering Committee of the International Rough Set Society.

**Yiyu Yao****Chapter C.24**

For biographical profile, please see the section "About the Part Editors".

**Andreas Zabel**

TU Dortmund University  
Dep. Mechanical Engineering  
Dortmund, Germany  
[zabel@isf.de](mailto:zabel@isf.de)

**Chapter E.59**

Andreas Zabel studied Computer Science and finished his Doctoral degree in Mechanical Engineering at the University of Dortmund (now TU Dortmund University). He is Chief Engineer of the Institute of Machining Technology (ISF). His research includes the simulation of machining processes, modeling and analysis of tool wear, as well as augmented and virtual reality for process planning.

**Sławomir Zadrożny**

Polish Academy of Sciences  
Systems Research Inst.  
Warsaw, Poland  
[Slawomir.Zadrozny@ibspan.waw.pl](mailto:Slawomir.Zadrozny@ibspan.waw.pl)

**Chapter B.19**

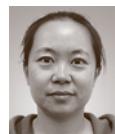

Sławomir Zadrożny is an Associate Professor (PhD 1994, DSc 2006) and a Deputy Director for Research at the Systems Research Institute, Polish Academy of Sciences. His current interests include applications of fuzzy logic in database management systems, information retrieval, decision support, and data analysis. He has authored and co-authored about 200 journal and conference papers. He is also a teacher at the Warsaw School of Information Technology.

**Zhigang Zeng**

Huazhong University of Science and  
Technology  
Dep. Control Science and Engineering  
Wuhan, China  
[zgzeng@hust.edu.cn](mailto:zgzeng@hust.edu.cn)

**Chapter D.33**

Zhigang Zeng is Professor in the Department of Control Science and Engineering, Huazhong University of Science and Technology, Wuhan, Hubei, China. He received his BSc degree in Mathematics from Hubei Normal University, Huangshi, China, his MSc degree in Ecological Mathematics from Hubei University, Wuhan, China, in 1993 and 1996, and his PhD degree in Systems Analysis and Integration from Huazhong University of Science and Technology, Wuhan, China, in 2003.

**Yan Zhang**

University of Regina  
Dep. Computer Science  
Regina, Saskatchewan, Canada  
[zhang83y@cs.uregina.ca](mailto:zhang83y@cs.uregina.ca)

Chapter C.25

Yan Zhang is currently a PhD student in the Department of Computer Science, the University of Regina, Canada. Her main research involves rough sets, granular computing, data analysis, and data mining. She has authored or co-authored more than 15 technical papers in international journals and conference proceedings. She is coauthor of two book chapters.

**Zhi-Hua Zhou**

Nanjing University  
National Key Lab. for Novel Software  
Technology  
Nanjing, China  
[zhouzh@nju.edu.cn](mailto:zhouzh@nju.edu.cn)

Chapter D.29

Zhi-Hua Zhou received BSc, MSc, and PhD degrees in Computer Science from Nanjing University, China, in 1996, 1998 and 2000. He joined the Department of Computer Science and Technology of Nanjing University in 2001 and at present he is a Professor and Deputy Director of the National Key Lab for Novel Software Technology. His research interests include artificial intelligence, machine learning, data mining, pattern recognition and multimedia information retrieval.
